It will not be attempted at this time to discuss the theory of Rotary Fans. The fan itself will simply be accepted as one of the recognised appliances in the construction of ventilating apparatus, available with other mechanisms in established forms and defined types for American practice.

The fans most generally in use for the ventilation of large buildings in America have been derived, in all essential particulars of conformation, from those designed by the writer for the United States Capitol at Washington in 1855 and 1856. These particular fans were based upon a type given by M. Combes (in his "Aerage des Mines"), where the fan blades or vanes were placed upon the face of a disk, and the fan itself thus constructed was located in front of a circular opening in the wall of a building, the wall forming one side of the zone of blades, in opposition to the outer edge or face of the disc, which formed the other side. In this construction no case whatever is demanded for the fan, which receives its air through the central circular opening in the wall, and delivers its air at all points of the periphery into a large but close room, from which room the ducts for conveying air branch in any desired direction.

The heating and ventilating at the United States Capitol was under the charge of Major-General M. C. Meigs (then Lieut. U.S. Engineers), who selected this type of fan as presenting certain structural advantages for its employment. The study of the conditions of fan construction, which was devolved upon the writer, led to some modifications in the forms of blades, &c., as accepted by M. Combes, with which changes these fans were employed in the ventilation of the United States Capitol buildings. More recently the disc type has been departed from, but in other respects the proportions of the Capitol fans have been followed, and have now become established in general practice. It was a recognised necessity that a fan should be reduced to its least practicable dimensions, and the most cursory observation showed that the passage of air through the fan itself was an accelerating flow, whose least velocity should be ,that at which the entering air approached the inner edges of the blades, and its greatest velocity should be that at which the escaping air left the tips of the blades; the action of the blades being to give an accelerating velocity, to be mainly derived from the increase of velocity of the blade surface as it became further from the centre. It followed as a resulting consequence that the area of any cross section of the passage through the fan (any one of which will be formed between the disc and wall or case side, and between any two blades) should reduce in proportion as the air accelerates, and that the air should thus be kept in contact with, and be acted upon by, the blades as the source of impulse. These propositions gave, for instance, where the disc of the fan was taken to have a diameter equal to one, the diameter of the mouth or central opening becomes seventy-four hundredths; the width of the fan at the mouth becomes seventeen-and-a-half hundredths; while the width at the periphery becomes one-tenth. The number of blades was found (by experiments as to most efficiency with several different numbers) to be about sixteen, a number giving the section of the several passages formed by blades, disc, and wall, most nearly a square one, or most nearly that section of a duct or passage where the sides offer the least resistance to flow of a fluid.

The advantages in effectiveness or economy in power over other fans as before made, with small central opening and great width of vanes in direction of the axis, is not very considerable; 10 to 15 per cent of higher useful effect

* A Paper presented to the American Society of Civil Engineers, January 26, 1881.

is all that can be claimed when 55 to 60 per cent is usual; but the advantage of obtaining at least twice the capacity simply by enlarging the mouth and by increasing the number of blades to suit their reduction in length, is of high importance when room to place a fan in a building is frequently one of the troublesome questions to be met. Since 1856 probably 150 of these fans have been put into use in various hospitals and public buildings. The principal modification adopted has been the frequent use of blades on both sides, with the same disc construction, sometimes (for fans of four to eight feet diameter) with iron in lieu of brickwork cases. This last arrangement presents some difficulties in the entering air passages, but it reduces the diameter of a fan to do any given work to seven-tenths that of a single disc fan.*

In general these fans are driven by a directly connected engine of suitable size: sometimes a belt and pulley is used for transmission from an independent engine. This condition, that of independence from other uses, is desirable for hall ventilation, so that an economy of working may be practised to meet the condition of occupied and unoccupied halls; but for hospital ventilation it is about as well to drive the fans from the general source of motive power always indispensable in large hospital establishments.

Boilers and their appliances, engines, &c., are not distinctive or peculiar to ventilating or heating apparatus, and call for no mention in this paper as to methods of construction.

The steam heating apparatus in all its details, as used in America, is peculiarly American, especially the apparatus of small wrought-iron tubes, which had its origin at the hands of the late Joseph Nason, between 1840 and 1850, and has now become one of the established industries of the land, employing a whole class of workmen known as steam-fitters, and supporting large establishments devoted entirely to the manufacture of and trade in tubes and fittings.

The little step in mechanism which is the foundation of this art is found in the use of the tapering thread on the end of the pipes, wherewith a perfectly staunch joint is cheaply provided and made. It is curious that with over forty years' practice in steam-fitting, until no workman in iron regards this taper screw joint as other than the matter-of-course way of making a pipe-joint, with this established habit of workmanship, no description or notice of the tapering screw is published in any text-book, nor have its peculiar advantages been considered by any general writer on constructive mechanism. The great importance of this improvement in making the joints of steam pipes to this industry of steam heating can scarcely be over-estimated; but it was not only in this particular, but in many others of detail, that Mr. Nason's ability as an inventor and adaptor was shown in the apparatus: while super-eminent above this, he was at once the best informed of his day on the theory, and the most able in the practice, of steam-heating. Under his tuition the whole trade originated—ten or twelve years since it was possible to trace the descent or pedigree of any concern in the business to the original source—at this time; the growth of the business going to a third or fourth race of firms or workmen pre cludes the following out of the continuity, although it certainly exists. The business, however, has been, and is, dependent upon the development of mechanical ingenuity, mainly from Joseph Nason, who gave form to the globe-valve, originated and derived or adapted from the practice of hot-water heating apparatus in England—either the Perkins's high pressure or the greenhouse low pressure system—all the essential details which now form parts of usual everyday construction in the United States. Curiously, steam-heating as practised here, is not yet fully known or used in England or France, and but little more known in Germany.

The writer of this paper became connected with Mr. Nason in 1848, when he was employed to superintend the construction of tube works at Malden, near Boston, for Messrs. Walworth and Nason, and from that time until now he feels able to claim some standing in advancing the industry of steam-heating. It will have been noticed by most who have to do with construction that the form and shape of valves, elbows, tees, and of details generally employed or made at any time in the country are strikingly similar. In fact they are universally copies, following exactly the designs and proportions, as to sizes and thicknesses, which the writer established and published in the catalogues of the Pascal Iron Works, nearly twenty years since.

From this general acceptance of the types of steam-heating apparatus and component parts anyone is at liberty to specify a definite construction of coils and mains with a correspondence of detail. He can measure and plan to use any arrangement of standard articles, selected from any trade catalogue of a steam heating establishment or firm, and feel sure that the work will have been so arranged that it can be bid for in open competition, and that he is getting the best work, or details of work, to effect his purpose in his own way. More than this, it may be regarded as tolerably sure that any patented improvement of detail or method is inferior to what can be procured and supplied from regular traders.

(To be continued.)

* The only full published account of this fan is to be found in the *Proceeding of the Institution of Civil Engineers*, 1869-70, but the publication in the catalogue of apparatus of the Pascal Iron Works, Class IV., 1863, and subsequently, gives essential particulars, and has perhaps much aided in the introduction of the fan. The catalogue was compiled by the writer of this paper.

PROCEEDINGS OF SOCIETIES.

CHEMICAL SOCIETY.

Thursday, June 16, 1881.

Prof. H. E. Roscoe, President, in the Chair.

The following certificate was read for the first time.—F. Sear.

During the evening a ballot was held, and the following gentlemen were declared, by the Scrutators (Messrs. Groves and Warington) to be duly elected Fellows of the Society.—A. B. Avarne, G. H. Bostock, W. Bedford, B. Browning, J. M. Collett, A. W. Duncan, J. E. Doyle, A. E. Davies, H. Frankland, A. J. Hailes, C. W. Marsh, A. Philip, T. K. Rogers, J. Schwartz, O. Trigger, G. Tate, J. P. Wilkes.

The President read a letter which he had received from Lieut.-Col. Malcolm, Hon. Sec. of the Museum Sub-Committee of the British Association, 17, Blake Street, York. It is intended to illustrate, at the forthcoming meeting of the Association, as far as possible, the progress which has been made in the construction of instruments of scientific research during the past 50 years. With this view scientific men, societies, and manufacturers, are invited to exhibit instruments of the latest patterns, and tools used in their construction, together with the instruments used in 1831. The Exhibition will last only from August 31st to September 8th. The President, therefore, invited Fellows of the Society who could exhibit such apparatus to forward, as soon as possible, details of the apparatus and space required to the above address.

Mr. W. H. Perkin then communicated a paper "*On the Isomeric Acids obtained from Coumarin and the Ethers of Salicylic Aldehyd.*" Some years ago, the author showed (*Chem. Soc. Jour.*, 1877, i., 388), that by the action of acetic anhydride and sodium acetate on the hydride of methyl salicyl, an acid (methyl-orthoxy-phenyl-acrylic acid) was produced. By treating the hydride of

salicyl in the same way coumarin was formed. Tiemann has since shown that this is preceded by the formation of coumaric acid, which has a constitution analogous to the above acid, but has an atom of hydrogen in place of methyl. Now coumarin when treated with alkalies gives a coumarate, which, however, splits up into coumarin when treated with acids; but if treated with methylic iodide, it produces a methylated acid of the same composition and, apparently, the same constitution as that obtained by the action of acetic anhydride on the hydride of methyl salicyl; its fusing-point is, however, nearly 100° lower than the acid from the hydride of methyl salicyl. It can be converted into it by the action of heat. The cause of this isomerism being unintelligible, the author has undertaken the present investigation for the purpose of examining the acids, their derivatives, and any homologues which might be formed from the other coumarins. The acid obtained from coumarin is called by the author the α-, the other β-methyl-orthoxy-phenyl-acrylic acid. The α acid was obtained in magnificent highly refracting crystals; it is changed into the β acid by heat and by violet or ultra-violet light. The two methylic ethers and the α- and β-ethyl acids were prepared and examined. Nascent hydrogen converts both acids into the same acid, dihydro-methyl-orthoxy-phenyl-acrylic acid. The actions of nitric acid and bromine were also studied and various derivatives obtained. Isomeric dibromides were obtained, and experiments made with the methylic ethers of the acids; the β-ether yielded 70 per cent of a dibromide, melting at 68·7°, and 30 per cent of a dibromide, melting at 125°; the α-ether yielded as a principle product a dibromide, fusing at 125° with a small quantity of the body melting at 68°. The action of bromine on the α- and β-ethylic ethers was also studied. The actions of fuming hydriodic and hypochlorous acids were examined. The derivatives from propionic and those from butyric coumarin were next prepared. These coumarins yielded acids analogous to that from ordinary coumarin. From the author's researches, it appears that in general, the effect of chemical action on the α acids, is to convert them into the same compounds as are yielded by the β acids under similar circumstances. This is probably due to the heat evolved by the chemical action converting the α into a β derivative. The limited action of bromine is an exception, but in this reaction but little heat is evolved. The hypothesis that the isomerism resulting from the difference of structure of this group is considered, but is not thought by the author to be established. The physical differences of the α- and β-ethers, described in the paper, are considered, and the author concludes that as the boiling-points, densities, refractive indices, &c., of the α compounds are all lower than those of the β body, and the α compounds are the less stable, it is probable that the molecules of the α body are further apart than those of the β body. Reference is made to the fact that the formation of these α bodies is always connected with dehydration and rehydration, and a suggestion is made that if a difference of proximity of the groups is the cause of the isomerism, it is probably due only to a difference of distance between the radical and the hydroxyl. It is also pointed out, that in most cases, where bodies are, what is called, physical isomerides, they are hydroxylised products.

Mr. FLETCHER then gave a short statement of the results which he had obtained from the measurement of the various crystallised bodies prepared by Mr. Perkin.

Dr. WRIGHT suggested that it would be interesting to determine the heat of combustion of one or more pairs of these α and β bodies.

Prof. HARTLEY thought that probably some difference might be found in the optical transparency of these isomeric bodies.

Dr. ARMSTRONG then communicated a paper by Mr. G. LOWE and himself, entitled "*Notes on Naphthalene Derivatives.*" The authors have continued their investigations as to the action of sulphuric acid on naphthalene, and confirm their previous statement that three and not two disulphonic acids may be obtained. By operating at 180°, a mixture in about equal proportions of the α and β disulphonic acids of Ebert and Merz is obtained; but at 100° a third acid is also formed, corresponding to the dihydroxy-naphthalene melting at 156°, which they have described. This third acid is obtained in relatively small quantity, and the authors have not yet established the conditions which are most favourable to its production, nor have they devised a satisfactory method of separating it from the isomerides. They have confirmed their observations on the action of fused potassium hydroxide on potassium β-naphthol-sulphonate, but doubt whether more than a single body is produced in the reaction. It crystallises from hot water (in which it is much less soluble than the dihydroxy-naphthalene previously described) in small plates melting at 218° to 220°: it separates from acetic acid in large ammonium chloride-like forms. The alkaline solution exhibits a blue fluorescence, and rapidly darkens on exposure to air. Dr. Armstrong then described an isomeric β-naphthol-sulphonic acid obtained by Mr. Stallard and himself by dissolving β-naphthol in cold concentrated sulphuric acid. The authors were led to the discovery of this substance by noticing that when less sulphuric acid than Schaefer prescribes for the preparation of β-naphthol-sulphonic acid is used, it is difficult to obtain the salts in the clear transparent crystals so characteristic of the β-naphthol-sulphonates. The salts of the new acid are much more soluble, and when submitted to the action of bromine or nitric acid readily exchange the sulpho group for bromine or NO_2, forming bromo- and nitro-derivatives of naphthol. The acid previously known retains its sulpho-group under similar treatment. Dr. Armstrong demonstrated this reaction to the Society, and pointed out that it was a good lecture illustration of the extraordinary difference of the SO_3H group, according as it occupied the so-called α or β position in naphthalene.

Mr. G. S. JOHNSON then read a paper "*On the Synthesis of Ammonia (Third Notice).*" This paper is practically an answer to the criticism of Mr. L. Wright on the previous communication of the author. Mr. Wright stated that the nitrogen used by the author was not pure, and that it contained nitric oxide, and that the ammonia formed was due to the presence of this impurity. The author of the present paper points out that he relied for the purification of his nitrogen from nitric oxide not on an acid solution of ferrous sulphate, but on pumice impregnated with hydrated ferrous oxide precipitated by the ammonia evolved on boiling the ammonium nitrite. He has repeated his previous experiments, and tested the N carefully for NO by mixing with air and bubbling through starch and potassium iodide solution. Although no blue colour was seen in half an hour, yet this pure N when mixed with H still formed ammonia. Other experiments were made in which the nitrogen was purified by mixing with air and allowing the mixed gases to stand for some hours over water rendered alkaline with potash. This also produced ammonia when mixed with hydrogen and passed over spongy platinum. The author finds that when the pure nitrogen is passed through heated asbestos before mixing with hydrogen it is no longer capable of combining with hydrogen in the presence of spongy platinum. This experiment was exhibited to the Society. As long as the asbestos was hot no ammonia was produced, but on allowing it to cool, after about twenty minutes a Nessler solution became distinctly yellow. The author thinks that this experiment indicates the existence of an active allotropic nitrogen analogous to ozone, and hopes to produce further evidence on this subject. He concludes that he has proved that the synthesis of ammonia from hydrogen and nitrogen, obtained by the action of heat upon a solution of ammonium nitrite, is possible in the presence of spongy platinum.

Mr. J. MOND said that after two years' work at every conceivable means of causing the direct union of nitrogen and hydrogen with spongy platinum, platinised asbestos, &c., he had only met with negative results, and had come

to the conclusion that the silent discharge was the only means of effecting the direct union of these two elements.

Mr. W. A. Shenstone then read a paper "*On the Alkaloids of Nux Vomica.*" The author has, with the aid of Messrs. Hopkin and Williams, extracted the alkaloids from 56 lbs. of the seeds of *Strychnos Nux vomica*. His object was to prepare and examine the alkaloids prepared by using as little heat as possible, and avoiding heat in the presence of acids or alkalies altogether. The process used is similar to that employed by Dr. C. R. A. Wright. A solution of sulphate of brucine was finally obtained, from which the alkaloid separated on exposure to ammonia vapour. The brucine was finally purified by conversion into hydriodide, regeneration with sodium carbonate, &c. The brucine obtained did not yield any evidence of the presence of strychnia, and gave a crystalline acetate. Many analyses of the product are given, which agree with the formula $C_{23}H_{26}N_2O_4$. About 20 ozs. of mixed crystalline alkaloids were obtained. The author searched the mother-liquors very carefully for the so-called isagurin, but all such bodies were proved to be brucine with a trace of some persistent impurity. By the action of alcoholic soda on brucine a hydro-brucine, $C_{23}H_{28}N_2O_5$, was obtained. Its colour reactions are distinct from those of brucine.

Prof. Hartley then read a short paper entitled "*Notes on Photographs of the Ultra-violet Emission Spectra of certain Elements.*" The author draws the following conclusions:—The ultra-violet spectra are comparatively free from air-lines. All the most important groupings of metallic lines appear in the ultra-violet region. The sharp clear cut appearance and the nebulous character of certain lines are even more strongly marked than in the visible spectrum. Not only are long and short lines noticeable, but many rays which consist of mere dots are characteristic of certain spectra, while certain strong lines appear to stretch not only across the spectrum, but above and below its boundary edge. When the photographs of the elements are arranged in Mendeleeff's series certain well-defined groups exhibit similarities in their spectra, *e.g.*, Mg, Zn, and Cd; Fe, Co, Ni: Al, In, Tl; Cu, Ag, Hg. Palladium also has a spectrum somewhat similar to the spectra of the iron group. Prof. Hartley exhibited some of the beautiful photographs on which the above statements are based.

Mr. S. U. Pickering gave a brief statement of the results arrived at in his paper "*On the Sulphates of Aluminium.*" He has examined the seven or eight sulphates of aluminium which are said to exist, but has in most cases not been able to find any evidence of their existence.

"*On Two New Oxides of Bismuth,*" by M. M. P. Muir. The author has repeated Boedeker's experiments on the action of aqueous potassium cyanide on a hot nitric acid solution of bismuth nitrate, but finds that the puce-coloured salt which is produced has the formula Bi_2O_7, and not $Bi_2O_5,2H_2O$, as assigned to it by Boedeker. The new bismuth heptoxide is a fairly stable compound towards heat: it begins to part with oxygen at about 200°; soluble in acids, giving deep red liquids, which are only very slowly decomposed and decolourised by boiling. A hot concentrated solution of caustic potash dissolves 25 per cent of the new oxide, forming a very deep red liquid, from which acids throw down a red-brown substance containing bismuth, oxygen, and much water, but, after washing with hot water, free from potassium. The portion insoluble in hot potash consists of another new oxide of bismuth. Bismutho-hypobismuthic oxide, Bi_4O_7, sp. gr. 8·5, reacted on by potash, dissolves in acids to purple-red liquids, only very slowly decomposed by boiling; does not lose oxygen till heated over a Bunsen lamp. Neither oxide takes up water from moist air.

The Society then adjourned over the summer recess.

NOTICES OF BOOKS.

The Law of Therapeutics, or the Science and Art of Medicine. By Joseph Kidd, M.D. Second edition. London: C. Kegan Paul.

"He is a truly scientific physician," says the author, is now often a by-word for contempt. There are, it must be admitted, medical practitioners without end who, contrary to the vulgar notion, are not in any sense "men of science." They reject all modern instruments and modes of research; they laugh at the use of the microscope and of chemical reagents in ascertaining the nature or the cause of disease. They have no good word to say for physiological investigation, and sometimes, in consequence, throw themselves into the arms of the anti-vivisectionists, who are not slow to parade them as "scientific" converts to the agitation. Such men, though making no advances in medical theory, are not unfrequently successful routine practitioners, guided by tact rather than by definite principles. Dr. Kidd aims at something the very opposite. He holds that "of all studies, that of Therapeutics, or the treatment of disease, ought to be the most accurate." Where human life is at stake it saddens him to think how much still depends upon chance. What man accustomed to exact scientific work does not share this feeling? In his historical survey of therapeutic laws, or rather the gropings after such, many interesting facts are brought into view. It is shown that hospitals were not, as Dr. Farrar assumes, unknown to the civilisation of antiquity. The dispensary of the ancient Egyptians and the "Asclepias" of the Greeks contained the germ of the modern hospital. Perhaps the canonisation of personal dirtiness and the abolition of the Roman baths, effected in obedience to the dictates of Oriental asceticism, made the need and the scope for hospitals all the greater.

Of Haller, the author speaks, in our opinion, much too highly. There must have been something sadly wrong in the mind of the man who could "damn himself to everlasting fame" by such an utterance as his "*nulla est epigenesis!*"

Of Hahnemann and his system, the author takes a discriminating view. He admits the so-called fundamental homœopathic principle, "*similia similibus curantur*," as an important therapeutic law, though not indeed to the exclusion of the antipathic law of Galen, *contraria contrariis curantur*. But the developments of homœopathy, the infinitesimal doses, and the idea of "potentiation" or dynamisation, Dr. Kidd treats with the contempt which they experience and deserve from men of scientific habits of thought. He appeals from Hahnemann drunk with mysticism to Hahnemann sober, and he considers that medical practice generally has been modified for the better by the promulgation of homœopathy.

A passage concerning the researches of Dr. Brown-Séquard should not be overlooked in the present fanatical temper of a large part of the British public:—"When Brown-Séquard, the distinguished man of science, settled down to practise medicine in Cavendish Square and at the National Hospital for the Paralysed and Epileptic, he quickly showed that the most minute and delicate experiments upon animals were to throw a flood of light upon the medicinal treatment of the diseases of man. Many epileptic and paralysed patients have had cause to bless the labours of the man who for so many years patiently experimented upon guinea-pigs and rabbits in the causation of epilepsy and paralysis."

"It is fashionable," says the author, "now-a-days for every clever writer to explain that disease is not an entity or a substance." Yet, as he adds, the poisons of cholera, typhoid, and doubtless other diseases are very positive entities from without. Of "expectant treatment," he writes that "Hospital physicians, accustomed chiefly to recent cases of disease, mostly of sub-acute nature, find good feeding, nursing, plenty of fresh air, and perfect rest,

do so much for their patients—often moved from homes devoid of any hygienic attribute to the large airy wards of the hospital—that they are apt to lose faith in medicine. To them it is much to abstain from the routine of evil drugging. The contrast of their results is so decidedly favourable in comparison with the bleeding, leeching, and blistering of an age not quite gone by; but away from the hospital, among varied and perplexing chronic diseases the fashion of scepticism with regard to drugs avails but little."

Dr. Kidd recognises the "*vis medicatrix naturæ*," but it seems that he overlooks that counter-agency which the late G. H. Lewes well named the *vis deletrix*.

The author's remarks on food are highly judicious. He is not an adherent of any of the modern fanaticisms, such as teetotalism, or that pseudo-vegetarianism which rejects beef and mutton, whilst tolerating milk, cheese, and eggs. Yet he is no friend of the indiscriminate use of alcoholic stimulants, and he believes in milk to an extent scarcely justifiable in times when so many cows are known to be affected with tubercular disease. He complains that the "doctor is beset by a multitude of infant's foods. These evils—for evils they are—and quack medicines as well, would soon disappear if the law of libel were cut down to reasonable limits, so that they might be safely criticised.

We regret our inability to devote more scope to Dr. Kidd's volume, and we trust that its teachings will be fully appreciated by the profession.

Tin, a Geological-Mining-Historical Monograph. (Zinn, eine Geologisch-Montanistische-Historische Monografie.) By E. Reyer. Berlin: G. Reimer.

The author of this useful compilation divides his subject geographically. He treats, first, of the geology of the Saxon and Bohemian tin regions, and gives a history of tin mining at Graupen, Altenberg, Zinnwald, Platten, Erenfriedersdorf, Geier, and Schlackenwald. It appears that the tin-deposits were discovered and utilised as early as the 12th century. In the 15th century the produce of the Saxon and Bohemian tin mines was greater than that of Cornwall, but it has since fallen into comparative insignificance. Most of the mines have been abandoned in the present century, and in 1850 the entire yield of the Erzgebirge was only 2500 cwts. Since that time it has not increased.

Passing over to England, the author describes the geology and the mining industry of Cornwall and Devon. There is appended a glossary of the peculiar Cornish technical terms for rocks and minerals—a language not much more intelligible to the ordinary Englishman than to the foreigner, and which on the "*omne ignotum pro magnifico*" principle, greatly aids promoters of mining companies in mystifying the public, since it is brought into use in every part of the world where Cornish mining engineers are sent.

The tin deposits of Spain, Portugal, France (Bretagne), Italy, Finland, Sweden, Greenland, and Siberia are also noticed.

Of more importance are the tin mines of south-eastern Asia. Not merely the Malay peninsula and the islands of Banka and Bilitong, but the entire eastern coast of the Bay of Bengal, Java, Sumatra, the western coast of Borneo contain deposits of this metal. The Banka tin works are no longer so productive as in the years 1855-59, but the average yield is still about 4400 tons.

The total Australian production for the year 1877 is given as 13,000 tons. As regards the future of Australian tin mining the author takes a judicious view intermediate between the pessimist accounts of Cornish mine owners, anxious for high prices, and the exaggerated views of the Australians.

The North American production of tin is insignificant. Peru, Bolivia, and Chili yield small quantities, but the Peruvian tin is contaminated with tungsten, arsenic, and antimony, and is consequently not in request.

The remainder of the book is devoted to an account of the probable origin of tin ores, and of the smelting processes adopted in the different districts. The applications of tin are briefly noticed, its uses in the art of dyeing being dismissed in a few lines. Various processes for the recovery of tin from tinners' waste, clippings, &c., are noticed. The work is enriched with a very complete bibliography of the subject.

The following consideration with which the author concludes may throw a light on the general average of profit which may possibly be expected from mining. During the last 500 years in the mere process of separating the tin ore from sand, &c., 1,462,000 masses of earth and stone, ten metres high by the same measurement in length and width have been worked through, sifted, and washed! If we consider that it takes a man, on an average, a day to work through a ton of detritus, we have three milliard days' works spent in this one department of tin winning!

Education, Scientific and Technical; or How the Inductive Sciences are Taught and How they Ought to be Taught. By Robert Galloway, M.R.I.A., F.C.S. London: Trübner and Co.

The subject of this book is, as the author admits, inadequately expressed by the title. Its object, whether successful or not, is one with which we most ardently sympathise: Prof. Galloway trusts "his work will assist in arresting the competitive examination system, at least in the Science Schools carried on by the Department of Science and Art, and by the City Guilds; a system which, with the exception of England, only retrograde nations, like China, adopt; and that it will aid in causing us to follow in our educational systems the examples set by enlightened nations like Germany."

This declaration gives the key-note of the entire work. The author sets out with the admission, now no longer suppressed, that we are far behind most of the Continental nations in scientific and technical education. The two commonly alleged reasons for this inferiority, viz., our later entrance into the field, and the lack of the necessary funds, he shows to be insufficient. As far back as 1787, the Society of Arts was alive to the importance of the question. Nor are the resources deficient. If we sum up the revenues of the universities and the endowed secondary schools, the sums voted by Parliament, or contributed by private munificence, for the promotion of higher education, the amount would be startling, and would, *if rightly applied*, secure for us, as the author says, "the best general, scientific, professional, and technical education of any country."

The question may next be raised whether we lag behind from any natural deficiency of the British and Irish mind? The author, in addition to other evidence which might have been found, brings forward German testimony to the contrary. Prof. Max Müller, who has had ample opportunities of observing, declares: "The intellectual fibre, I know, is not different in the youth of England and the youth of Germany."

The first cause of our short-comings may be found in that inbred dislike of organisation, which is perhaps our greatest national weakness. As Dr. Wiese declares, "an extraordinary amount of power, time, and money is still wasted from a want of plan and unity."

A second cause of our deficiency is our system of teaching, which is made to turn almost entirely upon honours and examinations. Some years ago we had a great outcry about "university reform." It was contended that the exclusive attention paid at Oxford and Cambridge to classics and mathematics was a mistake. The reformers were partly in the right. "Of observation, experiment, induction, analogy, the mathematician knows nothing." In a very similar manner the attention of the classicist finds his attention withdrawn from things and fixed upon words only. He never learns, or rather, he unlearns, to

observe forms, textures, colours, odours, grades of pressure, &c., or to note their differences and their likenesses. Instead of what *is* he cares merely what somebody has said about it. It is very significant, as the author quotes from Prof. Cooke, of Harvard University, that when the claims of scientific culture were first urged upon Oxford and Cambridge, they were opposed on the ground *that the experimental sciences could not be made subjects of competitive examination.* It is by no means clear to us that even Prof. Cooke feels the full absurdity of this argument. For what does it imply? Nothing less than a complete inversion of means and end. For even "eminent English scholars"—as distinguished from men of science—must admit that if the object of education is simply to pass an examination better than someone else, it is a mere waste of time. Unfortunately our sages have got over this difficulty. It was once remarked that if the ancient scholastics could have got hold of Newton's *Principia*, they would simply have erected a mountain of verbal disputations upon it. In a very similar manner our masters, tutors, and the like, having admitted the natural sciences in some sort into their colleges and schools, have simply made them also into a subject for examination papers. A reformation in the subjects taught is of very little moment without we amend the way of teaching.

In Germany "the principle of competition is almost entirely excluded as tending to foster a servile view of education, and to lead to spasmodic and exhausting efforts and feverish excitement rather than the healthy and harmonious development of the mental powers. The students' powers are carefully husbanded for employment in the serious toils of mature intellectual life: in England they are wasted in a ruinous and unmeaning rivalry of striplings." Instead of teaching a man how to *do* a thing we cram him to pass an examination in it.

Now there is scarcely a man whose opinion is worth the smallest scrap of paper upon which it could be written but condemns, more or less openly, our examinational system. Still it survives, and there is no immediate sign of its breaking up. The school master who should rise to a higher idea of education would simply lose his pupils. Where to make a beginning is the difficulty. If we had sufficient influence we should exhort all who have the disposal of appointments in their hands to announce "no examinees need apply."

The author's remarks on teaching chemistry are exceedingly valuable. He complains that our elementary chemical treatises, numerous as they are, are not simplified, but merely diluted. He considers that chemistry, as long as taught by the present methods, will never prove of any value to those who study it as a branch of general education (*i.e.*, to nine students out of every ten), but only to those who study it as a profession, and even the latter might become sooner and better acquainted with it than at present. The author's own system appears to have proved successful both at schools of a lower grade and at the Museum of Irish Industry.

In concluding this brief notice we will merely wish this book an extended circulation, and its ideas a still wider appreciation. It is a manly and an enlightened attempt to declare, as does Prof. Galloway, war against an increasing evil, the real nature and magnitude of which few have realised.

Illusions, a Psychological Study. By James Sully. London: C. Kegan Paul and Co.

The object of the author in the present volume is to "take a wide survey of the field of error," including not merely the ordinary illusions of the senses, but other errors, similar in their mode of origin. Although the work is avowedly addressed in chief to psychologists it is not without profound interest for the student of physical science, who has carefully to avoid finding his own hypotheses and expectations in the phenomena which he is observing. Mr. Sully makes the happy remark that:—"Our luminous circle of rational perception is surrounded by a misty penumbra of illusion." He distinguishes illusion from hallucination thus: The former is a mere partial and the latter a total displacement of external fact by a fiction of the imagination, but he admits that the line is narrow. He distinguishes illusions according to the kinds of knowledge which they simulate, *i.e.*, those of perception, of introspection, of insight, of memory, and of belief.

In the section on the illusions of perception, which will have for the majority of our readers the greatest importance, we particularly notice the author's discussion of the effects of expectation. He distinguishes here *sub-expectation* and *vivid expectation.* In the former state, though not distinctly anticipating any one kind of object, we think that something will happen or be seen. Any emotion throws the mind more or less into this state. A feeling of awe makes us ready to perceive whatsoever is strange, mysterious, or apparently supernatural. In vivid expectation some one thing is looked for, and, in consequence, it is supposed to be seen, heard, or felt. A characteristic instance is here quoted which may be true:—"An officer, who superintended the exhuming of a coffin, rendered necessary through a suspicion of a crime, declared that he already experienced the odour of decomposition, though it was afterwards found that the coffin was empty." Of a like origin is the evil odour which so many persons at once experience if they learn that a chemical manufactory, or especially sewage-works, exist anywhere in the neighbourhood. We have heard of an establishment of the latter kind having been complained of as an actual—not prospective—nuisance, when it merely existed as a plan in the engineer's office! How widely perception of another nature may be vitiated by expectation is shown in an incident which happened when Davy first exhibited the properties of potassium to his contemporaries. A gentleman of some scientific merit, lifting up a portion of the new substance, exclaimed, "Yes, it is certainly metallic, and very ponderous"! Such facts may well impress upon young chemists and physicists the necessity of great caution when investigating a new subject. It is a wise precaution in all cases where expectation may be the father to perception to submit the phenomenon to the view of some acquaintance who is expecting nothing. But we have eminent, or at least noisy men, who, lest they should see or hear what is non-existent, fall into the counter-illusion, and do not see phenomena really in their presence.

We regret that want of space does not allow us to extend any further our survey of this important work, which we can recommend as a masterly exposition of its subject.

Annual Report of the Director of the Mint to the Secretary of the Treasury for the Fiscal Year ended June 3, 1880. Washington: Government Printing Office.

This report is in its nature fiscal and statistical, and does not furnish any novel information on refining and assaying.

An Elementary Course of Practical Physics. By A. M. Worthington, M.A. London: Rivingtons.

The author's object in this work is to propose a course of physical instruction, calculated to afford a good training in skilful manipulation, exact observation, intelligent and orderly recording of phenomena observed, the intelligent application of arithmetic, geometry, algebra, and the varying of experimental conditions. He enumerates the articles required for his course, and shows that to fit a school laboratory for really useful work does not involve any really formidable outlay. He deprecates "cram," as does every man whose opinion is worth the scrap of paper upon which it can be written. But cram still goes on increasing, and will increase till the educational world has its Cromwell with the will and the power to do away with

competitive examination in its every form. We are not disposed to differ from Mr. Worthington in his high estimate of the value of physics as an agent for the cultivation of the intellect. The author's rules to be observed by boys working in the laboratory are very judicious.

CHEMICAL NOTICES FROM FOREIGN SOURCES.

Note.—All degrees of temperature are Centigrade, unless otherwise expressed.

Comptes Rendus Hebdomadaires des Séances, de l'Académie des Sciences. No. 20, May 16, 1881.

Transformation of Morphine into Codeine and Homologous Bases.—M. E. Grimaux.—Codeine is a methylic ether of morphine, and from the latter may be obtained a series of new bases, of which codeine is the type and morphine the substratum. The author gives these compounds the generic name of codeines. Codeine is codo-methyline, and a base, which the author has discovered, $C_{19}H_{23}NO_3$, is codethyline.

Principle of the Conservation of Electricity.—M. G. Lippmann.—The principle of the conservation of electricity is expressed by the condition of integrability (α). It is susceptible of new applications, and permits us, not merely to analyse certain phenomena, but to deduce from the them existence and the law of new phenomena, which experiment has not yet detected. As the first example, he shows that what may be called the coefficient of electric contraction of a gas is equal to its refractive power for light. The author applies the same analysis to various electric phenomena, such as the expansion of the glass of a Leyden jar during charging; electrisation by the compression of hemihedral crystals; the pyro-electricity of crystals. Among other results are the existence of the following phenomena not yet verified by experiment:—(1) The dielectric power of glass augments under the action of mechanical traction; (2) non-superposable hemihedric crystals change their form when submitted to electric influence, and this deformation is sometimes opposite in direction to that which electric attractions tend to produce; (3) a pyro-electric crystal becomes heated or cooled on the approach of an electrised body, according as such body is in a positive or negative state. The phenomena thus foreseen are the inverse of the phenomena from which they are deduced. To establish their existence, the equation (α) is each time necessary; the principle of the conservation of energy taken alone does not suffice.

Theory of Rotatory Polarisation.—M. En. Mallard.—A mathematical paper, not adapted for abstraction.

Graphic Method of Representing the Phenomena brought into Play in Dynamo-electric Machines.—M. Deprez.—The author has found a graphic procedure of great simplicity, which enables him to calculate directly the value of the current produced by a dynamo-electric machine in all possible conditions of the speed of the ring and the resistance of the outer circuit. This process is based on the construction of an experimental curve which varies in each machine, and which the author calls the "characteristic" of the machine. To construct it, every communication between the ring and the electro-magnets' excitors is suppressed, and the current of known strength is turned into the latter; an arbitrary speed of rotation is then given to the ring, which is the same in all the experiments. We measure then by any known method, the difference of potential which exists between the two extremities of the induced circuit, which is broken. If we vary the intensity of the auxiliary current thrown round the electro-magnets, the difference of potential of the extremities of the induced circuit will undergo corresponding variations, and on taking the intensities of the auxiliary current as the abscissæ of a curve, and the differences of potential of the extremities of the induced circuit as ordinates, the characteristic curve is obtained.

Hydrates Formed by Chloride of Calcium.—M. H. Lescœur.—The author considers that the existence of hydrates, containing respectively 1, 2, 4, and 6 mols. of water may be admitted.

Solubility of Mercurous Chloride in Hydrochloric Acid.—MM. F. Ruyssen and E. Varenne.—The solubility of mercurous chloride, unlike that of silver chloride, is greatly dependent upon time of contact.

Non-Existence of Microzyma Cretæ.—MM. Chamberland and Roux.—The authors controvert, experimentally, the presence of a supposed ferment in chalk as assumed by M. Béchamp, in 1866.

Crystallisation of Alums.—M. A. Loir.—The various faces of a crystal have not all the same power of attraction for a body contained in the solution employed to feed the crystal.

Berichte der Deutschen Chemischen Gesellschaft zu Berlin. Vol. 13, No. 11.

Simple Method of Determining the Temporary Hardness of Water.—V. Wartha.—In order to ascertain the alkalinity of springs on the spot, with samples not exceeding 10 c.c., and with a single reagent, the author makes use of a tube of 30 to 40 c.m. long, closed at the bottom, and with a mark showing the capacity of 10 c.c. From this mark upwards the tube is graduated into 0·1 c.c. To determine the temporary hardness the tube is filled to the lowest mark with the water in question, and a little piece of filter-paper, which has been previously steeped in extract of logwood and dried, is thrown in, thus giving the water a violet colour. Centinormal hydrochloric acid is then added from a dropping bottle, till the colour of the liquid inclines to an orange. The tube is then closed with the thumb and well shaken. The greater part of the carbonic acid escapes, and the liquid becomes red again. Acid is again added, and the shaking repeated until the next drop of the acid turns the liquid to a pure lemon-yellow, a point which a little practice is easily reached. The amount of acid used is read off on the tube itself. The author proposes to express the alkalinity of a water by the number of c.c. of centinormal acid needed to neutralise 10 c.c. He thinks that this method will be found useful both for sanitary and geological purposes.

Chemistry of the Platinum Metals.—Theodor Wilm.—Contrary to the prevalent view, all the platinum metals, if precipitated by zinc in a state of very fine division, are soluble to a considerable extent in nitric acid, whether weak or strong, so that palladium cannot be separated from such a mixture by means of nitric acid. The solubility appears to depend on the relative proportion of one or other of the metals in the mixture (mass action). Pure palladium, even in thin leaves, is not easily soluble in nitric acid, whilst all the other platinum metals are perfectly insoluble if in a moderately compact condition. Palladium cannot be isolated by agitation with mercury from a solution which along with the platinum metals contains base metals, such as copper, lead, &c., since the mercury precipitates, not merely the palladium, but all the other platinum metals, forming probably amalgams. From the platinum metals thus precipitated by mercury, metal free from mercury cannot be obtained by distillation and subsequent ignition, since a part of the mercury forms a stable compound with the platinoids.

Action of Bromine upon Toluol and Certain of its Derivatives.—C. Loring Jackson and A. W. Field.—This paper was read before the American Academy of Science on June 12, 1878.

An Explosion Furnace.—L. von Babo.—This memoir cannot be reproduced without the two accompanying illustrations.

MISCELLANEOUS.

An Industrial and Technological Museum.—An Industrial and Technological Museum of a very comprehensive character is in course of organisation at Sydney. It is to include animal, vegetable, and mineral produce in the crude and in the manufactured states; waste products, of whatsoever origin; foods with their constituents, and that necessary shadow side of the picture, their adulterations; educational appliances; sanitary apparatus and systems, models, plans, machinery, &c., for mining; agricultural machinery and manures; models, drawings, and descriptions of patents; a department of economic entomology; ethnological specimens, &c. One remark in the prospectus may call up a smile. The museum is intended to occupy a similar position to the South Kensington Museum. This might be construed to mean that it is to occupy a site as far out of the way of merchants, manufacturers, patentees, &c., as possible. We need scarcely say that the project has our best wishes.

Glycerin.—Notwithstanding the low price which now prevails for almost every description of raw produce and manufactured goods, there are a few articles which form notable exceptions. Perhaps one of the most remarkable of these is refined glycerin, which, within the last two years, has advanced from about £30 to £130 per ton avoirdupois for 30° B. This enormous advance is due partly to increased consumption, diminished production, and the influence of speculation working on a market devoid of stocks. In view of the present position of the article and the prospect of a continuance of high prices for a considerable time to come, the attention of soapmakers is now being turned to the utilisation of their waste "leys," and various new processes for recovering the glycerin contained in these liquors have lately been tried with more or less successful results. Apart from minor impurities, waste soap "leys" are generally found to contain glycerin, carbonate of soda or caustic soda, chloride of sodium, gelatin, and albumen. One of the processes for recovering the glycerin which promises to be the most economical and the most successful begins with concentrating the liquor until the salts contained therein begin to crystallise. The liquid is then cooled and filtered to rid it of gelatin and albumen. It is afterwards made to absorb carbonic acid, which precipitates bicarbonate of soda, and which is separated from the liquor in the usual way. After undergoing this process the liquor is then made to absorb gaseous hydrochloric acid until what remains of carbonate of soda has been converted into chloride, and further, until all, or almost all, the chloride of sodium has been precipitated and separated from the liquor in the usual manner. Arrived at this stage, the liquor contains water, glycerin, and hydrochloric acid. The acid is then evaporated entirely and absorbed in water for using afresh. The dilute glycerin remaining can be purified by filtering it through animal charcoal or by concentrating and distilling it in the usual way.—*Glasgow Herald.*

MEETINGS FOR THE WEEK.

MONDAY, 27th.—Royal Geographical, 8.30.

Society of Public Analysts, 8. "On the Estimation of Quinine in Wines, Tinctures, &c.," and "On the Figures or Patterns which Drops of Various Fats Assume under Certain Conditions," A. Wynter Blyth, M.R.C.S. "On a Modification of Wynter Blyth's Apparatus for Digestions in Ethers as Applied to Milk Analysis;" and "On a New Burner for Griffin's Gas Muffle Furnace," W. F. K. Stock, F.C.S., F.I.C. "Some Remarks on the Swedish Laws and the Quantity of Arsenic really Prohibited," C. Heisch, F.C.S., F.I.C. In reference to the Swedish laws for the sale of Poisons, Dr. Wallace will exhibit a certificate of a test for arsenic in a carpet, by the Government Chemist at Stockholm, with tube containing the result of the test and a piece of the carpet.

WEDNESDAY, 29th.—Society of Arts (Anniversary), 4.

TO CORRESPONDENTS.

A Correspondent.—We learn that the margarimeter can be obtained at 16, Rue Sauval, Paris.

THE JOURNAL OF SCIENCE

for JUNE (Price 1s. 6d.), include—

Hylozoic Materialism. Communicated by Robert Lewins, M.D.
The Border-Land of Chemistry and Biology.
Scepticism in Geology. By Robert Ward.
The Philosophy of Pain. By Frank Fernseed.
The Weights and Measures Question Reconside ed. By an Old Technologist.

Analyses of Books. Correspondence. Notes.

London: 3, Horse-Shoe Court, Ludgate Hill.

SOUTH LONDON SCHOOL OF CHEMISTRY.

VACATION ARRANGEMENTS.

Gentlemen can be privately instructed in any branch of Practical Chemistry during the months of July, August, and September. Those desirous of working out any Research or Patent (with or without advice) can secure a Private Laboratory to themselves.—For terms apply to W. BAXTER, Secretary, South London Central Public Laboratory, Kennington Cross, S.E

BERNERS COLLEGE of CHEMISTRY.

Instruction and preparation in CHEMISTRY and the EXPERIMENTAL SCIENCES under the direction of Professor E. V. GARDNER, F.A.S., M.S.A.

The Class Rooms are open from 11 to 5 a.m. and from 7 to 10 p.m daily.

Especial facilities or persons preparing for Government and other examinations.

Private Pupils will find every convenience.

Analyses, Assays, and Practical Investigations connected with Patents, &c., conducted.

Prospectuses and full particulars on application to Prof. Gardner at Berners College, 44, Berners-street W.

THE CHEMICAL NEWS

AND

JOURNAL OF PHYSICAL SCIENCE.

R. A., deoxidation of nitrates, 143
W., insoluble form of soda, 8
pitch-house explosions in tar distilleries, 221
Smoke and fog, 142
Soap of molassea, 211
Soaps, alcohol in transparent, 234
analysis of, 219
Society, Chemical, 41, 69, 92, 112, 140, 162, 175, 193, 217, 244, 267, 287
Industrial, of Mulhouse, 198
Manchester Literary and Philosophical, 7
of Arts, 13, 37, 223
of Industrial Chemists, 59, 81, 154, 164, 185, 194, 221, 281
of Medical Officers of Health, 245
Philosophical, of Glasgow, 44, 176, 219
Physical, 43, 81, 104, 126, 163, 175, 229, 254, 277
Soda, action of upon glycerin, 95
insoluble form of, 8
lime, determination of nitrogen by means of, 187
lyes, causticising, 279
manufacture of from sulphate, 72
Sodium, action of on chinoline, 145
on cinnamic ether, 245
alcoholates, action of on fumaric ethers, 218
boro-tungstates, 47, 61
chloride, displacement of the soda of by copper hydrate, 144
ferrocyanide, manufacture of, 119
hydrosulphite, 79
Soil, water, and atmosphere, alcohol in, 166
Soils, Hungarian wheat, action of artificial manures on, 178
Solar spectrum, normal, distribution of energy in the, 195
Sorbine and sorbite, 106
Soxhlet, F., estimation of fat in milk, 101, 111
Specific heats, apparatus for determining, 204
magnetism of ozone, 129
Speck, M., influence of light on the transformation of matter, 235
Spectabilis, Alstonia, bark of, 83
Spectra, absorption, of cobalt salts, 27
of organic bodies, 126
ultra-violet emission, photographs of the of certain elements, 289

Spectra, discontinuous phosphorescent, in high vacua, 237
Spectro-photometers, study on, 59
Spectroscopy, 211
Spectroscopic researches, 270
Spectrum, absorption, of ozone, 36
normal solar, distribution of energy in the, 195
of the colour-blind, 47
visible, absorption-bands in the, 92
Spence, P., smoke and fog, 142
Splenic fever, experimental production of the fungus of, 178
Spitzer, F., camphor chlorides, 259
and J. Kachler, hydro-camphen, 47
Sprengel, H., the so-called "Bunsen pump," 220, 256
Staedel, W., vapour densities of halogen-substituted ethans, 257
and E. Sauer, di-oxy-benzophenon, 257
Starch, chemical change of, 36
detection of in milk, 210
solution of, 37
Staveley, W. W., benzol boiling-points, 70
tests, 129, 186
pure coke, 228
Stebbins, J. H., azo-compounds, 48, 58
Steel, estimation of phosphorus in, 147, 186, 209, 230, 256, 278
for the manufacture of dyes, 239
hardening and tempering of, 277
manganese in, 266
Steiner, J., experiments with maltose, 54
Stenhouse, J., and C. E. Groves, history of orceines, 83
Stromeyer, A., and H. Hübner, nitrification of para-nitro-benzoic acid, 11
Strontia and baryta, action of carbonic acid on, 279
Struve, H., and O. Jacobsen, preservation of organic substances, 178
Strychnine, chlorine derivatives of, 36
Stumpf, M. chemical change of starch, 36
Succinic acid, cyanamide compounds of, 188
Sugar, action of caustic lime on pure solutions of, 36
beet, cultivation of, 36
beets, experiments with, 167
bone-black in the manufacture of, 36
gypsum in the manufacture of, 36
preparation of glycolic acid from, 174
works, purifying waste-waters from, 118
Sulliot, M., application of chamber crystals, 232
Sully, J., "Illusions" (review), 291
Sulphate, chromous chloride and, preparation and properties of, 222
manufacture of soda from, 72
Sulphide, arsenic, as a poison, 196
group, ammonium, separation of the heavy metals of the, 153
liquid phosphorus, 270
uranyl, decomposition and transformation products of, 153
Sulphides, determination of sulphur in, 89
of copper, 267
Sulpho-chloride, phosphenyl, new synthesis of, 11
Sulphocyanide, tin, 84
Sulphe-hydantoine, 72
Sulphur, combustion-heat of, 258
determination of in sulphides, &c., 89
production of native, in the subsoil of Paris, 81
strength of solutions of in carbon disulphide, 192
Sulphuretted hydrogen apparatus, 191
Sulphuric acid, action of upon substituted nitro- and amido-benzols, 198
behaviour of, recently heated to 320° with oils, 195
burns, treatment of, 233
manufacture, loss of nitrous compounds in, 78
solubility of sulphur dioxide in, 121
"Sulphuric Acid and Alkali Manufacture" (review), 89
Sulphurous acid, oxidation of, 193
Superphosphates, coarse and fine, 13
reversion of, 178

TANATAR, S., manufacture of sodium ferrocyanide, 119
Tannin of oak bark, influence of the soil on the, 118
Tanret, C., waldivine, 234
Tar distilleries, pitch-house explosions in, 222
of cork, 196
Tartaric acid, reaction of, 110
and uvic ether, preparation of, 280
Tate, A. N., Society of Chemical Industry, 185
Tatlock, R. R., determination of potassium as potassium platino-chloride, 273

EDITED BY WILLIAM CROOKES, F.R.S., &c.

No. 1127.—JULY 1, 1881.

SELENIUM AND ITS APPLICATIONS TO THE PHOTOPHONE AND TELEPHOTOGRAPHY.*

By SHELFORD BIDWELL, M.A., LL.B., M.R.I.

Before entering upon my subject, I must claim your indulgence upon two grounds. A week ago I had not the remotest idea that I was to have the honour of addressing you here this evening; the time which I have had for preparation has, therefore, been exceedingly limited. In the second place, it is my desire (in accordance with the traditions of this Institution) not merely to give a description of the experiments in which I have for the last few months been engaged, but, as far as possible, to reproduce them before you. Now, these experiments are mostly of a very delicate nature. In the quiet of a laboratory—where time is practically unlimited, and where an operation, if it should fail at first, may be repeated an indefinite number of times—success is tolerably certain to be finally obtained; but in exhibiting delicate experiments before an audience, one is working under the most unfavourable conditions, and, in case of failure in the first instance, the attempt cannot generally be repeated. Moreover, the substance with which we are chiefly concerned, selenium, is apparently extremely capricious in its behaviour. This appearance is, of course, really due to our present ignorance of its properties; but the fact remains that, on account of the great uncertainty of its action, it is a very difficult substance to deal with.

Selenium is a rare chemical element which was discovered in the beginning of the present century. In many of its properties it closely resembles sulphur, and, like sulphur and some other substances, it is capable of existing in more than one form.

The ordinary form is that called vitreous. Selenium in this condition is as absolutely structureless as glass, and in appearance resembles nothing so much as bright black sealing-wax, with, perhaps, somewhat of a metallic lustre; its real colour, however, when seen in thin films, is ruby red. Its melting-point is a little higher than 100° C. In its second modification selenium is crystalline. When in this form its surface is dull, its fracture is metallic (not unlike that of cast-iron), its colour is grey or leaden, and it is quite opaque to light; its melting-point also is considerably higher, being 217° C.

Vitreous selenium, if melted and kept for a certain length of time at a temperature between its own fusing-point and that of crystalline selenium, will crystallise; and I think I am right in saying, from casual observation, though I have made no experiments to verify the point, that the length of time necessary for crystallisation depends upon the degree of temperature, being proportionately shorter as the temperature approaches 217° C.

Vitreous selenium is an exceedingly bad conductor of electricity; it is, indeed, an almost perfect insulator. Crystalline selenium is a moderately good conductor, and it possesses this very remarkable property, which has been utilised in the photophone and other inventions, that it conducts better in the light than in the dark, the change in its resistance to the passage of a current of electricity through it varying, according to Professor W. G. Adams, as the square root of the illuminating power.

Let a galvanometer be connected to the two poles of a battery by means of two copper wires. The passage of a current of electricity will at once be denoted by the deflection of the magnetic needle; or, if a little mirror is attached to the needle, and a beam of light be reflected from it upon a scale, the movement of the spot of light will indicate the movement of the needle. Let, now, one of the wires be cut, and the two ends be joined together by a piece of crystalline selenium. The spot of light will again move, but its deflection will be very much less than it was before, showing that the resistance of the selenium is very much greater than that of the wire. Moreover, if the piece of selenium be alternately exposed to and screened from a beam of light, the deflection will be greater when it is in the light than when it is in the dark, showing a corresponding variation in its resistance. This remarkable property of selenium was first announced and exhibited by Mr. Willoughby Smith in 1873. But the effects produced by the simple arrangement which I have just described are small, and very delicate instruments are required for their observation.

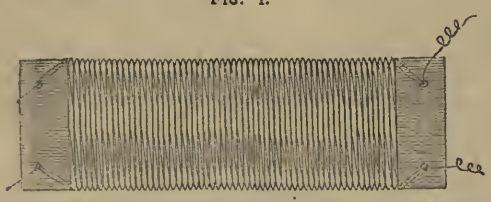
Since that date several devices have been proposed for exaggerating the effect, but they all depend upon the fact that the amount of the variation increases with the extent of the selenium surface acted upon. It has lately been the fashion to call these arrangements "cells," which, in most cases at all events, seems to be a very inappropriate name. It has been suggested that they should be termed "rheostats," a name which well expresses the purposes for which they are generally used, and is less likely to lead to confusion than the other. In deference to custom, however, I shall call them by the usual name.

The simplest selenium cell which could be devised would be made by placing two short pieces of copper wire parlalel to each other, and very near together, and con-

* A Paper read before the Royal Institution of Great Britain, Friday, March 11, 1881.

necting them by a narrow strip of selenium. The effect produced by light is increased by lengthening this arrangement. We might go on increasing the wires with advantage until they were 10 or 12 feet long or more, every additional inch of length producing an increase of "sensitiveness" as it is called. But a cell of this length would be cumbersome and unwieldy to use, and in fact could hardly be lifted without being destroyed. Dr. Werner Siemens therefore adopted the device (among others) of coiling up the wires so as to form a double spiral, and thus made a convenient and portable cell of great sensitiveness. But it is very difficult indeed, as I know by experience, to produce these double wire spirals of any considerable size without the two wires touching one another at some point. After many attempts I succeeded in producing spiral cells about $\frac{3}{4}$ inch in diameter, but I found it impossible to exceed this size, and as it was not large enough I adopted a simple and very effective variation of Siemens's method, which I believe has not been previously suggested. A copper wire is wound after the fashion of a flat screw around a narrow slip of mica, the threads of the screw being about 1-16th inch part. Beside this wire, and at a distance of 1-32nd inch from it, a second wire is wound in exactly the same manner, each of its turns coming midway between two consecutive turns of the first. Care is taken that the two wires do not touch each other at any point. Over one surface of the mica a film of melted selenium is spread, and after being worked smooth and uniform it is crystallised. By this means the two wires are connected with each other through half their entire length, by a series of very narrow strips of crystalline selenium.

FIG. 1.



Mica Plate, wound with Two Copper Wires ready for Selenium Coating.

I have here a tiny selenium cell which has been constructed in this manner. Each wire makes about six turns, and the area of the selenium upon its surface is about half that of a threepenny piece, its thickness not much exceeding that of a sheet of ordinary note-paper. Its resistance, though it is very high relatively to that of good conductors, is, compared with anything of the kind that I had ever seen before, remarkably low, and its sensitiveness to light is great. When a bat's-wing gas flame is held at a distance of 3 inches from it, its resistance is less than one-third of that which it measures in the dark. Larger and more carefully constructed cells, of course, show better results. No form, however, that I have tried (and I have made several dozens) has in my hands been superior to that of a double flat screw.

When cells are to be made of any considerable size, the labour of winding on the wires with sufficient regularity is very great. By the help of a lathe this difficulty may be reduced to a minimum. The method of proceeding is this:—A cylinder is turned of hard wood, of length and diameter slightly greater than that of the proposed cell. This cylinder is cut longitudinally into two equal parts, and between the two semi-cylinders thus formed a slip of mica is placed sandwich-like. The ends are secured with screws, and the whole is smoothed down in the lathe. When the edges of the mica are quite flush with the surface of the wood, a screw of from thirty to forty threads to the inch is cut upon the cylinder. On removing the mica from the wood its two edges are found to be beautifully and regularly notched. The first wire is then wound into alternate notches, and the second into the others.

I will throw upon the screen the image of a slip of mica with the two wires wound upon it, and ready for the reception of the selenium coating. It will be seen that the turns are perfectly regular, and close as the wires are to each other they do not touch at any point. (Fig. 1.)

The next step is to apply the selenium, and to do this properly is an operation which requires a certain amount of practice and patience. The mica is heated to a temperature slightly above 217° C., and melted selenium is spread over its surface as evenly as possible with a metal spatula. The cell is then cooled, and its surface should be smooth and lustrous. Before you is an embryo cell which has reached this stage of its preparation. The selenium being still in the vitreous condition, is a perfect insulator, and when the cell is connected in circuit with a battery and a reflecting galvanometer, the spot of light is found to be absolutely motionless. I now propose to crystallise the selenium in your presence. The mere crystallisation occupies a very short time. It is only necessary to place the cell upon a brass plate, and raise it by means of a Bunsen burner to a temperature somewhat below the fusing-point of crystalline selenium. The method described by Professor Adams in his classical paper published in the *Philosophical Transactions*, is entirely different. He heated a bucket of sand by placing in it a red-hot iron ball. At the expiration of an hour he removed the ball, and placed in the heated sand his pieces of vitreous selenium, wrapped up in paper. After remaining for twenty-four hours, the selenium was generally found to have attained the crystalline form, and the resistance of some of his specimens thus prepared was far lower than that of any which have been made by myself. Their sensitiveness, however, does not appear to have been great. The method of crystallisation which I generally adopt, and which is due to Prof. Graham Bell, has at all events the merits of simplicity and rapidity. In two or three minutes the whole surface of the selenium film becomes dull and slate-coloured, and if, when the cell has attained this condition, it be removed from the hot metal plate, I have little doubt that on testing it with a galvanometer, it will be found to conduct electricity and to be sensitive to light. (Exp.) According to Prof. Graham Bell, nothing more is necessary for obtaining the greatest degree of sensitiveness. The old-fashioned process of long heating and slow cooling may, he says, be altogether dispensed with. In this matter my experience differs entirely from his, for I find that cells which have been kept for some hours at a temperature just below the point of fushion, and then allowed to cool very gradually, are vastly more sensitive to light than those which have not been thus annealed.

The following table shows the resistances in the dark and under different degrees of illumination, of a few cells taken from my stock. The resistance of No. 6, when exposed to a lime light at 10 inches, is less than one-fiftieth of its resistance in the dark.

Resistances in Ohms.

Cell No.	In Dark.	Gas Jet at 12 Inches.	Gas Jet at 6 Inches.	Gas Jet at 3 Inches.	Lime Light at 10 inches.
4	400,000	190,000	150,000	80,000	
6	250,000	80,000	54,000	29,000	5,700
7	430,000	160,000	110,000	64,000	With Alum Cell.
9	87,000	52,000	42,000	33,000	
10	62,000	32,000	26,000	17,000	14,000
11	100,000	63,000	50,000	33,000	24,000
12	22,700	9,100	6,600	4,500	—

It is an interesting question, which of the coloured components of white light has the greatest power in effecting these changes in the resistance of selenium; or, again, whether the effect is produced by light at all, or is due simply to heat. Captain Sale came to the conclusion, on moving a piece of selenium through the solar spectrum, that the maximum effect was produced at or just outside the extreme end of the red, at a point nearly coinciding with the maximum of the heat rays. Prof. Adams per-

formed the same experiment with the spectrum both of the sun and of the electric light, and found that the action on the selenium was greatest "in the greenish yellow and in the red portions of the spectrum." The greenish yellow is the point of maximum illumination, which is a remarkable fact; but his words seem to imply that there was a second maximum in the red. The violet and the ultra-violet rays, he says, produced very little, if any, effect. In consequence of the discrepancies in these results, I determined to repeat the experiment for myself. The source of light which I used in the first instance was an oxy-hydrogen lime light, and the spectrum was formed with a bisulphide of carbon prism. The experiment was repeated six times, and three different selenium cells were used. The results were precisely the same in every case, and proved in the most marked manner that the greatest influence occurred in the boundary-line between the red and the orange; thus differing completely from the results obtained both by Capt. Sale and by Prof. Adams. Moreover, the resistance when the selenium cells were placed in the ultra-red, 2 inches beyond the limits of the visible spectrum, was in every case lower than when it was in the blue, indigo, and violet. But even in the ultra-violet the resistance of the cells was lower than when they were quite removed from the spectrum.

My friends, Mr. Preece and Mr. W. H. Coffin, who were present during these experiments, suggested that it would be desirable to vary them by making use of different sources of light, and different methods of dispersion; and a few days afterwards, by the great kindness of Mr. Norman Lockyer, they were repeated in Mr. Lockyer's laboratory by Mr. Preece and myself with the electric light and a magnificent diffraction grating. Nine experiments were made with three cells, and the results were as absolutely concordant as those which we had previously obtained; but they all concurred in placing the maximum at the extreme edge of the red, thus agreeing with Captain Sale's observations. One other remarkable effect must be noticed. In the case of a single cell—that which I distinguish as No. 6—with which three experiments were made, a second maximum was observed in every case in the greenish yellow, though the effect was about 20 per cent smaller than at the extreme red. The electric light, however, is from its great unsteadiness most unsuitable for experiments of this nature, and since no such exceptional phenomenon was ever observed before or since, I am inclined to believe that, by a coincidence which, however remarkable, is by no means impossible, the light happened to be unusually intense just on the three occasions when this particular cell was in the greenish yellow. A third series of experiments made with a gas flame and a bisulphide of carbon prism agreed with the first in placing the maximum at the orange end of the red. Many more combinations of sources of light and dispersion remain to be tried, but time for these and for innumerable other experiments which have suggested themselves has hitherto been wanting: for an operation which may be described in a dozen words not unfrequently requires as many hours for its performance.

(To be continued.)

NOTE ON THE SPECTRUM OF SODIUM.*

By CAPTAIN ABNEY, R.E., F.R.S.

On examining the spectra of different metals, there is one point which is striking in the extreme, viz., the absence of any very marked lines in the region between λ 7000 and λ 7600, which latter number we may take as the visible limit of the spectrum. With the exemption of the well-known pair of lines of potassium I am not aware that any lines in spectra, which have been carefully studied, have been found below this limit, though recently in the spectra of some of the rarer earths some few lines have been recorded. Having photographed the bright line arc spectra of several metals, it appears, so far as examination has been made, that only those which can be volatilised at a low temperature have any lines in the ultra-red.

Sodium is an example of this. It has a pair of lines at wave length of about 8187 and 8199 of an intensity of about 3, taking the intensity of D lines as 10. It will be noted the difference in wave-length between this pair is greater than that of the D lines. They do not seem to have any corresponding dark lines in the solar spectrum, though there are three faint lines which lie close to that wave-length.

In the calcium spectrum there are a pair of very faint lines which lie between λ 8500 and 8600. These exact wave-lengths have not at present been determined.

Iron, cobalt, nickel, copper, magnesium, and potassium have, up to the present, given negative results, but will be examined again.

* A Paper read before the Royal Society, June 16, 1881.

ON THE ABSORPTION OF GASES BY SOLIDS.*

By J. B. HANNAY, F.R.S.E., F.C.S.

During the progress of the investigations which I have from time to time had the honour of bringing under the notice of the Royal Society, I have again and again noticed the apparent disappearance of gases inclosed in vessels of various materials when the disappearance could not be accounted for upon the assumption of ordinary leakage. After a careful examination of the subject I found that the solids absorbed or dissolved the gases, giving rise to a striking example of the fixation of a gas in a solid without chemical action.

In carrying out that most troublesome investigation, the crystalline separation of carbon from its compounds, the tubes used for experiment have been in nine cases out of ten found to be empty on opening them, and in most cases a careful testing by hydraulic press showed no leakage. The gases seemed to go through the solid iron, although it was 2 inches thick. A series of experiments with various linings were tried. The tube was electro-plated with copper, silver, and gold, but with no greater success. Siliceous linings were tried—fusible enamels and glass—but still the tubes refuse to hold the contents. Out of thirty-four experiments made since my last results were published, only four contained any liquid or condensed gaseous matter after the furnacing. I became convinced that the solid matter at the very high pressure and temperature used must be pervious to gases. This I find to be the case, and to a very remarkable extent. I am still investigating this matter, but as I have so much on hand it may be some time before I can finish the work, so I wish to place on record the results so far as I have proceeded. I find that glass, when at a temperature of about 200°, absorbs a large quantity of gas when the latter is under a pressure of 200 atmospheres. Oxygen and carbon dioxide have been used, and have been found to be largely absorbed, and on cooling the glass under pressure the gas is retained permanently fixed. So much is absorbed that, on quickly raising the temperature to the softening temperature of the glass, the sudden escape of gas drives the glass into foam. On slowly raising the temperature and retaining it at 300°, most of the absorbed gas is given off without any visible action.

The frothing up of the glass by the outrush of gas is very striking. Other silicates, and also borates and phosphates, absorb gas, especially carbon dioxide, under great pressure. Metals absorb hydrogen and some of its compounds with carbon. As the treatment of quantities of matter sufficient for analysis at these high pressures and temperatures is a matter of great difficulty, the majority of experiments being failures, the work proceeds

* A Paper read before the Royal Society, June 16, 1881.

but slowly; but I hope during the summer and autumn to be able to elucidate the subject quantitatively, when I shall detail the results to the Society.

ESTIMATION OF CARBONIC ACID.

By T. S. GLADDING.

The following apparatus for the estimation of CO_2 by absorption has been used in our laboratory for several years, and has proved itself indispensable on account of its great convenience and accuracy.

It consists of the ordinary generating flask, followed by an empty U-tube, to retain condensed water-vapour; this is succeeded by four potash bulbs of the Geissler form. The first of these contains concentrated H_2SO_4 to dry the gas. The next two contain potash solution, of sp. gr. 1·27, for absorbing the CO_2; the last contains concentrated H_2SO_4 to absorb the moisture taken up from the potash solution. Then comes a U-tube containing soda-lime and serving as a guard.

The last three Geissler bulbs constitute the weighable portion of the apparatus. Perfectly dry air, plus CO_2, enters these and perfectly dry air alone escapes. The increase in weight gives the amount of CO_2.

The advantages of this apparatus are:—

1. The superiority of concentrated H_2SO_4 over $CaCl_2$ as a drying agent on account of (*a*) its greater thoroughness; (*b*) its non-absorption of CO_2, as is the case with $CaCl_2$, requiring its previous saturation by a current of the gas; and (*c*) its greater cleanliness and simplicity of renewal, which takes but a moment, and is necessary only at long intervals.

2. The rapidity with which an analysis may be made. The bubbles of gas may pass at the rate of five per second with perfect safety, and an analysis including all weighings, and a final aspiration of four or five litres of air be completed in less than two hours.

3. The large quantities of substance that may be used and the consequent increase of accuracy attained. Five grms. of bicarbonate of soda may be used as safely as one grm. in the old form, and duplicates easily agree within a few hundredths of a per cent. An analysis of Iceland spar, taking 5 grms., gave 43·97 per cent.

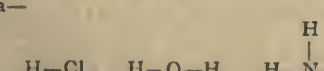
A strong aspiration must be maintained from the beginning of the analysis, the flow of gas being regulated by a screw-clamp placed before the generating flask. 100 c.c. of water are added to the carbonate, and then normal HCl to slight excess. Not a trace of HCl is carried over on boiling. All the corks are of soft rubber, and black rubber tubing is employed for connections.

55, Fulton Street, New York.

CHEMICAL AFFINITY AND ATOMICITY.*

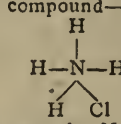
By WILLIAM DURHAM, F.R.S.E.

Though the theory of "valency" or "atomicity" has done good service to chemistry, and clearly enough explains many chemical combinations, yet it is very generally admitted that it is defective and fails to account for many observed facts. In this theory, hydrogen being taken as possessing unit of valency, the elements are divided into groups according as they combine with one, two, or more atoms of hydrogen, or other similar element, and are classed as monatomic, diatomic, &c., or shortly, monads, dyads, &c. This arrangement may be illustrated by such compounds as hydrochloric acid, water, and ammonia—



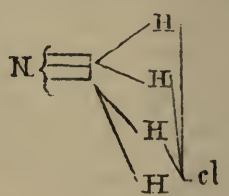
where hydrogen and chlorine are monads, oxygen a dyad, and nitrogen a triad. There are many examples, however, of elements of one class acting as if they belonged to another. Cl, for example, a well established monad, forms with silver, Ag, another monad, a compound, Cl_2Ag_4, in which both cannot be monads. With this latter element, Ag, oxygen forms a compound, OAg_4, in which the oxygen must act as a tetrad. Nitrogen forms NH_4Cl, in which it appears to act as a pentad and so on. Then, again, there are whole series of compounds of which no satisfactory account can be given, such as the double chlorides, $PtCl_42KCl$, $PtCl_42NaCl6H_2O$. In the former of these we have one tetrad atom united to eight monads, and in the latter, in addition to this, there are six molecules of water fixed on. Many other cases, equally difficult of explanation, might be given. Various hypotheses have been brought forward to account for these anomalies, none of which seem to me satisfactory.

The whole difficulty seems to be in the assumption that chemical affinity acts in atomic indivisible units. Because matter is atomic in its structure it seems to have been assumed that the chemical affinity associated with these atoms must also act as an indivisible unit. Let us take a simple case: nitrogen, usually considered a triad, forms, as we have seen, the compound—

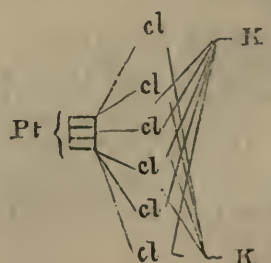


in which it acts as a pentad. Now, in this formula this difficulty at once presents itself. We have here chlorine, which usually has such an intense affinity for hydrogen and such a weak affinity for nitrogen, represented as directing all its energy towards the nitrogen and having no effect on the hydrogen whatever, and this, too, when in such close contact as the atoms must be in a molecular state.

Now, let us get rid of this idea of affinity acting in an atomic fashion. Suppose chlorine to have affinity equal to one and nitrogen equal to three, but capable of being spread out, and see how the compound would be represented. We should have the nitrogen spreading out its affinity over the 4 atoms of hydrogen, giving, *on the average*, ¾ to each; similarly, the chlorine would give ¼ to each. Therefore the whole affinity acting on each atom of hydrogen would be $\frac{3}{4}+\frac{1}{4}=1$; conversely, the nitrogen would be acted upon by affinity $=3$, and the chlorine by 1, and the whole molecule would be bound together thus—



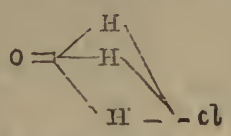
Probably, also, the chlorine would act on the nitrogen, and *vice versa* to a small extent. This principle, applied to the other difficulties, gives the key to unlock all; thus the double chloride of platinum and potassium would be represented by—



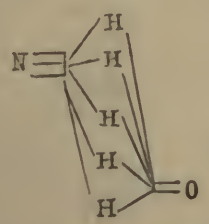
* Abstract of a paper read before the Royal Society of Edinburgh.

Water of crystallisation, &c., it is evident, could be represented by the same means.

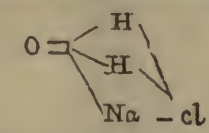
Then, again, the affinity may act, not in increasing the number of atoms taken up, but in the intensity of the combination. Thus, in the carbon compounds, where every addition of CH_2 increases the boiling-point and density, the affinity = 2 added by every such increase spreading itself over the whole hydrogen atoms, increases the intensity of the action, and draws the whole molecule closer together. This does not exclude the idea of the carbon atoms acting on one another also. If this spreading action of affinity be admitted we may go a step further. Let us take hydrochloric acid in water, which comes very nearly to what is called a chemical compound, but not quite. Suppose we represent a molecule of each, connected thus—



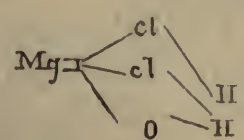
Now, this compound does not exist, because the energy of combination is not strong enough; but suppose we surround the HCl with numerous molecules of water, H_2O, all acting upon it as represented above, it is manifest it would reach a point when the HCl would be firmly held by the water, and, conversely, the water by the HCl. On the one side of this point, HCl would tend to escape, and on the other side, water, which we find from experiment actually to be the case. Ammonia gas might be represented similarly—



dissolved in water. Carrying this idea still further we might represent solutions pure and simple in the same way. Thus, common salt in water would be—



That this action is not fanciful we may see from the behaviour of magnesium chloride, $MgCl_2$. This salt dissolves readily in water, but cannot be recovered by evaporation, because it obstinately retains the last traces of water, until at length mutual decomposition takes place, and HCl is liberated, while MgO remains. Now this evidently arises from the great affinity of Mg for O and of Cl for H, as the formula indicates—



Why not then conclude that this is the explanation of solubility, which just means adding more water. This also explains the solubility of the salts of the alkaline metals, as they all have intense affinity for oxygen, and it is significant that the chlorides which are not soluble in water, viz., those of silver, mercury, and lead, are those metals which have least affinity for oxygen.

Many other phenomena may be explained on the same principle, such, for instance, as the effects of dilution on chemical action, alloys, solution and occlusion of gases. The phenomena of electrolysis and dissociation support this principle also. There are some physical facts also on which this view of chemical action may throw some light. According to Regnault, gaseous volume diminishes exactly as the pressure increases; then gradually there is a slight inequality, indicating an attraction between the molecules of the gas; then, again, this attraction becomes changed into a repelling action. Now, suppose the molecules of gas, brought sufficiently near to allow their affinities to act, we should have, according to my idea, a separation of the atoms of the molecules and a drawing together of the molecules. Suppose the gas was CO, then the carbon of one molecule would attract the oxygen of its neighbour, and conversely, this would produce attraction, until all the atoms of O and C were at equal distances, when there would be no tendency to draw closer; in fact, they would be at molecular distances under the circumstances of pressure, &c. Now, if we assume that the motion in a molecule is revolution round a centre, and if we also assume that affinity varies with distance as gravity does, then we can easily understand where the repulsion comes from. As all the atoms revolve round a centre by compression we increase their angular velocity, and by this means we increase also their centrifugal force at a greater rate than the affinity increases, and hence the tendency to fly out. Andrews's critical point may be explained in the same way. As long as the temperature is above a certain point, increasing the pressure only increases the angular velocity, but as the temperature diminishes the affinity at length is strong enough to establish a new position of equilibrium.

It appears to me, therefore, if we get rid of the idea of chemical affinity acting in an atomic indivisible manner, we are enabled to explain many difficulties, and to arrange in one graduated series many phenomena, hitherto considered distinct, and to establish a chemical continuity in harmony with what we find in all the other operations of nature.

ON THE

VENTILATION OF HALLS OF AUDIENCE.*

By ROBERT BRIGGS,
Member of the American Society of Civil Engineers.

(Continued from vol. xliii., p. 287.)

IN the arrangement of ventilating and heating apparatus for Halls of Audience upon the foregoing type, a few figures of proportions required may here be stated:

It having been accepted what number of people are to occupy a certain hall—taking the maximum number—the total quantity of air needed each minute will be derived by a simple multiplication of this number by the quantity per person, per minute, which the occupancy of the hall demands. That is, for a hall occupied by occasional sessions of one or one and a half hours, say ten feet, while for a legislative hall for frequent long sessions, thirty feet may not be too large, while proper judgment should determine intermediate values for other conditions of occupancy. The figures of total quantity of air needed each minute being determined, the sectional area of the duct, near the fan, is got by dividing this figure by 600.†

* A Paper presented to the American Society of Civil Engineers, January 26, 1881.

† 600 feet having been stated previously as the desirable rate of flow of a forced current in a duct per minute.

Now, this area is simply that of the periphery of the fan multiplied by its width, and as the width of the single fan at the periphery is =one-tenth diameter, it follows that the area of outlet is $=\pi D$ (=circumference), multiplied by $\frac{1}{10}$th D (=width) $=\pi D^2$ divided by ten. Taking the value of π (=ratio of circumference to diameter); making the division, and extracting the square root from the figures given, it follows that D (=the diameter of the proposed fan) =0·073 times the square root of the number of feet of air to be moved each minute. This rule can be expressed more simply in algebraic characters, as follows:—

$$Nq=Q;\ \frac{Q}{600}=\frac{\pi D^2}{10}$$

Where N=maximum number of persons to be supplied with air for ventilation.

„ q=least quantity of air per person, per minute, in cubic feet.

„ Q=total quantity of air to be supplied, or the least quantity in cold weather, also in cubic feet.

„ $\frac{Q}{600}$ =sectional area of duct near fan, in square feet.

„ D=diameter of single fan, that is of a fan which carries its blades and receives its air on one side only, in lineal feet.

„ π=ratio of circumference to diameter.

Reducing the above equation to give the value of D, then:—

$$D=0{\cdot}073\sqrt{Q},\text{ nearly,}$$

and for a double fan or one receiving its air on both sides, then:—

$$\mathfrak{D}=0{\cdot}053\sqrt{Q},\text{ nearly.}$$

When $\mathfrak{D}$=diameter of double fan, or of one carrying blades and receiving air on both sides of the discs, in lineal feet.

The inlet or suction air duct or passage to a fan should have, as an absolute necessity to supply the air, 1·4 times the area of the outlet or distributing duct. To compensate for resistance of air in passage along the ducts, and yet to preserve the smallest efficient areas of distributing ducts and branches, the sectional area of such distributing ducts or branches, at any given distance from the fan, should be increased over what is derived from

$$\frac{Q}{600},$$

by adding 0·0025 times ($\frac{1}{400}$) for each foot of distance, and there is required a constant addition of 0·25 ($\frac{1}{4}$) a square foot, which becomes a necessity to meet the great resistance of small passages. The area of a main duct at any given distance from the fan should be formed by computing after this method—the area of *each* branch, which may be considered as *trumpet shaped or expanding from* the fan to the point of bifurcation (from which point the *branch* may be deemed parallel), and this area is to be used when summing up an aggregate of total area of cross sections at such distance.

It may be needful to call attention of those who may plan a ventilating apparatus, that the air-ducts must be exclusively devoted to their purposes and should not be used, or even made so as to be available for passages. They may be employed for the lines of supply or return mains or distributing pipes, but the ducts should not be encroached upon by coil chambers constructed within them. Clear, unobstructed, smooth passages, with all angles rounded and all corners filled in, and all enlargement avoided, should present the least of resistance to the flow of air.

The foregoing formidable array of rules and data have been presented of necessity, for guidance in construction. They represent absolute and unalterable conditions in forced ventilation, and will enable any one to design, without mistake, when engaged in making original plans. It may be objected that the dimensions of ducts obtained by these rules are excessive, nearly to the point of impracticability, but in reply to this it must be stated that they (the dimensions) are less *by one-half* than can be employed for ventilating by heated currents alone (which is cold weather ventilation only), or for ventilating by exhaust shafts, heated in same way to induce currents (which is closed window ventilation). The frequent assertion of success of self-acting (as they are called) ventilating apparatus, often confutes itself, when the incompatibility of size of ducts is investigated.

As to the methods of distribution of currents from the branch ducts within a hall, and amongst an audience, the subject would call for longer discussion than there is room now to consider. It will only be said that at the mouth of discharge of each branch, baffling boxes must be arranged and provided, so that the efflux shall take place from an extended surface, at a not greater velocity, within one foot of the surface, than two feet per second; a condition which calls for the area of surface to be ten times as great as the sectional area of the branches. And it is further required that the direction of afflux should be *upward* in general, or when horizontal it should meet some other current of afflux near by, and be directed upwards. The augmented current of afflux in horizontal directions, as in the risers of the seats or steps, of an amphitheatre, is sure to engender local currents of much greater intensity than the original ones, and to become seriously objectional to an audience.

Whatever be the dimensions given to the supply ducts and passages, it must be remembered that those for removal of air must have adequate size, and if economy in the impelling force be studied, must be at least of equal dimension. In cold weather, with a high building—and all buildings are more or less high—the labour to be performed by any ventilating appliance in inducing a flow of air is materially reduced by the ascensive force of the columns of hot air in the building. As the weather becomes warmer, more and more motive-power is demanded to impel the current, but whatever motive power be expended, the movement of any quantity of air will cost in motive-power as the square of the velocity. The supposition of any change in sectional areas (omitting some frictional considerations), which shall reduce them below the area accepted as the least at the fan, admits of a reduction of the fan itself to conform.

A thoroughly arranged ventilating apparatus calls for distributed removal of air as positively as it does for distributed supply, and for complete efficiency, all flues and branches of efflux should have, after providing the branches, similar baffling mouths to those described at mouth of entry, 1·4 times the area of the supply flues and branches.

With a forced ventilation, these flues should not have that compensation in reduced area, as they become high, which is essential to self-acting hot air shafts. The condition of ventilation assumed, supposes the expulsion of larger quantities of air, as the relative temperature inside and out, becomes more equal, and at the point of equality, the value of the height of the building as a shaft becomes nothing,

This large size of flues of efflux opens another source of trouble. It is almost indispensable that all the eduction flues shall be gathered into one single main flue, with judicious arrangement of the branches at their points of junction, so that they shall *direct* themselves into the general current of effluent air, and entirely and completely fill the great flue or shaft, thus preventing any eddies or back currents from establishing themselves, from room to room, from one part of a room to another; or worse yet, from the outer air down one side of a main shaft and up the other. With numerous ventilating flues or chimneys to open fire-places in any one building, whether supplied with air by forced ventilation, or by any other ventilation, or if unsupplied with air altogether, but merely furnished with *ventilating flues*, or yet again, where numerous

chimneys only exist, *the chance for a down draft* for some of them goes beyond the theory of chances, and becomes a certainty.

At all events, for a hall, the ventilating branches must be gathered into one general eduction shaft, while it may be possible for separate rooms to have separate independent ventilating flues, with a little possibility of most of them working the right way, if the weather is not very cold.

A few figures of the proportions of steam heating apparatus, in combination with ventilating, may be given. In most buildings to be ventilated as halls there will be found rooms and passages, whose requirements in occupancy will demand a much less liberal supply of air than the halls, or sessions rooms themselves.

The quantity of air supply to such buildings will be derived from two systems, whilst additional heating capability will be required from a third system. The system dependent upon ventilation of session, audience, or largely occupied rooms, has been discussed already, but the least quantity for occasionally occupied rooms is much in excess of what is needed, where the heated air is made merely the vehicle for transporting heat to a room to be warmed. The temperature of currents for ventilation solely, can scarcely exceed 70 to 80 degrees in the coldest weather in the most exposed hall, while rooms warmed more economically with smaller quantities of air, may have hot air currents of perhaps 110 degrees from steam heated surfaces. In the second case, the volume of air requisite will be found by deciding on the extent of heating surface for a given room of given exposure of outer wall, and position in the building. This extent of heating surface may vary from 1 square foot to 40 cubic feet of space in the room, to one square foot to 120 cubic feet of space in the room. The latter value representing a room of ordinary living size, with the least usual wall or window surface, sheltered from cold winds, and in the second story of a warmed building; while the former value is that of the exceptional case of great exposure, or of situation on the ground floor of the building. When an allowance for these circumstances has been made, and the quantity of heating surface needed for heating any room by indirect heating (as it is termed), has been reached, it may be accepted that 3 cubic feet of air per minute must be given to each square foot of heating surface, as the greatest quantity when the thermometer is at zero, at such time as the least supply for ventilation is supposed. A square foot of steam heating surface, with steam at 30 to 40 pounds pressure may be taken, *if well exposed*, to be capable of heating 3 cubic feet of air from zero to 100 degrees, or 5 cubic feet of air from 50 degrees to 70 degrees (or 80 degrees) in a minute.

It will be noticed that the heating capabilities of surfaces is referred to the cubic space in the building. The great loss or transfer of heat in any building takes place at the windows, so great that the computation might almost be confined to their surface as a unit to estimate on, and the surface of the walls or the cubic contents of the rooms be neglected. But, on the other hand, it is the *exposure* of the window which becomes of most account, and that has to be allowed for by judgment, and not by estimate; and with *exposure* a wall may become, if thin or thick, a material element in consideration.

Finally, the windows do bear a definite proportion to cubic space; or, if they do not bear the usual proportion, they may be *allowed* for; until the skill in guessing comes back to a guess based on cubic contents, as equally valid with one based on window surface.

The third system of steam heating which finds examples in all large buildings—in passages, at or near doorways, or invariably somewhere—is direct heating by coils placed in the rooms to be heated. For this method there is demanded 1 square foot of heating surface for each 80 cubic feet of space within the walls of an exposed room, or of a room where the heating is demanded at short notice; as in an office which is allowed to become cold at night. While 1 square foot of direct heating surface is ample to warm 200 cubic feet of space continuously, without intermission day or night, special demands to heat doorways and open passages must be estimated on special grounds.

For heating in chambers with indirect heating (ventilation) box coils, as they are denominated, are best, while for office heating, vertical coils are decidedly preferable, although their surface is not so effective as that of horizontal pipe coils by about 20 per cent.

The main pipes for steam and return connections, by branch or direct mains to each cluster, coil, or radiator, should have the equivalent of 1 circular inch of sectional area for steam (or flow) connections (equal to 1 inch steam pipe nearly) for every 500 square feet of effective steam surface, augmented or enlarged 0·0025 ($\frac{1}{400}$) times for each foot from the point of first distribution or branch from the main. The condense water or return connection will follow the same rule, with the equivalent of $\frac{1}{4}$ a circular inch for the same surface (equal to a $\frac{3}{4}$-inch pipe nearly). The aggregated area of great mains need not be so large as would follow from aggregating the branches, but should be increased in size up to the point of any branch, as if the enlargement of that branch, for distance, occurred at the point of branching, and not at the coil or heating surface. This rule will, if carefully read, prove easy to apply.

Flow mains should rise to some point (where they can be trapped or drained), vertically, and then have a descent of a $\frac{1}{4}$-inch in 10 feet, regularly, to the end. If circumstances do not allow this, steps of vertical rises, well trapped, should be succeeded by lines of descending grade. The return main should have a corresponding fall towards the boiler, or other condense water recipient.

Boilers of the common tubular form require about 1 square foot of boiler surface (reckoning all the surface, of whatever kind, exposed to the fire or to the gases of combustion, between the grate and the boiler chimney) to each 9 square feet of heating surface in coils or radiators.

The grates of such boilers should have 1 square foot of surface to about 30 square feet of boiler heating surface. These ratios give 1 square foot of grate to 270 of radiating surface.

The chimney flues for the boilers (the stack) demand a sectional area from one-tenth of the grate surface, for chimneys of 50 feet high, to one-twelfth of the grate surface for chimneys of 100 feet high. These last dimensions are smaller than customary, but sufficiently large if no further requirement will ever be put on the apparatus.

The maximum quantity of coal to be consumed on these grates will not exceed 8 pounds per square foot of grate per hour, while the average quantity will not be over 20 to 30 pounds of coal per square foot of grate in 24 hours for 6 months of a year. A fan delivering 20,000 to 40,000 cubic feet of air per minute, will demand from 20 to 60lbs. of coal per hour to supply steam, as a rough estimate.

In planning boilers, it is usual to allow one extra boiler for contingencies. There is no necessity to estimate on the supply of steam for the power needed to impel the fan, where buildings are warmed and ventilated, as the exhaust steam of the engine should be utilized for heating purposes, and little extra steam is demanded for this purpose of driving the fan, so little, that the quantity may be neglected in the total of allowances for successful warming.

Further discussion might be had nto the mechanical details, constructively, or as to either their ratios to the great units of individuals to be supplied with air for ventilation, or of cubic space in buildings; of some possible interest to the construction of apparatus; but my purpose has been only to give such figures and data as are indispensable for arranging the ventilation of halls of audience. Every word of superfluous description, and each extra figure, has been carefully eliminated with the sole view of making this information complete in its ostensible direction. The paper, however, cannot properly be concluded except by calling attention to some

requirements, that seem not to have heretofore been adverted to by other writers, but which really control the working of any apparatus, for either warming or ventilating, or both, and which call for modifications in arrangement and construction, almost amounting to a novel system.

The temperature of steam heated surfaces, for steam of such pressure as is usually carried in heating apparatuses, where the boilers furnish steam for running the fan engine, that is at 40 to 60 pounds pressure, will run from 290 degrees to 310 degrees; and these temperatures are practically uncontrollable whenever the steam is admitted to any coil or radiator; so that the external surface of the coil or radiator in air is sensibly the same, 290 degrees to 310 degrees. Some slight but unreliable reduction of temperature in the steam may be had by throttling the supply pipe, but this method becomes especially unreliable when the condensed water is returned, without trapping, at the same pressure, to the boiler. Coils give off heat determinedly until the last moment of being shut off. They fill with water, and becomes very noisy with water hammers; when a small volume of steam in some way is interposed between two columns of cooled water that instantaneously condenses it and forms a vacuum, bringing such columns into solid contact with each other. In exposed places throttled coils freeze up. The nicest adjustment may secure the end of lower temperatures of surfaces, and corresponding lower temperatures of air currents passing them; or of desired constant temperature of air current, obtained by giving less heat to a warmer entering air; but the least change of boiler pressure disturbs it all; in a moment the coil is virulently active with heat, or obstinately passive by water clogging.

There are two methods of meeting this difficulty. The first is the division of a coil into sections, so that one or more of the sections can be employed in heating or be shut off at will.* Some person in control of the apparatus, or at least of the coil for heating, will thus have the means at his disposal to produce any wished for temperature, down to the temperature of the outer air. The second method is found in passing around the coil, unwarmed, such part of the current of entering air as will reduce or temper down that remainder of the current which is permitted to pass through the coil, and is heated by contact with the heated surfaces. A comparatively simple arrangement of the casing of the coil, with register or louvre (blind) valves, and some baffling contrivance to secure the admixture of the two currents, is the mechanism of this method, which, as a method, is nearly as efficient as the former one.† In one essential regard it is more efficient, that is, the by-passing method gives an instantaneous change of temperature of the air delivered in the rooms, while the sectional method calls for time to elapse until the closed-off sections shall have lost their heat, or the newly opened ones increased in temperature, before any effect is produced on the temperature of the air.

It now becomes proper to remark upon the great general cause of failure of the well planned, thoroughly constructed, and entirely controllable apparatuses for heating and ventilating. Anomalous or paradoxical as it may sound, it is a fact, that the most complete apparatus may be the *most* perfect failure. Every improvement in mechanism may have been schemed; every contingency of working may be adequately provided against, and yet the accomplishment, in warming and ventilation, will have resulted disastrously. The fact is certain, and to what fundamental error can it be ascribed? The mistake can, in my mind, be traced to the assumption, upon which the operating of apparatuses have been universally based, *of control* of the individuals warmed or ventilated, as regards their sensations of comfort, or their requirements for health. The error lies in giving the regulation of temperature to an engineer, or even to a general director (in case of an important building). An engineer may be a thoroughly competent mechanic; even more, he may be well informed in the practice, and possibly in the theory, of heating or ventilating. A director may have the theory and practice of heating and ventilating at his command, and be eminent in science or medicine as well; but from either of these control will be resented, and any effort to enforce needful authority will be thwarted. If this be the condition of operating an apparatus in competent hands, what happens when those less likely to enforce authority are placed in charge? The usual engineer is a well-taught mechanic, with ability to run and keep in order an engine, to direct the fireman, and possibly able to do his own steam fitting in repairs; one who in the pride he would take in a well kept apparatus, beyond the keeping of which he has no ambition, commands respect in his vocation. For such an engineer the capability cannot be expected which would allow him to direct or deviate when differing requests are made.

(To be continued.)

* In the heating apparatus constructed at the U. S. capital in 1855-6, this method was introduced by Mr. Nason, and the complete control of temperature, in cold weather, for any given supply of air in every room in the building, was given to the engineer or his assistants.

† This arrangement, which was suggested by Mr. Faber do Faur, was introduced in one instance at the U.S. Capital in 1858, and was entirely successful in the attainment of its purpose.

PROCEEDINGS OF SOCIETIES.

THE SOCIETY OF CHEMICAL INDUSTRY.

A DINNER in connection with the inauguration of this Institution took place at Cannon Street Hotel, London, on Tuesday evening last, June 28. The chair was occupied by Prof. Roscoe, F.R.S., President of the Society.

The company having dined, the toasts of "Her Majesty, the Queen," and "the Prince and Princess of Wales and the rest of the Royal Family," were proposed successively by the Chairman.

The CHAIRMAN, in submitting the next toast, said:—Gentlemen, I have now the honour of proposing to you the toast of the evening—"The Success of our new Society of Chemical Industry"—(Loud cheers). The proceedings of this day, and especially the numerously attended meeting which I am now addressing, show me—and I think that you will all agree with me—that the success of this new Society is already achieved—(Hear hear). Nor is it unnatural that this should be so, for I think that it is clear that the want of such a Society really exists, and, moreover, that we have hit upon the right time for founding it. We are almost overdone with different societies. Nevertheless, this Society, has, I think, opened out a new and distinct field of action. Scientific chemists have their society, the Chemical Society, of which I have the honour to be the President. There are other societies, such as the Institute of Chemistry, for analytical chemists; but, strange as it might appear, there has hitherto been no association which would bring together, as we in this Society propose to do, all those great industries which depend upon the utilisation of chemical principles. I should have been the last person to be here to-day in the position which I have the honour to hold, if we, in this Society, interfered in the slightest degree with the older and sister society to which I have made reference. There is no reason to believe or to fear that the Chemical Society of London will, in the least, interfere with us, or that we shall in the least degree interfere with them. There is plenty of room for both—(Applause). What we desire to do is to bring together for the purpose of discussion and of social meeting, gentlemen from all parts of this kingdom, and also from the Continent, who are interested in the pursuits in which chemistry is applied to the arts. You have heard from the Report of the Council which has been read that our Society already

numbers in its first months about three hundred members, and, amongst those, are the names, not only of many of the foremost men among the scientific chemists of the country, but also of men eminent in the more special directions of applied chemistry. And not only is this the case with Englishmen, but, as you have heard this morning, we have already on our list some of the most distinguished of those who have made the subject of applied chemistry their study on the Continent. I need only mention the names of Prof. Hofmann of Berlin—(applause)—of Dr. Caro of Mannheim of Dr. Martius of Berlin, and of Prof. Lunge of Zürich, to assure you that our Society is well appreciated on the Continent. With your permission, I should like to be allowed to read a few words of a letter which I have received from the first-named of these gentlemen, Prof. Hofmann, whose name is honoured wherever science, both pure and applied, is recognised. He writes to me as follows:—"I have heard with much pleasure of the Society of Chemical Industry under your auspices. I need not tell you how much I sympathise with this movement. Having had the privilege in early life of associating with many of the leading representatives of chemical industry in Great Britain; remembering as I do, with feelings of sincere gratitude, how often, and how effectually, my scientific labours have been furthered by their liberal assistance; deeply impressed, moreover, with the conviction of the material advantages which are likely to accrue from their alliance, not only to industry and science but to the progress of mankind—I consider it both a duty and a pleasure to join your Society which you have just started, and which, I have no doubt, will soon become a worthy sister of our Chemical Society of London. Will you be so good as to enrol my name in the list of members, and to convey to the Fellows of the Society the expression of my heartfelt wish for the rapid success of the Association"—(Applause). Thus you see that our efforts are appreciated in Germany. I might read you other letters from the gentleman I have mentioned; but I will not detain you with them. Suffice it to say that they all express their great pleasure at hearing that such a society is founded; they all believe that it will be productive of great good, and they have all joined our ranks with pleasure. It has been well said by Lord Derby, who, when he says anything, always says it well, that "the rule of thumb is dead"—(hear, hear)—and that we are standing at its grave. Well, gentlemen, if the rule of thumb is dead, I suppose that some other rule has been born to take its place; and I presume that the only one that can take the place of the rule of thumb is the rule of head. Now, it appears to me that in this rule of head, or of knowledge, or of science, which is coming forward, our society has a great field which it may now very opportunely occupy. Not only is our society founded for the purpose of bringing together those who are interested specially in the application of the sciences; but, as is evident from the position which I have the honour to occupy, it is your intention to endeavour to bring more closely together the bonds which unite applied with pure science—(Applause). This appears to me likely to produce a fruitful union. I believe that our society has a very important part to play, and that we shall find that year by year as our gatherings go on that the importance of our society is more generally felt, and that the recognition of it increases. I have much pleasure in proposing "The Success of our Society," and coupling with this toast a gentleman whose name is one of the pillars of the state of applied chemistry, for I need scarcely say that the name of Muspratt is one of the oldest and most respected in the chemical history of this or any other country. I have much pleasure in proposing this toast, and in coupling with it the name of Mr. E. R. Muspratt.

Mr. Edmund R. Muspratt replied as follows:—Mr. Chairman and gentlemen of the Society of Chemical Industry, when I entered this room I did not think that I should have the honour of responding to this toast. At the same time I feel very much the honour that you have done me. The President has called to your attention the fact that there already exist in this city two societies for the promotion of chemistry—the one the Chemical Society, and the other the Institute of Chemistry. This shows a very different state of things from that which existed at the time when my old teacher and revered friend, Baron Liebig, came to this country. He often used to tell the story of how when he came to England he found that every one associated the name of chemist with a little boy in a white apron smelling of castor oil. The very fact of our having already those two societies and of our inaugurating this third society in association with chemistry, shows the great progress we have made since then. I would also call your attention to a remark which was made by Professor Dumas some twenty-five years ago at the Société D'Encouragement of Paris. I came across it when I was over in Paris at the time that the commercial treaty was being negotiated. The French chemists tried to make out that they were very much behind us in England, particularly in the alkali manufacture, and that it was necessary for them to have protection; but I called attention to what had been said by Dumas, a chemist whom they all knew and respected. Speaking specially of chemical science, he said that "science sometimes destroyed the balance of commerce," and I contended that it was by the encouragement of science that the French could maintain a rivalry with us. I am glad to say that they have maintained that rivalry in spite of having done away to a small extent with their prohibitive duties. I think that we may learn that when we are met by hostile tariffs throughout the world, we must not have refuge in the old system of protection, but that we must have refuge in the application of science to our industries. I trust and believe that one of the great functions of this Society will be to promote that application of science to industry which will enable us to compete with all the world. To-day we have had a very interesting meeting. Two very different questions have been brought before us, namely, the alkali and the manufacture of beer. This shows how general the application of chemical science is. We see that chemistry is required in the making of one of the most useful substances for industrial art, and also in the making of one of the most useful foods—for I maintain that good lager beer is a very excellent food—(Cheers). I trust that you will have an equally successful meeting to-morrow, and that we shall have the benefit of a discussion upon the great question of the Patent Laws, because, after all, it is very important that we should understand how far it is desirable that patents should be granted. It is perfectly clear that the granting of a patent is the granting of a monopoly, and a monopoly is, I may say, necessarily an evil, but it is necessary to allow the evil to exist in order to bring forth the inventive powers of man. It is for that reason that in modern times we have altered the Patent laws from what they were originally, when patents were monopolies pure and simple. I trust that to-morrow the Society will be useful in forming public opinion upon the great question of the Patent Laws.

The Chairman—Gentlemen, you are all aware that we are acquainted with a class of chemical compounds which are called molecular compounds. These, though not joined together in the intimate manner in which true chemical compounds—such as our Society, for example—are joined together, still are connected by bonds of amity and of unison. Such is the case with the learned societies. Each one helps the other; and we have on the present occasion the honour of the presence at our table of two Presidents of distinguished scientific societies. One of these is intimately connected with us, even more so than the other. I propose the "Health of the Kindred Societies," and I couple with the toast the name of my distinguished friend on my left, Mr. Thomas Greenish, who is President of a Society very closely allied to ours—the Pharmaceutical Society.

Mr. Thomas Greenish, in reply, said—The President has called upon me this evening to respond for the learned

societies. I fancy that he could have chosen the representative of some society occupying a more exalted position than the Pharmaceutical Society. But it was said by Burke, "I honour the man that loves that little platform on which he exists." If I speak on the present occasion of the Pharmaceutical Society, it is because it is that "little platform" on which I stand, and with which I am connected. Perhaps, Gentlemen, there is no body which takes a more intimate or a livelier interest in this associathan the Pharmaceutical Society—(Hear, hear). That Society and its members are intimately associated with chemistry and chemical industry. In fact no step can be taken in pharmacy without bringing in chemistry, or without some connection with chemical industry. I am sure that the members of the Society to which I belong will wish you every success in this undertaking. In looking over the papers which have been read to-day I saw one on lager beer. It is a large industry in this country; but having myself seen the difference of manufacture between the beer of the Continent and that made in this country, I certainly must give the palm to the beer of the Continent. There is a method in its manufacture which either does not suit the climate of this country or does not suit the palate of the people. But the industry is one which, I think, requires some attention and some advancement in this country. Gentlemen, I am sure that you will be wished by the members of the Society with which I am associated, all that success which your Society deserves.

The Chairman—Gentlemen, the next toast that I have the honour to propose to you is that of "Our Visitors." We have several distinguished gentlemen here present with us this evening. I regret that many of you were unable to be present at our morning meeting; but those gentlemen who had the advantage of being present will not wonder when I say that the President of the Society of Telegraph Engineers is truly and really a member of our Society, we were informed that our chimney tests for hydrochloric acid and other noxious vapours pale and dwindle before the test which the President of the Society of Telegraph Engineers can apply to the same subject. We heard then from Mr. Varley that the non-insulation of the telegraph wires is an excellent and most delicate test for the presence of these noxious vapours. I have great pleasure in coupling with the toast of "Our Visitors" the name of my distinguished friend Professor Carey Foster, the President of the Society of Telegraph Engineers.

Professor Carey Foster—Mr. President and gentlemen, I feel it an extremely great honour to be called upon to reply to the cordial toast which you have drunk to the visitors who have partaken of your kindness this evening. Our President has reminded us of the death of the late potentate, the rule of thumb, and that his lamented decease has rendered it necessary that a successor should be brought to the front. I suppose that we may consider that we are now at a sort of christening feast of the successor, and adopting this view, perhaps it is not quite unfair to take some little interest in the name of this new ruler. The Society of Chemical Industry seems at first sight to be, perhaps, like the name of a foreign society rather than of an English society. We have heard of a Mathematical Society, but never of a Society of Mathematics; we have heard of a Society of Engineers, but never of a Society of Engineering. But I suppose that we may interpret this impersonal form which you have given to the name of your Society as meaning that it is not to be a society for the promotion of the selfish interests of individuals—industrious chemists—but that it is to be a society for the promotion, in a public and liberal spirit, of the progress of one of the most important of our industries, or rather of the very numerous industries which depend upon chemical science—(Applause). That really seems to be the justification for this impersonal form of the name of the Society. As our President has already said, there cannot be the smallest fear of entrenching upon the ground already occupied by the older Chemical Society, for there can be no doubt that chemical science benefits by the progress of chemical industry quite as much as chemical industry depends upon chemical science—(Applause). I will not detain you further, but will simply return you the very hearty thanks of myself and other visitors this evening for the toast which has been drunk.

Mr. J. C. Stevenson, M.P.—Mr. Carey Foster, in the remarks which he made a little while ago, passed a little criticism upon the name of the Association, and he observed on what he called its impersonal character in being called a Society of Chemical Industry rather than a Society of Industrial Chemists; and he ventured very properly, I think, to draw from the circumstance of the name, the consideration that you are not here engaged in a mere attempt to carry out your individual self-interest, but that you have a higher view—the promotion of industrial science in its largest aspect—(Hear, hear). That was the abstract view which he took of the name and object of your Association. But we cannot always ascend to the region of the abstract. We must come down sometimes, if not nearly altogether, to the lower ground of the concrete. It is no use to talk about the chemical industry in the abstract without remembering that there must be persons to carry on that industry, and that we cannot have an Association of Industrial Chemists and an Association of Chemical Industry without having persons to guide it, and a president to preside over its deliberations —(Applause). I am very glad that it has fallen to my lot to have the honour of proposing the toast of the first president of this first social gathering in connection with this new Association. It is our business as industrial chemists, or as what I may call very properly by the more sober name of chemical manufacturers, to apply on a large scale, and for purposes of industry, and, I should hope, sometimes, though not always, of profit—(laughter) —the principles of chemical science, which are discovered for us in the laboratory, and revealed to us by those who make science more especially their study. Everyone must know the vast difference between facts discovered and manipulated in the laboratory and those facts turned to practical account in the work of a manufactory, and I think that no one is better able to appreciate than the members of this Association how many a process which looks fair and promising in the hands of the scientific chemist utterly breaks down as a means of industry on a large scale when brought to the test of being worked, not by the grain, but by the ton. In that case we have to face the consideration of how far you can carry scientific processes into practical effect with due regard to economy, and due regard to wear and tear, and due regard to the materials of construction out of which you are obliged to make your apparatus on a large scale. These difficulties do not present themselves at all to the man who is working in the laboratory with glass vessels, and indiarubber and glass tubes. It is here that the whole difficulty of this Society of Chemical Industry exists, and I have no doubt whatever that it will be found, in the deliberations of the Society, that the most interesting questions will be how far you may be able to carry out in a practical and useful, and, I hope, profitable form, those discoveries and improvements which are suggested to you by those who take a purely scientific view of the question. Among the ranks of the scientific chemists, I know no man who would be better able to appreciate a difficulty which I have ventured to suggest than your President, Prof. Roscoe. In him a true appreciation of the facts of science is combined with an equally true appreciation of the practical difficulties of carrying those facts into practical operation. My acquaintance with your President commenced in a way which enables me to speak most heartily as to his appreciation of the difficulties of the manufacturing industry, for it was my pleasure to be associated with him on a Royal Commission with regard to noxious gases. That Commission had some very pleasant meetings, prolonged over a series of several months, and we visited many scenes of chemical industry, and among the most

interesting and pleasing reminiscences of my membership of that Commission, I regard the fact of my having made the acquaintance of your President, Prof. Roscoe, on that occasion. You have got a man who most thoroughly appreciates, as I know he can, the difficulties which attend the practice of industrial chemistry; and I may say that he and I sometimes stood alone in resisting proposals made by the rest of the commission, who did not so thoroughly appreciate the difficulties which might be found in practically carrying out things which were very desirable indeed in themselves, but which would have been a very great burden to be imposed by the law upon the chemical manufacturers of this country.—(Applause). With regard to legislative interference, I do not complain of it so long as it is wisely and judiciously directed; but we are "in for it," and we must deal with it, and the services and the advice and the testimony of a man of the experience of your President ought to be of very great value to those who are engaged in industrial pursuits, in helping them to hold their own in resisting projects of law which may be very desirable and reasonable in themselves, but which we, as practical men, know would be very disastrous and disappointing if an attempt was made to carry them out. For these reasons, though no reasons whatever were required, I ask you to join with me in drinking the health of our President. He has done his work well already to-night, and I am sure that you will agree with me that we should drink his health in the most cordial manner, with wishes for his long life and prosperity, and a desire that he may for a long time preside over the deliberations of this society.

The toast was drunk with much cheering.

Prof. ROSCOE, in replying, said—Mr. Stephenson and gentlemen, I can scarcely find words to thank you for the terms in which you have proposed, and for the cordial manner in which you have drunk, my health. I can only say that it affords me the very greatest pleasure to be of any service, in however small a matter, in promoting the chemical industries of this country. This society, as I have said before, has been founded at the right time, and I think that there is very little doubt of its permanent success—(Hear, hear). Perhaps I may be allowed, at this the first meeting, to state in one or two words the mode in which this Society has come about. Some very good friends of mine in the North were good enough about a year ago to come to me and ask me if I would assist them in forming a chemical society in Lancashire, to be constituted on much the same principles as a society which has existed for several years, and done very good work on the Tyne—the Newcastle Chemical Society. I considered their proposition, and I called to their attention a proverb which we sometimes hear in the North, which applies more to political matters than to those which are under our consideration this evening, namely, "What Lancashire thinks to-day England will think to-morrow"—(Laughter and applause). I asked them whether they did not think that that applied to chemical industries as well as to political matters. Being Lancashire men they were, I suppose, flattered by the idea, and the consequence was that I undertook to write to a number of friends and to see a number of friends of mine in London. Amongst others I may mention the President of the Institute of Chemistry, Professor Abel, whose absence this evening we all deplore because he has taken the most active interest in the matter. There was also Prof. Williamson, who favoured us with his company this afternoon, and a number of other men of high standing both in pure and in applied science. I am glad to say that their replies were favourable. They did not think that the new society would trench on any of the older ones, and they did think that there was an opening for such a society. The result is what you have witnessed to-day, and I think that we may all congratulate ourselves on having a very auspicious opening. But, gentlemen, the work of this Society has not been the work of the President. It has been far more the work of the officers of the Society. Without the co-operation, and the hearty co-operation, of those who now form your officers, it would have been impossible to do what we have done. I allude to Mr. Cook, the Treasurer; Mr. Davis, the Secretary; and Mr. Tyrer, Mr. Carey, our Northern Secretary, and Mr. Mond, our Secretary for Foreign Affairs. It is those gentlemen whom I have named to whom you owe to a great extent the success of our meeting; and, therefore, in thanking you for myself I have very much pleasure in asking you now to drink the health of the officers of the Society, coupling with the toast the name of Mr. Davis, whom we all know and respect, and whose untiring labours I do not think that you can all appreciate, but I can assure you that I can, and that I do appreciate them—(Applause).

Mr. GEORGE E. DAVIS (Hon. Gen. Sec.), in reply, said—I thank you for coupling my name with the toast which has just been drunk, but I do feel that you are praising me somewhat too highly. I have only done my duty in connection with the organisation of affairs, and I think that equal praise is due to the three other Secretaries—Mr. Mond, Mr. Carey, and Mr. Tyrer. When I attended the first meeting which was held in connection with the formation of a Society of this kind, I little thought that within three months from that time I should see an assemblage of gentlemen connected with chemistry such as I see before me this evening. Perhaps some of you may not know that the first meeting was held at Widnes on a night on which there were 6 or 7 inches of snow on the ground, and the second meeting was held in somewhat similar weather. The next meeting was held at Owens College, and there we obtained the assistance of Professor Roscoe, and from that time the Society began to grow; and I am firmly of opinion that it is chiefly owing to Professor Roscoe's hard work in the matter that this Society has attained its present position in such a short space of time. Perhaps there are very few people who think that there is much work connected with the formation of a Society of this kind; but I can assure you I do not know how Dr. Roscoe has been able to give the time and attention to it which he has done. He has placed himself entirely at my disposal, and I have sat with him for hours arranging how matters should be conducted. I think that he ought to have the larger share of any thanks which are given to me. I have great pleasure in coupling with this acknowledgment the names of the other three Secretaries, and of Mr. Rider Cook, the Treasurer.

Mr. GOSSAGE.—As a representative of the soap manufacture of this country I should like to say one or two words, because our President referred to what might be considered a slur upon the soap manufacturers. They have been throwing away a large amount of glycerin, which chemists and others have looked upon as an absolute loss to the world. But we who are soap manufacturers have not seen our way to gathering it with profit to ourselves, and that which is not gathered profitably cannot be of much use to the world in general—(Hear, hear). It was pointed out to the foreman of William Gossage and Sons by one of the members of the Rivers' Pollution Commission that we were throwing into the River Mersey a large quantity of glycerin, which a young man who referred to the loss of glycerin had put at 4s. a pound. At the time that this glycerin was being thrown into the river, the real market value was about 2d. a pound, and the other calculation was utterly fallacious. At that time the candle manufacture of this country and of the Continent supplied to the world a larger quantity of glycerin than it could consume, and consequently the tedious process of collecting glycerin from the spent lees could not be carried out profitably. Since then it has become a positive fact that the sources of glycerin are being reduced. Paraffin scale is taking the place of decomposed fats for candle making, and petroleum is taking the place of candles to the exclusion of the production of glycerin. That we have not been idle, and that we have more or less worked on the lines of the production of glycerin, is a fact which has come to my know-

ledge, more particularly within the last month. That we have to a greater or less extent arrived at the same point is also a fact. We are working at the process, and I believe that we shall succeed in recovering the glycerin from the spent lees, and thus remove the slur which has been cast upon us as chemical manufacturers. In many instances the members of manufacturing firms are too few in number to be able to carry out on a manufacturing scale all the ideas which occur to them from time to time as means of utilising what may be called by-products. If this Society had existed ten or twenty years ago, and we could have applied to it for men to carry out those rough ideas which we arrive at, I think, gentlemen, that the progress of this country would have been much greater—(Applause). I also think that a variety of waste-products would have been worked up more successfully than they have been during the last ten or fifteen years. I think that it is apparent that we, as soap-makers, are working our best to support the Society of Chemical Industry. You can almost count the soap makers of the United Kingdom upon your fingers, and we are represented by five members here. Hence it appears that the soap manufacture is not behind other manufactures of the kingdom—(Applause).

The PRESIDENT then proposed "The Press." He would not trouble them at that late hour by saying much upon this subject. The press was an agency whose importance was patent to all, and it was especially important to them as a new Society. He would couple with the toast the name of Mr. Mitchell, the representative of the *Times*.

Mr. MITCHELL, in replying, thanked the President for coupling his name with the toast. It had afforded him much pleasure to be present on that occasion. He had for many years written upon the subject of bringing the work of scientific men to bear upon the ordinary operations of life—not only in our manufacturing industries, but also in domestic affairs. With regard to the press generally, it was a very compound body. It included the work of the brain of the leader writer, the somewhat laborious work of the shorthand writer, the trouble of the compositor, the worry of the proof-reader, and the running about of little boys, commonly called "printer's devils." It also included the worry of those who had to stand the racket of the huge machines, and of the persons who had to rush off to the railway stations and catch the newspaper express. He took it that the toast was intended to comprise the work of all these persons, and he wished to acknowledge it in the same spirit.

PHYSICAL SOCIETY.

Saturday, June 25th, 1881.

Professor FULLER in the Chair.

SENOR Olympio de Barcelos was elected a member.

Mr. GRANT exhibited an apparatus for showing the position and direction of the curve of zero-electro-dynamic induction. It consisted of two coils of insulated wire mounted on stands; one being fixed, while the other was free to revolve round it at a fixed distance.

Prof. W. E. AYRTON explained the determination of the refractive index of ebonite made by himself and Professor Perry. The result for oxyhydrogen light was 1·7; but at the suggestion of Prof. Fitzgerald, of Dublin, this was checked by measuring the polarising angle of ebonite by reflected light. Lime-light was employed in these experiments and different pieces of ebonite. The result was 1·611. Professors Ayrton and Perry had repeated their former experiments, using the electric light, and a battery of 70 volts. E.M.F. The result confirmed the one first obtained. They had also determined the index of refraction in the ordinary way from the red rays which they observed to pass through the prism of ebonite. Result for the least refrangible rays 1·66.

Mr. BOYS remarked that one could see better through thin ebonite, if it was varnished or wetted, than when untreated.

A letter was read by the CHAIRMAN from a Sub-Committee of the British Association, inviting the members of the Society to send exhibits to the jubilee meeting of the British Association, at York.

Dr. JAMES MOSER read a paper "*On the Microphonic Action of Selenium Cells*," in which he argued that the action of the selenium cell, in the photophone, was that of a microphonic contact, or bad joint between the metal electrodes, or metal plates of the cell and the selenium. The heat rays of the photophonic beam caused the joint to expand and contract; hence, the variation in the current passing through the receiving telephone. Dr. Moser also exhibited a piece of selenium, which increased, not diminished, in electric resistance when light fell upon it. He further shewed a standard Daniell cell of the gravity type, which consisted of a glass vessel containing the copper plate at the bottom immersed in sulphate of copper solution and the zinc plate at the top, immersed in sulphate of zinc solution, and a clear line of demarcation between these solutions was produced by suspending an independent piece of zinc midway between the plates, so as to decompose all the sulphate of copper which diffused upwards to that point.

Prof. MCLEOD said that he had produced the same result by surrounding the zinc plate with a cage of copper wire, connected to the copper plate. Copper deposited on the cage, and the cell was in constant use.

Dr. LODGE said that arrangement would not, however, serve as a standard of electro-motive force, because all the copper plate should be in the copper solution. In his cell, the copper and solution are both in a test-tube immersed in the zinc solution, and diffusion has to take place up this test-tube and down the cell, so as to enter a second tube, open at the bottom in which the zinc is placed.

Dr. GUTHRIE shewed a new experiment to the effect that when a magnet is suspended over a disc of copper, and the disc rotated, the magnet is repelled upwards. The experiment was shewn by suspending the horse-shoe magnet from one end of a scale beam counter-weighted. As a possible explanation, he suggested that the vertically resolved force of the induction current before the magnet might be greater than that behind the magnet.

The SECRETARY read a paper by Prof. BALFOUR STEWART and Mr. W. STRODE "*On Results Obtained by a Modification of Bunsen's Calorimeter*," described to the Society in January last year. With a new instrument made by Casella, they have determined the mean specific heat of iron to be 0·1118, and that of sulphur 0·1756; the true values being given as 0·1138 and 0·1776. The advantage of the method is its simplicity, and the fact that very small quantities of the substance may be used.

Dr. LODGE then explained experiments by Mr. SUTHERLAND showing that a Daniell cell keeps its E.M.F. very constant when heated, because the thermo-electric effect at the junction of the zinc with the solution is balanced by that at the junction of the copper with the solution.

After remarks by Dr. MOSER and Prof. PERRY, the Society separated until November next.

CORRESPONDENCE.

CURIOUS ACTINIC PHENOMENON.

To the Editor of the Chemical News.

SIR,—The "Curious Actinic Phenomenon" referred to in the CHEMICAL NEWS, vol. xliii., p. 283, is not by any means a new thing. It was not only noticed, but was a difficulty, when I began to manufacture the pigment nearly ten years ago. For several years thereafter, however, I supplied Mr. Thos. Griffiths, F.C.S., with the article which

was not subject to this actinic influence. Much explanation would seem to be required in order to understand Dr. Phipson's remarks on this subject.

A gate post painted with white, on which there was a leaden hue in the sunlight, would *naturally* appear whiter at night, and would not be black under any circumstances, unless in the total absence of light.

If the pigment were "prepared by precipitating a solution of sulphate of zinc by another of sulphide of barium" and calcined, as it seems to have been, whence comes the protoxide of iron, and in such quantity, and how can sulphide of barium of arsenic be present?

Pigment containing the ingredients named by Dr. Phipson would not be white, and could scarcely contain 16 per cent of oxide of zinc unless by mechanical addition.

In fact, the pigment, properly made, does not contain a trace of either iron, lead, arsenic, or manganese, and yet insolation produces this bluish colouration unless means be taken to prevent it.

Of course, the Doctor's statements spring from a laudable desire to keep us informed, and one must not be captious; but his theory on this subject is improbable.— I am, &c.,

JOHN B. ORR.

107, Cannon Street, E.C.,
June 29, 1881.

CHEMICAL NOTICES FROM FOREIGN SOURCES.

NOTE.—All degrees of temperature are Centigrade, unless otherwise expressed.

Comptes Rendus Hebdomadaires des Séances, de l'Académie des Sciences. No. 21, May 23, 1881.

Barometer Based upon the Equivalence of Heat and Pressure upon the Volume of a Gas.—C. Decharme.—To find the atmospheric pressure it is sufficient to take the temperature with a common thermometer, and the volume of the gas in an air thermometer.

Production of Sound by the Force of Radiation.—A. Graham Bell.—A translation of a memoir read before the National Academy of Arts and Sciences, April 21, 1881.

Radiophony: a Thermophone Reproducing the Voice.—E. Mercadier.—With the simple apparatus which the author calls a thermophone, he has been able to reproduce a continuous scale of musical sounds, from the deepest to those corresponding to more than 2000 complete vibrations per second, and in an equally continuous manner the succession of perfect chords of which the fundamental sound runs through this long scale.

Modification of Neef's Interruptor for Ruhmkorff's Coil.—The vibrating spring is fixed, being elongated, and its two extremities are fixed by means of two columns. In the middle of the length of this plate is a small mass of soft iron, which is attracted by the bundle of iron wires of the coil. The screw which fixes the mass of soft iron is platinised, and opposite it is the tapering rod, which serves to produce the interruptions of the current in the induced circuit of the coil. An antagonistic spring, capable of being variously regulated, gives the suitable tension. Neef's interruptor thus arranged gives a considerable number of vibrations in a very short time.

The Rotatory Power of Artificial Codeine.—E. Grimaux.—The author's result is $(\alpha)_D = -130{\cdot}34°$. Under the same conditions natural codeine shows $(\alpha)_D = -133{\cdot}18$.

Proportion of Carbonic Acid Contained in the Air.—A. Muntz and E. Aubin.—The authors have found in 10,000 parts of air in the outskirts of Paris 2·73, 2·90, and 2·99 of carbonic acid. The mean for the day is 2·85, and for the night 3·00. The values thus found differ little from the figures obtained by M. Reiset on the sea-shore, near Dieppe.

Preliminary Thermo-chemical Study of Reactions without the Intervention of a Solvent.—M. Lorin.—A continuation of the author's studies on the action of the acids upon salts without the intervention of a solvent. It appears that formic acid displaces, more or less, all the acids. Its combining power is intermediate between that of the organic acids and that of the most powerful inorganic acids. Thermic reactions assign thallium a place among the alkaline metals.

Silico-molybdates.—F. Parmentier.—Silicic acid gives under certain circumstances yellow precipitates with the alkaline molybdates, which are more soluble in acids than the corresponding phospho- and arsenio-molybdates. Their general formula is $2R,SiO_2,13MoO_3+nAq$.

Action of Ammonia upon Isobutylen Chloride.—S. Œconomides.—Besides the isobutylen chloride the author has obtained the hydrochlorates of certain mixed bases.

Journal für Praktische Chemie.
Parts 19 and 20, 1880.

On Lead Glycerides and the Quantitative Determination of Glycerin.—T. Morawski.—The author traces the hardening of "glycerin putty," a mixture of lead oxide and glycerin, to the separation of water. In addition to the mono-plumbo-glycerin formerly known, he has obtained a sesqui- and a penta- compound, and a plumbo-nitrato-glyceride. The method for the determination of glycerin is not yet fully elaborated.

Phospho-tungstic Acid.—Max Sprenger.—For this acid the author gives the formula $P_2O_5,24WO_3+61H_2O$. He has examined its salts, and on decomposing the barium salt with sulphuric acid he obtains another acid,—

$$P_2O_5,22WO_3+x\ aq.$$

Researches on the Volume-Constitution of the Sulphates, Chromates, and Seleniates.—H. Schroeder.—Among the principal conclusions reached in this memoir are the following:—Manganese in its sulphates and seleniates is isostere with cobalt, iron, zinc, magnesium, and copper. In its hydrates the water in the manganese compound occupies a stere more space than in the corresponding compounds of the other radicles. The water in the hydrated nickel salts is generally more condensed by a half or a whole stere than in the corresponding salts of magnesium, zinc, iron, cobalt, and copper. The stere of the seleniates is slightly greater than that of the corresponding sulphates. The stere of an ammonium compound is slightly greater than that of the corresponding potassium compound.

Para-oxy-phenol and Certain Aldehyds and Alcohols Derived from Hydroquinon.—Dr. A. Hantzsch.—An account of para-diazo-phenetol-chloride, the corresponding sulphate para-oxy-phenetol, ethyl-para-oxy-salicyl-aldehyd, the corresponding aceto-ethyl- and diethyl-compounds; the behaviour of the aldehyds with oxidising agents, mono-nitro-diethyl-para-oxy-salicyl-aldehyd, the behaviour of the aldehyds with reducing agents, and of ethyl-para-oxy-saligenine.

ON STRATIFED DISCHARGES.*

VI.—Shadows of Striæ.

By WILLIAM SPOTTISWOODE, President R.S., and J. FLETCHER MOULTON, F.R.S.

One of the most interesting questions connected with the subject of stratified discharges is this: What is the physical, as distinguished from the electrical, nature of the striæ themselves? Are they, in fact, to be regarded as aggregations of matter possessing greater density than the gas present in the dark spaces, or are they to be considered as indicating merely special local electrical conditions? The fact of their having a definite configuration, especially on the side which is turned towards the negative terminal of the tube, that of their temperature being higher than that of the dark spaces, the manner in which they are affected by solid bodies, and other considerations, all tend to give support to the view that the striæ are loci of greater density than the dark spaces. Still it can hardly be said that as yet any experimental proof of this has been given sufficiently decisive to decide the question conclusively. And it is in the hope of contributing something towards the solution of this question that the following experiments are submitted to the notice of the Royal Society.

In the former papers of this series (*Proc. Roy. Soc.*, vols. 23, 27), and in our memoirs "On the Sensitive State of Vacuum Discharges" (*Phil. Trans.*, 1879, p. 155, and 1880, p. 561), we have described experiments which show how a discharge through a tube, whether sensitive or non-sensitive, may be affected in various ways by intermittent discharges *ab extra*. In the experiments now to be described the problem has been reversed, and it has been proposed to ascertain how far such an external discharge can itself be affected by the internal one. The discharge *ab extra*, however, presents such feeble luminosity, that it is not possible to come to any certain conclusions on this head by direct methods. But, as has been before pointed out, the intermittent discharge *ab extra* is eminently calculated to produce Crookes's green phosphorescence, and the effect produced on this phosphorescence by the striæ of the internal discharge proves to be not only well marked, but even striking, and of this we now propose to give an account.

In the second of the two memoirs above quoted, Section 14, we studied "the effect of intermittent inductive action of an impulsive type upon continous discharges." In the present instance the instrumental disposition was not very different from that which was there described. The two terminals of a Holtz machine were connected in the usual way with the two terminals of the tube, so as to produce a stratified discharge. A narrow strip of tin-foil, or a wire, was stretched along the tube opposite the column of striæ, but not extending much beyond it. The reason for the latter precaution will be mentioned below. The positive terminal of a second Holtz machine (in practice we used for this purpose a Töppler machine) was connected with the tin-foil, and the negative terminal with one (either) terminal of the tube. An air-spark, or interval across which sparks could pass, was interposed in the part of the circuit between the machine and the tin-foil. The effect of this arrangement was similar to that described in our first memoir, p. 170, viz., in the interval between two sparks the tin-foil and tube became charged like a Leyden jar; the tin-foil being the outer coating, charged positively, and the gas inside serving as the inner coating, charged negatively. When the spark passed across the interval mentioned above, the jar (*i.e.*, the tube) became discharged, and the electricity previously held bound on the two coatings was set free.

When the first (say the "internal") machine was not working, or when it was disconnected—*i.e.*, when no regular discharge was passing through the tube—then, whenever a spark passed at the second (or "external") machine, a negative discharge with its accompanying Crookes's radiation took place from the inside of the tube next the tin-foil, and the opposite side of the tube became covered with a sheet of green phosphorescence (the tube being of German glass). The length of the sheet was equal to, or very slightly greater than, that of the tin-foil strip, while the breadth was measured by the angular dispersion from the strip, as described in the second memoir.

When, however, other things remaining as before, a discharge from the internal machine was sent through the tube, and a good stratified column was produced, it was found that the green phosphorescence was entirely cut off from the parts of the tube opposite to the striæ, while on the parts opposite to the dark spaces it remained, in the form of phosphorescent rings, as brilliant as before. The experiment was repeated with various tubes with various degrees of strength of current, and with various densities of gas (produced by heating a chamber of potash in connection with the tube). It may be added that when, as is sometimes the case, through greater exhaustion, the striæ became feebler in illumination and less compact in appearance, the shadows cast by them lost proportionally in sharpness of definition and in completeness of extinction of the phosphorescent light.

The reason for not extending the tin-foil beyond the column of striæ is, that when this is done the negative discharge from inside the strip combines with that going on in the main dark space behind the ancnored striæ in such a manner as to shorten the column by the length of the strip. When this takes place, as is often, although not always, the case, the experiment is frustrated.

The brilliancy and definition of the phosphorescent rings may be increased by inserting a small Leyden jar in the circuit, care being taken that the jar shall discharge itself completely each time. If this is not the case, the main discharge is followed by subsidiary discharges, which tend to blur the effect. The angle of dispersion may be increased, or rather supplemented, by placing more than one strip on the tube, distant from one another by an angle of 90° or 120°. By this means the rings may be made to comprise the entire circumference of the tube.

It should be here mentioned that if the striated column be carefully examined at the moment when the external discharge passes, it will be noticed that the entire column (or more strictly speaking, the part of it lying between the positive column and the end of the tin-foil nearest to the positive terminal) undergoes a slight displacement. This displacement amounts usually to half the distance between two striæ. The actual shadows cast in the green phosphorescence are those due to the displaced striæ, as may be easily verified.

It thus appears that the striæ are competent to cast shadows in the radiant showers issuing from the inside of the tube adjacent to the tin-foil, which part acts as a negative terminal. Many experiments have contributed to show that these radiant showers, although accompaniments of the discharge, are not carriers; and that, having once issued from their source, they continue their own course irrespective of that of the discharge proper. They are, in fact, material showers, and, although not improbably charged with electricity, yet their ulterior course does not appear to depend on their electrical condition. Under these circumstances they can be arrested only by a material obstacle, and consequently the phenomena above described may be considered as furnishing an experimental proof that the striæ represent local aggregations of matter, and not merely special electrical conditions of the gas.

* A Paper read before the Royal Society, June 16, 1881.

ON THE INFLUENCE OF COAL-DUST IN COLLIERY EXPLOSIONS.*

No. III.

By W. GALLOWAY.

THE information that can be gleaned from a study of the three great colliery explosions of the past year—namely, Risca, Seaham, and Penygraig—appears to throw more light upon the question than anything that has been elicited experimentally either by myself or others since I last had the honour of addressing the Fellows on the same subject. These explosions took place on the 15th of July, the 8th of September, and the 10th of December respectively, and they cost the lives of no fewer than 385 persons in all—Risca, 120; Seaham, 164; and Penygraig, 101.

For the purposes of the present paper I visited Risca Colliery on the 24th of October, and Seaham Colliery on the 24th of November, and I have had the rare opportunity of becoming thoroughly conversant with every circumstance connected with the Penygraig explosion, and with the events which immediately preceded and accompanied its occurrence.

A careful consideration of all the preceding details has irresistibly convinced me that, whatever may be the results of experiments with coal-dust made on a small scale, this is not a mere question of "adding fuel to the flame," of "aggravating the consequence of an explosion," of "spreading an explosion," or of "lengthening out the flame of fire-damp," or that of a blown-out shot. Expressions of that kind not only fail to convey a true idea of the actual state of matters, but they are apt to be misleading. I might describe the impression upon my own mind to be somewhat as follows.—Given a well-ventilated or badly-ventilated dry mine with moderately clean fine dry coal-dust lying everywhere all over the workings, and of any quality varying from a long-flaming house-coal, like that of Blantyre, on the one hand, to a semi-bituminous steam coal, like that of Penygraig, on the other hand, then if an explosion be begun at any point in one of the only three possible ways—(1) By the coal-dust being raised and ignited by a blown-out or other shot; (2) by an explosive accumulation of firedamp and air being ignited by a blown-out or other shot; (3) by an explosive accumulation being ignited accidentally by a defective or other safety-lamp, or in any other manner—and if it accumulates a certain degree of fuel without dying out, that force will go on increasing, and the explosion will inevitably extend to every open space in the workings, whatever may be their extent or ramifications. I make no mention of firedamp as necessary to the attainment of this result, with the exception of the comparatively small quantity required to create the first disturbance. It must not be imagined, however, that I lose sight of the *latent* firedamp contained in the air of every mine of this class. On the contrary, I am satisfied that that firedamp plays a most important part in every great explosion, and I have endeavoured strongly to urge this view in both of my previous papers.

International Medical and Sanitary Exhibition.—An Exhibition of Medical and Sanitary Appliances, &c., promoted by the Parkes Museum of Hygiene, will be held at South Kensington from July 16th to August 31st, 1881. The opening ceremony will take place at the Royal Albert Hall, on Saturday, July 16th. The chair will be taken at 4.30 p.m. by the Right Hon. Earl Spencer, K.G., supported by the Right Hon. Earl Granville, K.G., the Right Hon. J. G. Dodson, M.P., Sir James Paget, Bart., F.R.S., and J. Eric Erichsen, F.R.S.

* Abstract of a Paper read before the Royal Society, June 16, 1881

COLLIERY EXPLOSIONS.*

By F. A. ABEL, C.B., F.R.S., President of the Institute of Chemistry, Chemist to the War Department, &c.

ON November 19th, 1880, I received a communication from Mr. Thomas Bell, Her Majesty's Inspector of Mines, Durham District, informing me that a series of samples of dust from Seaham Colliery, collected subsequent to the explosion of September 8th, 1880, by himself and assistants, and by the Miners' Executive at Durham, had been forwarded to me to Woolwich, and that in accordance with my request larger quantities of the same samples had been sent, for purposes of special experiment by me, to Garswood Hall Colliery near Wigan, with the exception of three, which it was thought might have been burnt by the explosion, and of which only small quantities had been collected.

The descriptive list of the samples accompanying Mr. Bell's letter is appended.

A memorandum containing a few additional particulars with regard to these samples was afterwards received by me from Mr. Bell, and also a skeleton plan of the colliery; upon which were indicated by letters, corresponding to the markings of the samples, the places where they were collected.

The samples, 13 in number, which were sent to Woolwich, were in the first instance dried at a temperature of 100° Farhenheit, and passed through a sieve of 50 meshes to the inch, so as to remove the coarser particles, which in some instances existed in very large proportion in the specimens.

I.

The accompanying is a tabulated statement of the results furnished by chemical, mechanical, and microscopic examination of the finer, or sifted, portions of the whole of these samples.

It will be seen from an examination of the table that there were considerable differences in the amount of actual *coal*-dust contained in the different samples. The sample marked X, collected from the screens, was found to consist almost entirely of coal; taking it, therefore, as representing approximately in composition the coal-dust itself furnished by this colliery, an estimate which, though rough, is sufficiently near for purposes of practical comparison, was based upon it (as shown in the table) of the proportion of coal-dust existing in the several other samples of sifted dust.

This comparison shows that the actual coal-dust in the other samples ranged from about 96 to 54 parts in 100 of the sifted dust, dried at 100° Fahrenheit.

The samples K, L, collected at the curve in the Stone Drift near No. 1 and 2 pits, consisted chiefly of coal-dust, while those taken from off props and stones on the off side of No. 1 Engine Plane (S) from beyond the end of the Stone Drift No. 1 pit, 3rd East way (V), and from near the Maudlin Engine (M), also contained very large proportions of coal. The sample from No. 3, Hutton Seam, South way (N) consisted, on the other hand, of little more than half its weight of coal. This sample presents special interest, as will be seen further on, in reference to the question of the influence of dust in promoting or aggravating explosions in coal-mines.

The microscopical examination of portions of the samples, as received, was specially directed to the detection in them of coal particles which had been affected by heat. No such particles were discovered in samples K and L (taken from the curve in the Stone Drift), in M (collected near Maudlin Engine), in V (collected beyond the end of the Stone Drift, in No. 3 East way), nor in sample X, taken from the screens. A few particles of

TABLE I.

PARTICULARS REGARDING SAMPLES OF COAL-DUST COLLECTED IN SEAHAM COLLIERY, 15TH AND 16TH NOV., 1880.

Sample.	Where taken.	Coke including Ash.	Ash.	Volatile Matter (including Water).	Mechanical Water given off at 300° F.	Volatile Matter minus Mechanical Water.	Percentage (approximate) of Coal-dust in sample. Coal-dust containing 10 per cent Ash and 1 per cent Moisture.	Colour of Samples. Order from Black to Grey.	Percentage of Dust passing through sieve of 80 meshes to the inch. After having passed through sieve of 50 meshes to the inch.
†K	From floor of curve in stone drift	78·39	14·96	21·61	2·65	18·96	93·39	2	98·8
L*	From curve in stone drift, scraped off baulks of timber near the roof on which it was deposited, in some places, more than an inch thick.	79·24	12·00	20·76	3·07	17·69	95·93	2	100
†M	From near Maudlin Engine, supposed to have been affected by explosion.	79·55	25·31	20·45	5·28	15·17	80·41	2	84·3
†N	From No. 3, Hutton seam, south way.	85·50	55·41	14·50	1·81	12·69	53·78	8 light grey	81·4
†O	From old incline floor.	82·21	37·43	17·79	3·63	14·16	69·94	4	85·7
P*	From old incline floor, mostly scraped off timbers blown out by the explosion, the rest off flat stones.	86·86	42·50	13·14	3·67	9·47	64·83	3	92·5
Q*	Scraped off flat stones, &c., on return side of Polka doors.	89·15	34·22	10·85	3·67	7·18	73·11	5	100
†R	Off side of No. 1 engine plane at long turn.	81·27	37·36	18·73	4·21	14·52	69·43	7 greyish brown	74·3
†S	Do. do. do. do. off props and stones.	80·16	24·13	19·84	2·64	17·20	84·23	3	94·7
†T	From floor in No. 1 travelling road.	79·40	36·44	20·60	4·10	16·50	70·46	7 greyish brown	77·9
†U	From floor in stone drift, No. 1 pit, third east way.	80·60	40·92	19·40	2·91	16·49	67·17	6	80·9
†V	From ground, three pillars beyond end of stone drift, in third east way, No. 1 pit.	76·55	24·87	23·45	3·21	20·24	82·92	5	85·6
†X	From 1 and 2 screens, probably accumulated slowly and over a long period.	79·72	10·25	20·28	1·00	19·28	99·75	1 black	100

Microscopic Examination.

K.—Coal particles glistening and sharp, various sizes, very few mineral particles.

L.—Particles uniform in size, but much finer than K, all glistening and sharp, very few mineral particles.

M.—Large sharp coal particles mixed with fragments of minerals.

N.—A *very* few large particles of coal-dust and a small proportion of very fine particles, some of which appeared to have been affected by heat. Consists largely of fine sand and other mineral particles.

O.—Some coarse mineral particles and coarse coal particles mostly covered with greyish dust; the larger proportion consists of fine glistening particles; some of the coarser particles appeared to be coked.

P.—Fine, and much more uniform in size than O; some coarse mineral particles. Some coal particles had been affected by heat.

Q.—Particles much collected together, less glistening than other samples, fine dust apparently clinging to them. Many of the particles had been acted upon by heat.

R.—Very large proportion of coarse mineral particles, a few coal-dust particles, and much coke.

S.—A few rather coarse mineral particles, a comparatively large proportion of uniformly fine coal-dust, of which some had been affected by heat.

T.—All clean coarse particles of coal, coke, and minerals; no very fine dust.

U.—Coarse particles of coal and minerals, with fine sand, and coke-dust particles adhering. Great variations in size.

V.—Clean coarse particles, chiefly coal. A small proportion of fine; some particles of wood and straw.

X.—Coal-dust particles, fine and very uniform. No mineral particles observed.

---

sample H, from South way, No. 3, Hutton Seam, appeared to afford evidence, though not of a very decided nature, of having been acted upon by heat; the same was the case with sample O, from the floor of the Old Incline. A few particles in sample P, from the same locality (scraped off timbers and flat stones), furnished more decided evidence of exposure to a high temperature. The remaining five samples all contained coked particles of dust, the proportions being comparatively small in samples (U) from floor in No. 1 Stone Drift, 3rd East way) and S (from props and stones at off side of No. 1, Engine Plane), while they were considerable in sample R, from the same locality, in Q (collected off flat stones on return side of Polka doors), and in T (from floor in No. 1 Travelling Road).

The memorandum from Mr. R. S. Wright, which was transmitted to me in the Under Secretary of State's letter of November 4th, 1880 (and is appended to this report), specified the points which it was desired to have elucidated by the examination of dust samples; it states that samples of burnt dust should be analysed with a view to an opinion whether such burnt dust is—

(1.) The ash or product of dust burnt by an explosion of fire-damp; or is

(2.) The remains or product of dust which has itself been explosively burned (with or without fire-damp) whilst suspended in air.

The meaning which is intended to be attached to the term "explosively burnt" is not very obvious, but it may

be at once stated, with reference to this part of the memorandum, that—

(1.) Although some coal-dust particles in several of the samples exhibited signs, as described, of having been exposed to a high temperature, the samples Q and R are the only two which might be described as *burnt* dust; even these contained respectively 7 and 14·5 per cent of volatile matters (exclusive of 3·67 and 4·2 per cent of water, not driven off at 100° Fahrenheit), and consequently consisted in part of unburnt dust.

(2.) It therefore appears evident, either that the upper or superficial portions of these samples, in the positions in which the dust accumulations were found by the collectors of them, had been attacked by the heat of the explosion, the portions beneath the surface remaining unaffected, or that portions of the dust suspended in the air at the time of the explosion, and partially burnt while taking part in its development and propagation, or consequent upon their exposure to the heat of the explosion, had been deposited after the explosion upon the top of accumulations of unburnt dust. In either case the burnt dust must obviously have become mixed in the process of collection with a more or less preponderating proportion of unburnt dust, upon which it had, in some instances, been deposited or produced only to the extent of a thin film.

(3) The chemical and microscopical examination of the dust samples collected in the Seaham Colliery in November last did not consequently furnish any data to lead to conclusions as to the *extent* to which the dust may have taken part in the production or augmentation and transmission of the explosion.

(4.) On the other hand, the examination has served to show—

(*a*) That the dust samples collected in different parts of the colliery differed very considerably in the proportion of coal-dust and of other matters which they contained, as well as in their mechanical condition;

(*b*) That, after the explosion, coked or partially burnt dust existed, though apparently not in very considerable proportion, at several points very distant from each other and in different directions, as in the samples U from near extremity of stone drift, No. 1 pit, P from old incline floor, R from south way, Hutton seam, and S from No. 1, travelling road;

(*c*) That the dust samples K, L, and M, collected from the curve in Stone Drift, and from near Maudlin engine—*i.e.*, at those points selected for the purposes of this enquiry which are nearest to the spot where the shot was fired at the time that the explosion occurred—afforded no evidence of having been subjected to the action of a high temperature.

With regard to points 1 and 2A in Mr. Wright's memorandum, neither chemical nor microscopical examination could furnish any indication of a characteristic difference between "the ash or product of dust burnt by an explosion of fire-damp, and that which has itself been (explosively?) burnt with or without fire-damp, whilst suspended in the air." If, in the latter case, the quantity of dust suspended in the air (in addition to, or without, fire-damp) be such that the proportion borne by the atmospheric oxygen is that, or in excess of that, required for the combustion of the inflammable constituents of the coal particles, the latter *might* be *completely* coked and even partly burnt *to ash*, though the completeness of the result would depend much upon the inflammability and fineness of the dust, upon the rapidity of the explosion, and upon the amount of heat developed. It is more than probable, however, that at any rate a large proportion of the coal-dust suspended in the air at the time of a fire-damp explosion, or of an explosion produced, if it be possible, by the sole agency of coal-dust, would only be partially coked, and such would also be the case with deposits of coal-dust exposed to the heat and flame of a fire-damp explosion.

In the latter case, if the coal be a caking coal, and the dust contain but little matter foreign to coal, a crust, or conglomerate, of partially coked dust may be formed, but the non-existence of any evidence of such aggregations in the samples collected in the Seaham Colliery cannot be accepted as any positive indication that this particular action of heat had not taken place in the localities where the specimens had been collected, because any coked dust of this particular form would have become again reduced to dust in the handling, transport, &c., of the samples.

The ten larger samples of dust sent to Brynn from Seaham (of which smaller portions had been received at Woolwich and examined, and which are marked † in the descriptive list) were found to be all more or less moist, and as means for their proper desiccation, without application of excessive heat, did not exist at the colliery, they were transmitted to Woolwich, where they were carefully dried in a core-drying stove in the Royal Arsenal Shell Foundry, and sifted so as to separate all coarser particles; the sifted samples were then packed to exclude access o damp, and returned to Brynn for experiment.

The samples were compared with each other, and also with samples of coal-dust obtained from various collieries at which serious explosions had recently occurred, with respect to the proportion of fire-damp to air which a suspension of each particular sample in the gas-mixture would cause to be exploded readily by contact with the naked flame of a Davy lamp.

In this way a reliable estimate appeared to be arrived at of the comparative sensitiveness, or of the comparatively dangerous character, of the different dust samples.

The results of this comparison are given in the second part of this report.

(To be continued.)

SELENIUM AND ITS APPLICATIONS TO THE PHOTOPHONE AND TELEPHOTOGRAPHY.*

By SHELFORD BIDWELL, M.A., LL.B., M.R.I.

(Concluded from p. 2.)

By the help of a reflecting galvanometer I now propose to show you the various effects produced by different parts of the spectrum of the electric light formed by a bisulphide prism upon the resistance of a selenium cell. The maximum deflection is seen to occur when the selenium is at the extreme outer edge of the red.

The effect of interposing various coloured glasses between a gas flame and the selenium cell was also tried. The greatest effect was produced by orange glass, the smallest by green. It was, too, observed as a remarkable fact that the light transmitted by a dark blue glass produced a greater effect than that which had been passed through a blue glass of much lighter tint. But on a spectroscopic examination the darker one was found to transmit a certain portion of red light. I also tried the effect of radiation from a black-hot poker held at a distance of about 6 inches from the selenium, and upon the first trial found that the resistance, instead of being diminished was increased by several thousand ohms. I imagined this to be due to a rise of temperature in the selenium, and was thus led to experiment upon the effect of temperature. In this matter, too, there is a remarkable discrepancy between the authorities. Prof. Adams says that an increase of temperature *increases* the resistance of selenium, and even suggests that a selenium bar should be used for the construction of a very delicate thermometer. Dr. Guthrie, Messrs. Draper and Moss, and others, make the directly opposite assertion that the resistance of selenium *diminishes* with heat. I repeated my poker experi-

* A Paper read before the Royal Institution of Great Britain, Friday, March 11, 1881.

ment, which had in the former case apparently corroborated Prof. Adams, and now to my utter astonishment I found that the resistance was greatly diminished. This second experiment, therefore, seemed to support Dr. Guthrie's statement. A great number of experiments were now undertaken for the purpose of arriving at the truth of the matter, with the details of which I will not weary you. Solutions of alum in water, of iodine in bisulphide of carbon, plates of glass and of ebonite were interposed between the selenium and the sources of light and heat. The selenium was now fried, now frozen; and the most contradictory results were obtained. At one moment I felt convinced that Prof. Adams was right, at the next there appeared to be no shadow of doubt that Dr. Guthrie's was the true theory. In fact, it seemed as if the selenium was possessed by a demon which produced the variations in accordance with the caprices of its own unaccountable will. At length, when the confusion was at its height and the demon most bewildering, the true explanation was suddenly revealed, and so exceedingly simple is it that now the only marvel is that it should have so long eluded discovery. The secret of the matter is this, and it discloses one of the most remarkable properties of this most remarkable substance:—There is a certain degree of temperature at which a piece of crystalline selenium has a maximum resistance. If a piece of selenium at this temperature is exposed to either heat or cold—it matters not which—its resistance will at once be diminished; and extremes of either produce a far greater variation than is ever effected by the action of light. A selenium cell which, at the ordinary temperature measured in a dim light 110,000 ohms, was reduced by immersing it in oil at 115° C. to 18,000 ohms. The resistance of the same cell was reduced by immersing it in turpentine at −6° C. to 49,000 ohms. In the case of the single cell with which I have hitherto made the experiment, the temperature on each side of which the resistance is diminished is 24° C.* Let this piece of selenium be gradually raised from a temperature of zero to a temperature of 100° C. While passing from zero to 24°, its resistance will rapidly increase. Passing from 24° to 100° its resistance will again rapidly diminish. (This experiment was successfully shown.)

Until Prof. Bell directed his attention to selenium, all observations concerning the effect of light upon its conductivity had been made by means of the galvanometer. But it occurred to him that the marvellously sensitive telephone which he has invented might with advantage be used for the purpose, and on the 17th May, 1878, he announced in this theatre "the possibility," to use his own words, "of hearing a shadow by interrupting the action of light upon selenium." A few days afterwards Mr. Willoughby Smith informed the Society of Telegraph Engineers that he had carried this idea into effect, and had heard the action of a ray of light upon a piece of crystalline selenium.

When a selenium cell, a telephone, and a battery are connected in circuit, a uniform current of electricity will, under ordinary circumstances, flow through the telephone, and a person listening would hear nothing. Suppose, now, that a series of flashes of light were allowed to fall upon the selenium. In the intervals of darkness the selenium cell would offer a greater resistance to the passage of the electric current than during the intervals of light. The strength of the current would be constantly varying; and if the flashes succeeded one another quickly enough and with sufficient regularity, a musical note would now be heard by a person listening at the telephone. The exact pitch of this note would of course depend upon the rate at which the flashes succeeded one another, being high when the succession is rapid, low when it is slow. The nature of this sound is very peculiar, reminding one of the moaning of a syren or the rising and falling of the wind. With a sufficiently sensitive cell, powerful battery, and delicate telephone, the sound may be heard at a distance of many feet.

I shall interrupt the steady beam of light which is now falling upon the cell by causing a zinc disk with radial slits cut in it to rotate in the path of the beam, and the sound produced by the rapid succession of light and shade upon the selenium cell will be heard in the telephone. When the cell is screened from the light, the sound at once ceases. When the screen is removed, the sound is again heard as before. By using a system analogous to that of dots and dashes, an intermittent beam of light might be employed to convey photophonic messages to a distance.

But Prof. Bell has gone further than this. He was not satisfied with merely *interrupting* a steady beam of light, producing alternately strong light and total darkness, but he aimed at graduating its intensity in correspondence with the varying phases of the complex sound-waves produced by the human voice. It is evident that if a beam so regulated were allowed to fall upon the selenium cell, the exact words spoken, with their articulation unimpaired, would be reproduced in the telephone. Prof. Bell adopted a device which is equally marvellous for its extraordinary simplicity and for its perfect efficiency. The beam of light is made to fall upon the face of a small flexible mirror, whence it is reflected to the distant selenium cell, lenses being used for the purpose of rendering the rays parallel and condensing them where required. The speaker directs his voice upon the back of the mirror, which takes up the sound-waves and is thrown into a state of vibration, thus becoming alternately concave and convex. Now, when it is concave the light reflected by it is more concentrated, and the selenium cell more brightly illuminated. On the other hand, when it is convex, the opposite effect is produced; the rays are more dispersed and the illumination of the cell less intense. And since the movements of the mirror are in exact correspondence with the sound-waves of the voice, so also will be the intensity of the illumination of the selenium cell. The strength of the current passing through it will vary in the same proportion, and will cause the telephone plate to vibrate in consonance with the mirror, and thus to reproduce the exact sounds by which the mirror was set in motion.

In the small experimental photophone which is before you, the receiving station is within 20 feet of the transmitter, and any sounds heard in the telephone would of course be utterly drowned by the actual voice of the speaker at the mirror. It is necessary, therefore, to prolong the telephone wires, and carry them to a distant room, where the sounds that have travelled along the beam of light can be heard without interruption. Prof. Bell, using, instead of a lens, a large reflector for receiving the beam of light, has heard words which were spoken when the mirror was 700 feet away from the selenium cell.

It is impossible to exhibit the photophone in action to an audience, because the effects can only be heard by a single person at a time. But I may mention, that in the course of some experiments with this little instrument which Prof. Tyndall very kindly permitted me to make here on the 7th of December last, every word transmitted by it was perfectly understood.

I propose now to say a few words upon another and very different application of selenium. In point of interest and importance it cannot be compared with the photophone: but since it is a child of my own I naturally regard it with a certain amount of affection. It occurred to me a few months ago that the wonderful property of selenium, which we have been discussing this evening, might be applied in the construction of an instrument for transmitting pictures of natural objects to a distance along a telegraph wire. I have constructed a rough experimental apparatus in order to ascertain whether my ideas could be carried out in practice, and it is so far successful, that although the pictures hitherto transmitted are of a very rudimentary character, I think there can be little doubt

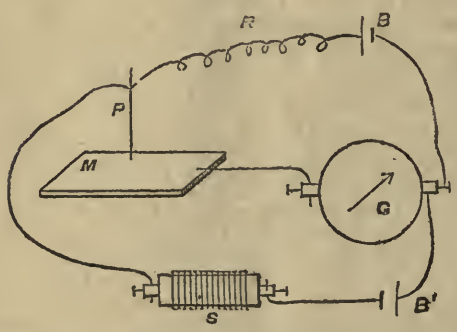
* The experiment has since been repeated with five other cells, and their temperatures of maximum resistance were found to be 23° 14°, 30°, 25°, and 22° respectively.

that further elaboration of the instrument would render it far more effective.

Iodide of potassium is very easily decomposed by a current of electricity. If a piece of paper which has been soaked in a solution of this substance be laid on a piece of metal, M, Fig. 2, which is connected to the negative pole of a battery, B, and a piece of platinum wire, P, which is connected with the positive pole, be drawn over its surface, the path of the point will be marked by a brown line, due to the liberation of iodine. Let the platinum wire and the metal plate be connected to a second battery B' in such a manner that a current of electricity may pass through the paper in the opposite direction; and let a variable resistance, R, be inserted between the platinum wire and first battery, B, and the selenium cell, S, between the platinum wire and the second battery. And let the resistance be so adjusted that when the selenium cell is exposed to a strong light, the two opposite currents through the paper and the galvanometer, G, neutralise each other; then the point when drawn over the paper will make no mark. But if the selenium cell is shaded, its resistance will be immediately increased, and the current from the first battery will predominate. The point, if moved over the paper, will now trace a strong line, which, if the selenium is again exposed, will be broken off or enfeebled according to the intensity of the light. (Exp.)

If a series of these brown lines were drawn parallel to one another and very close together, it is evident that by

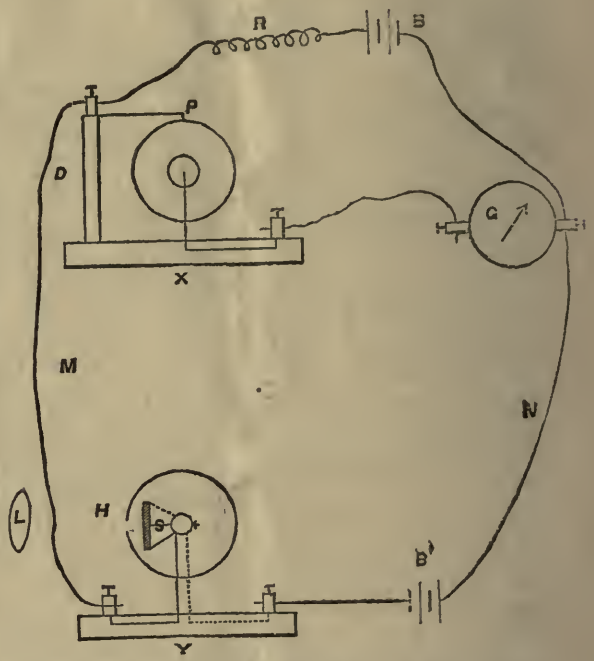
Fig. 2.



regulating their intensity and introducing gaps in the proper places any design or picture might be represented. This is the principle of Bakewell's copying telegraph, which will transmit writing or pictures drawn upon tinfoil with a non-conducting ink. My instrument differs from his in that the current is varied simply by the action of light. The transmitting instrument, Y, Fig. 3, consists of a small cylindrical box, 2 inches deep, mounted upon a horizontal spindle, upon which is cut a screw having sixty-four threads to the inch. This works in two bearings 4 inches apart, one of which has an inside screw corresponding to that upon the spindle. At a point midway between the two ends of the cylinder a pinhole, H, is drilled, and behind the hole a selenium cell, S, is fixed. One terminal of the selenium cell is connected (through the spindle and stand of the instrument) with the negative pole of a battery B', the other with the line wire, M, to the distant station. The receiving instrument, X, contains a similar brass cylinder, similarly mounted. A platinum point, P, presses gently upon its surface, and is connected both to the line wire and, through a variable resistance, R, with the positive pole of a local battery, B, the negative pole of which is connected through the galvanometer, G, with the cylinder. A wire or earth connection, N, between the negative pole of the local battery and the positive pole of the other, completes the arrangement.

To prepare the instruments for work the cylinder of the transmitting instrument is brought to its middle position and a picture not more than 2 inches square is focussed upon its surface by means of a photographic lens, L. The hole, H, in the cylinder is then brought to the brightest point of the focussed picture, and a scrap of sensitised paper being placed under the platinum point of the receiver, the variable resistance is adjusted, so that the two opposite currents through the paper neutralise each other. When

Fig. 3.



this is accomplised the two cylinders are screwed back as far as they will go, the cylinder of the receiver is covered with sensitised paper, and all is ready to commence operations.

The two cylinders are caused to rotate slowly and synchronously. The little hole in the transmitting

Fig. 4.

Image Focussed upon Transmitter.

Image as Reproduced by Receiver.

cylinder will in the course of its spiral path cover successively every point of the focussed picture, and the amount of light falling at any moment upon the selenium cell will be proportional to the illumination of that particular spot of the picture which, for the time being, is occupied by the pin-hole. During the greater part of each revolution

the platinum point will trace a uniform brown line upon the prepared paper, but when the pin-hole happens to be passing over a bright part of the picture, this line is enfeebled or broken. The spiral trace by the point is so close as to produce, at a little distance, the appearance of a uniformly coloured surface, and the breaks in the continuity of the line constitute a picture which, if the instrument were perfect, would be a counterpart of that projected upon the transmitter.

The pictures upon which I have hitherto operated have been mostly simple designs, such as diamonds and squares cut out of thin metal, and projected by a magic lantern (see Fig. 4). But the instrument is in its earliest stage of infancy. It is at present hardly a single month old, and I regret to say that since its birth it has been shamefully neglected, circumstances having prevented me from giving it even the ordinary care and attention which all young creatures ought to receive. Nevertheless, I cannot but think that it is capable of indefinite development; and should there ever be a demand for telephotography, it may in time turn out to be a useful member of society.

ON THE

VENTILATION OF HALLS OF AUDIENCE.*

By ROBERT BRIGGS,
Member of the American Society of Civil Engineers.

(Concluded from p. 8.)

Any man may warm himself as he pleases. It is impossible for a number of men to tell one man what will please each of them individually, and for that one man to please them all. It is not the provision of means of control that will secure the wished for result. With every appliance failure is certain, unless those appliances pass into the hands of the persons to be warmed themselves. The neglect of this essential condition has led to repeated failures, until there is a popular belief that no ventilating apparatus can be successful, and there exists a general preference either for direct steam heating; where an occupant of a room can manipulate the cocks or valves to his own liking, or for mere current warming; where opening or closing a register, also by any person in the room, controls the heat supply satisfactorily, when no importance is attached to the air thus adventitiously furnished or closed off. Only hospitals, or jails, or orphan asylums are happily ventilated, regardless of the volition of the sufferers, but greatly to the delight of ventilation doctors, whose experimental results are pleasant to contemplate.

While commenting thus freely upon the drawbacks of previous efforts, it is a suitable requirement upon the fault-finder that he should offer a remedy; and a remedy will now be proposed, which is: That to the engineer, or persons in charge of the apparatus, should be delegated the running of the same mechanically, in a defined way, without his or they assuming the regulation of the temperature of comfort in any room or hall, or part of a room or hall, where the magnitude of the same admits of division into parts. The temperatures desired or attained being positively controlled, within certain limits, by the occupants, or by representatives of the occupants, such as floor officials or ushers, in the rooms or halls. The limits of temperature proposed are 50 degrees for the lowest and 80 degrees (possible) for the highest. The supply of air at any one time should be constant and invariable, so that the equilibrium of distribution will not be disordered by the closing-off or wide-opening of registers for admission of air—the usual process for controlling temperatures with heated currents at present.

The arrangement of apparatus to effect the foregoing, becomes necessarily a matter of original plan and construction, and is as follows: The boilers, fan engine, and fan may be assumed, for convenience of running, as well as for better and simpler construction, to be placed in juxtaposition in vaults, at any desirable point about the buildings or grounds. Where the grounds near the building fall away, so that the boiler can be located above ground, and yet below the levels of the coils, this disposition of boiler is preferable. One of the advantages of the proposed method is, that except the cost of ducts and mains, the placing of boilers some distance from a building, say some 300 or 400 feet, is not objectionable.

When the desirable level for the boilers, with regard to the coils, for direct return of condense water without force, cannot be had, the return mains can descend to some separating recipient, where the condense water can be trapped-off to a hot well from which the boilers will be fed by a pump; or the coils may be trapped separately or in clusters, and their condense water taken by return mains to the hot well; or the coils may be trapped-off, and the hot condense water wasted; or yet, again, the return mains with regular descent may carry the condense water to a *closed hot well*, placed below the boiler level, under the boiler pressure, from which it will be elevated by a *closed pump* to supply the boiler.*

The main duct should be dry, air-tight, and closed as a passage way, absolutely without openings into rooms, vaults, or general passages, excepting only such doors as may be necessary to give access to the duct for the purposes of the apparatus. Every precaution should be taken to make the main duct *inconvenient* as a thoroughfare. This main duct, in the arrangement of apparatus here proposed, may be carried under ground or under floors, anywhere amongst the foundations or cellar walls of the building; only prescribing that it shall be well built in smooth finished masonry, without angles, dry, air-tight, and closed. Ducts smaller than 12 square feet sectional area may be built of thin galvanised iron, or may be built of wood (with narrow, 3-inch wide boards, tongued and grooved, mill-planed both sides), and lined with light sheet tin, with soldered joints. The wood-work of ducts need not be expensive, but it should be substantial. While small ducts or branches can be cheapest made of thin galvanised iron, in permanent structures, brick-work ducts, with arched or slate-covered roofs, of all sectional areas, branch ducts included, is the best construction. Coil chambers should be built in the manner, and of similar materials, described for ducts.

Returning to the arrangement of apparatus:—There is to be constructed either directly in advance of the fan chamber or close behind it, connecting to the main duct, an *auxiliary coil chamber* to hold an auxiliary heating coil. This auxiliary heating coil should be built in at least four separate sections (with perhaps a larger number for an extensive apparatus), and this coil should, in its aggregate of surface, have enough to heat the entire volume of air required for winter ventilation from zero (or from the supposable lowest temperature of winter) to 50 degrees. Besides this sectional arrangement of the coil, it (the coil) should be so placed in the coil chamber that the air can be passed or by-passed, through or around any one or other or all of the sections, under the regulation of sliding doors or of louvered blinds, so that not only complete but instantaneous control of the heat of the entering air can be had.

With the use of these means of control of the heat of the air entering the ducts, to meet every temperature of the external air, the duty of the engineer so far as relates to the *heat* in the building (for the most part) ceases. He will be required to see at all times, when the outside temperature ranges below the limit of 50 degrees, that the air passing into the main duct has a constant temperature of 50 degrees.

* A Paper presented to the American Society of Civil Engineers, January 26, 1881.

* This last very valuable improvement in the arrangement of return mains was proposed and introduced by W. E. Worthen, M.A.S.C.E., of New York. It presents the same advantages, as regards the "air difficulty," that is found in direct return to the boilers.

This temperature offers great advantages in the transmission of air-currents. It allows them to be carried under ground, in cellars, near foundations and under floorings, to any desirable distance, without loss or gain of heat in the transmission. It places all the local coils in the building on an equality in the demand upon them to supply hot or heated currents. It will be found that half the heating surface for the entire building will be demanded in this auxiliary coil, and that this surface will be peculiarly efficient, because of the great difference between the temperature of the coil surface and that of the effluent air from the coil. With the reduction of dimension of the local distributing coils, a corresponding reduction of dimension of flow- and return-mains will be permissible. And an advantage of the highest importance is yet to be stated; all risk of freezing up the return-mains or the lower pipes of the local coils (or occasionally an entire coil) is obviated, while nothing but positive neglect could allow freezing to occur in one of the sections of the auxiliary coil.

The local distributing coils should, perhaps, be sectional, in not more than two sections for the larger coils, but it is questionable whether any division of these may be necessary, although the writer would advise it in construction. These coils should be in chambers arranged for the air to be passed or by-passed, through or around them, by the regulation of slides or valves *to be placed under the control of the occupants of the room or of the officers or ushers in a hall.* The means for regulation should be solely in the rooms or halls themselves, and any gradation of temperature of entering air from 50 to 80 degrees should be instantaneously commanded, without, however, varying the quantity of air regularly supplied. If, with these provisions, by any accident or neglect the extreme of heat or of cold be allowed in the air supply for a short time, the effect will not be serious, for the instant restitution to what the occupants of a room may deem their temperature of comfort is feasible. The settlement of degrees of discomfort amongst the number occupying a room will have to be effected by tolerance, much as the fresh air is got in a railway-carriage, where there is no one to blame but the passenger when a window is opened or closed.

In halls it is manifestly proper that the floor should be separated in divisions, each having its own supply of air, so that the local regulation may meet not only the small differences of local requirement which always occur, but also the differences of individual demand of equally general, and even more urgent, occurrence. The galleries of halls have not merely a small difference in requirement, but at all times they demand two or three or even more degrees *less* temperature for entering air than the floors. In some cases, as in the Senate Chamber or the Hall of Representatives at Washington, and generally in all legislative or council chambers, the galleries are occupied by a crowd of spectators, clothed, in cold weather, in heavy outer garments, while the floors must be comfortable for the members, who are by no means crowded together, in usual indoor clothing. At evening sessions when gaslights are required, the increase of temperature therefrom will be found mainly in the galleries, and it then becomes essential to supply them with cooler air than the rest of the hall. It is a consequent necessity for the successful ventilation of halls that the gallery supplies of air be distinct and separate from those to the floor; and it is much better to arrange for these supplies in separate divisions, one, if not two, to each side of the hall.

The duty of the engineer of the apparatus, so far as the local coils are concerned, will require him to put in use one or both sections of such coils to meet the demand of the season or day as regards mere warming and positive heating. Beyond this he has, whenever the external temperature is below 70 degrees, only to see that each coil is supplied with steam, and in satisfactory operation as a steam coil, under full boiler pressure. With this, and with his charge of the temperature derived or proceeding from the auxiliary coil, his responsibility for heating the building in cold weather ceases. As the weather becomes warmer in any year, and when the external temperature reaches 50 degrees, the auxiliary coil is thrown off. At 65 to 70 degrees the local coils cease to be operative, and thereafter the engineer, running the fan at double rate when summer ventilation is required, supplies to such hall (the ventilation of which was based on 10 cubic feet of air per person per minute) the maximum of 20 cubic feet, which quantity will be found nearly all that can well be delivered amongst a crowd, where each person occupies say 4 square feet of floor space, or the average theatre allowance.

Economy in running an apparatus must always be considered in planning the same, and no building can be *ventilated* to the full extent continuously, whether its hall be occupied or not, with any proper regard for expenditure. It follows that, notwithstanding what has been said about exonerating the engineer or director of the control of the heating, there must yet be left, with these persons or one of them, the means of reducing the air supply to meet the real necessities of use or vacancy,—of complete or partial occupancy. This may be effected in part by the running of the fan, but it will be found necessary to provide for regulation of air delivery by closure of ducts or branches to some extent. As the local coil surfaces are unalterable, the effect of employment of a greatly reduced volume of air at times will be to enable them to give currents of much higher temperature than 80 degrees.

Thus in a hall with 1200 people, at a minimum of 10 cubic feet per person per minute, we have 12,000 cubic feet per minute. If the local coils can take this air at 50 degrees, and heat it to 68 degrees, which may be supposed to give 70 degrees in a room in moderate weather, and if the same local coils can take this air at 50 degrees and heat it to say 75 degrees in the coldest day (the 80 degrees heat from local coils is supposed in this case to warm up the room after it may have been chilled for want of heat), and also to give 70 degrees in the room, it is evident that, reducing the quantity of air to 1200 cubic feet per minute, these same local coils are sufficient in extent to carry the 1200 cubic feet from 50 degrees to over 125 degrees in the same minute of supply, and at this temperature the room will be warmed to 70 degrees against zero out of doors, at greatly less expenditure of fuel. For in one case there is wasted of vitiated air 12,000 cubic feet which had been taken at zero and allowed to escape at 70 degrees, while in the other case only 1200 cubic feet, taken also at zero and escaping at 70 degrees, is demanded in effecting the heating.

This possibility of economising in the working of every system of ventilation is the bane of all methods. Ventilation is not economic as a process of warming. In many instances, after a demonstration of successful ventilation, the working of the apparatus is permitted to degenerate to the barest warming. There is demanded a conscientious persistency in maintaining a thorough ventilation, where the warming can be made satisfactory without it, that surpasses the moral appreciation of a money-getting manager or of an economic official.

In presenting this optimist view of the subject of practical ventilation of halls of audiences, it must be accepted as indicating the path of advance, not as demonstrating the impropriety of advance. No expenditure is justifiable which cannot have the assertion of necessity; nothing surpassing the admitted wants of society will be appreciated or willingly paid for. The current belief and faith in the necessity for purer air in halls must be entertained by the audiences before the expenditure for provision or of maintenance of ventilating apparatuses can be warranted. It is sure that people do become less tolerant to the closeness and odours of halls, court-rooms, school-houses, year by year. This is evidenced by the extravagant schemes of sanitation of such places on the one hand, and by the boasts of impossible accomplishments with wholly incompetent means on the other, that find so frequent publica-

tion. It has been the purpose of this paper to set forth the least quantity of air supply compatible with relative purity in the air of an occupied hall, and then, without gloss or extenuation, to set out the difficulties and costs in obtaining this least quantity, and the inconvenience and discomfort attendant, so that they shall all be appreciated as incident to the problem of ventilation.

Above all, in the effort to give or establish practical limits for the necessities of ventilation in halls of audiences, which can with safety be aspired to at this present time, and with justice be demanded by the community from all those who control the management of audience or session rooms, it is not wished to be misunderstood by supposing that this paper has been, or is, advocating the dispensing with any real demand in quantity or quality of the supply of fresh, pure air. Compliance with the present *system of ventilation* of hot-air furnaces, which *system* is merely heating to requisite intensity, with adventitious supply of air, is as far from the ideal of perfection as the scheme of giving to the occupant of a hall the healthful air of the mountains, with the freedom and volume of the west wind, is from the possibility of construction or of operation. Little by little modern society appreciates the conditions of healthful, civilised existence. The removal of cause of offence is the first requisite of sanitation, and it is the first requisite of ventilation. Our tolerance of personal uncleanness in small ways, and in large ones also, goes far to account for the offensiveness and unhealthiness of many places of public gathering. Arguments on this point, and social enforcements of regulations in this regard, in theatres, court-rooms, galleries of public halls, school-rooms, public conveyances of all kinds (especially the latter), will be more efficient than the indoctrinating of surmounting the difficulty by gales of fresh air, furnished regardless of comfort and expense.

Finally, after establishing the *requirements* for necessary and indispensable ventilation of audience halls and of audiences, it becomes the indispensable preliminary that the original planning and subsequent erection of the buildings shall provide suitable rooms for apparatus, together with ducts, distributing passages, and flues, in order to render available the methods of the mechanical engineer; by which methods ventilation, with comfortable heating, can now be effected with controllable, positive, and satisfactory result.

CORRESPONDENCE.

ON A NEW METHOD FOR THE ESTIMATION OF NITRATES IN POTABLE WATER.

To the Editor of the Chemical News.

Sir,—Mr. J. West-Knights read a paper before the Society of Public Analysts with the above heading on the 16th of March last. Allow me to state that it is not a *new method*, but only a slight modification of Mr. Edward Nicholson's process, as described by him in the *Madras Monthly Journal of Medical Science*, for May, 1871, and also in the Chemical News, vol. xxv., p. 89.—I am, &c.,

William Johnstone.

King's Lynn, July 4, 1881.

THE ACTION OF NITRIC ACID ON METALS.

To the Editor of the Chemical News.

Sir,—In the Chemical News, vol. xliii., p. 284, I read a note by M. E. Maumené "On the Action of Nitric Acid on the Metals." According to M. Maumené's theory, the formation of ammonia by the action of tin on nitric acid takes place according to the following equation:—

$$14Sn + NO_3(HO)_{10} = 8SnO + 6Sn + NH_3 + 7HO.$$

Now since only 8 equivalents of Sn take part in the reaction, why use 14? What *rôle* do the other 6 parts of Sn play?

I shall be much obliged to my learned friend if he will explain this obscure point of his "*Théorie Générale*."—I am, &c.,

Dr. D. Tommasi.

Florence, June 27, 1881.

CHEMICAL NOTICES FROM FOREIGN SOURCES.

Note.—All degrees of temperature are Centigrade, unless otherwise expressed.

Comptes Rendus Hebdomadaires des Séances, de l'Académie des Sciences. No. 22, May 30, 1881.

Discontinuous Phosphorescent Spectra Observed in High Vacua.—W. Crookes.—This paper has been communicated in full to the Royal Society. M. E. Becquerel remarked that he had previously observed some of the facts observed by Mr. Crookes. (See *Ann. de Chimie et de Physique*, 3rd series, vol. lvii., p. 40.)

New Interruptor for Induction Coils.—M. Deprez.—The author states that the apparatus of M. Ducretet (*Comptes Rendus*, May 23) is merely a form of that which he produced nearly a year ago, and laid before the *Société de Physique*. The elasticity commonly given to the organs of the ordinary interruptor, and the amplitude of movement which it consequently possesses, are injurious to the effects proposed to be obtained.

The Conic Mirror: A Reply to M. Pifre.—M. Mouchot.—The mirror is an apparatus for concentrating the heat of the sun's rays. The author contends that its action is more powerful than M. Pifre is willing to admit.

Discussion of the Theory of the Three Fundamental Colour-Sensations of the Eye. Distinctive Characters of these Colours.—A. Rosenstiehl.—The fundamental colours possess the following properties:—By their mixture, two and two, they produce all the colours perceptible to our eyes. They produce at the same time the sensation of whiteness to a less degree than the other colours. The sensation of pure whiteness depends on the equal excitement of the three fundamental sensations. As regards complementary colours he finds that the colours situate on the one and the other side of a primary colour, and which are to the eye equidistant, have their complementaries so close together that it is difficult to distinguish between such as are consecutive.

Essence of Wild Thyme.—P. Febve.—The author has obtained from this oil a cymene, $C_{20}H_{14}$, and a thymol, $C_{20}H_{14}O_8$.

Geological Microzymas.—Reply to MM. Chamberland and Roux.—A. Béchamp.—The author refers to former experiments in which he has obtained alcohol, lactic, acetic, and butyric acid by means of the microzyma of chalk.

Vanadiate of Lead and Copper from Laurium.—F. Pisani.—The mineral is a cupriferous eusynchite, containing equal equivalents of lead and copper, as in psittacinite and mottramite.

Journal für Praktische Chemie.
Parts 19 and 20, 1880.

Formation of Urea in the Animal Organism.—E. Drechsel.—The author shows that urea is formed from ammonium carbaminate.

Nos. 1 and 2, 1881.

Researches from the Chemical Laboratory of Prof. A. Saytzeff at Kasan.—These consist of a memoir by

B. Sorokin on the constitution of diallyl, and a paper by W. Lebedinsky on allyl-di-iso-propyl-carbinol and its product, β-di-iso-propyl-ethylen-lactic acid.

Contributions to the Chemistry of the Chrom-ammonium Compounds.—O. J. Christensen.—The author gives a very full account of roseo-chrom-hydrate, the corresponding chloride, bromide, iodide, sulphate, nitrate, platinum bromide, sulphato-platinum chloride, sulphato-platinum bromide, mercuric chloride, bromo-chromate, the double cyanides of roseo-cobalt and roseo-chrome with iron, cobalt, and chrome. He mentions that whilst the two atoms of chlorine in chloro-purpureo-chrome chloride are most intimately combined, and are not precipitated by silver nitrate without the aid of heat in the roseo-chloride, all the chlorine is precipitated by silver nitrate in the cold. In an appendix the author treats of the preparation of chloro-purpureo-chrome chloride.

Changes of Colour in the Solutions of the Salts of Chrome-oxide.—G. Doyer van Cleef.—The author concludes from his experiments that the neutral chrome salts, which dissolve with a violet colour, undergo a gradual decomposition in solution, and that the changes of colour of the chromic salts when heated are due to a similar decomposition carried to a greater extent.

Loss of Water by Certain Salts Chromic of Oxide.—G. Doyer van Cleeff.—In chromic sulphate there is no marked difference between the mode of combination of twelve of the mols. of crystalline water and of the remainder.

Silver in Commercial Bismuth and Certain Connected Phenomena.—R. Schneider.—It appears that distinct traces of silver are to be found in many samples of the commercial preparations of bismuth. Pure oxide of bismuth free from silver is not sensitive to light.

History of the Oxidations in the Animal Body.—M. Nencki.—The author submits the researches and conclusions of Hoppe-Seyler to a severe criticism.

Nos. 3 and 4, 1881.

Crystalline Albumen in Pumpkin Seeds.—Dr. G. Grübler.—Pumpkin seeds contain an albumen which may be easily obtained in well-developed octahedral crystals. The proteine contained in the seeds consists chiefly of such crystals. Crystalline albumen is distinguished from the amorphous variety by a far smaller proportion of ash and of phosphoric acid, and by a higher proportion of carbon, nitrogen, and sulphur.

Formation of Dihydro-anthranol and Anthracene from Anthraquinon.—Dr. H. R. von Perger.—Dihydro-anthranol is obtained from anthraquinon by the action of zinc powder and ammonia.

The Compounds of the Mono- and Bi-basic Fatty Acids with the Phenols.—M. Nencki and N. Sieber.—By the alternate application of mono-basic fatty acids and phenols with zinc chloride an entire series of aromatic oxy-ketons have been formed. The authors have also obtained a succinyl fluoresceine by heating hydrated succinic acid and resorcine along with zinc chloride or with strong sulphuric acid.

Benzol and Dipropargyl. Confirmation of Theory as regards the Formation-heat of the Hydrocarbons.—Julius Thomsen.—The liberation of heat on the formation of hydrocarbons of constant volume from gaseous carbon and hydrogen is a multiple of a constant magnitude, about 14,700 cals. The single combination of two carbon atoms yields the same quantity of heat as the combination of one hydrogen atom with the atom of carbon. The double combination of two carbon atoms effects the same liberation of heat as the simple combination. The threefold combination of two carbon atoms occasions no liberation of heat. The liberation of heat on the formation of a hydrocarbon from amorphous carbon and gaseous hydrogen, the volume remaining constant, may be calculated according to the formula—

$$(C_nH_{2m}) = -n\,d + (2m + x + y)r,$$

x and y denoting the number of the single and double valences. The constant difference between the combustion-heat of two adjacent members of a homologous group of hydrocarbons is 159,840 cals. The great difference between the combustion-heat of the isomeric hydrocarbons benzol and dipropargyl as deduced from the author's theory is confirmed by the experiments of Berthelot and Ogier.

Supposed Isomeric Æthans.—Julius Thomsen.—The æthans obtained from zinc ethyl and by the electrolysis of acetic acid have an equal combustion-heat, 373,250 cals. Ethyl-hydride and dimethyl are probably identical.

Thymo-quinon-chlorimide and its Transformations.—Dr. M. Andresen.—This memoir does not admit of useful abstraction.

Researches from the Laboratory of Prof. A. Saytzeff, at Kasan.—This paper describes β-dipropyl and β-diethyl-ethylen-lactic acids, and the oxidation of allyl-dimethyl-carbinol and diallyl-carbinol with potassium permanganate.

Nos. 5 and 6, 1881.

Determinations of Chemical Affinity (Third treatise).—Dr. W. Ostwald.—The author investigates the circumstance that the monobasic salts in presence of their neutral salts have a greater solvent power than without them. This fact is the more remarkable since, according to present thermo-chemical, volume-chemical, and optico-chemical researches, it was not to be expected.

Contributions to the Chemistry of the Cobalt-ammonia Compounds.—S. M. Jörgensen.—This memoir is devoted to the nitrato-purpureo-cobalt salts, the composition and reactions of which are described in detail.

Researches from the Chemical Laboratory of Prof. Alex. Saytzeff, at Kasan.—These consist of a memoir by A. Semljanitzin on allyl-methyl-propyl-carbinol, and on its derivative, β-methyl-propyl-ethylen-lactic acid; a paper by K. Rjabinin on the methyl- and ethyl-ethers of diallyl-carbinol, and on β-methoxyl-glutaric acid obtained from the former; a memoir on the formation of β-methyl-oxy-glutaric acid from diallyl-methyl-carbinol, by B. Sorokin; a paper on the transformation of the oxy-valerianic acid obtained from allyl-methyl-carbinol into iso-propyl-acetic acid, and on the β-iso-dipropyl-acetic acid, by Al. Schirokoff; and studies on the calcium and barium salts of the diethyl and methyl-propyl-acetic acid.

Behaviour of Argentiferous Bismuth on Re-crystallisation.—Clemens Winkler.—The author admits an error in a former paper.

Myko-protein.—F. Schaffer.—Myko-protein belongs to the true albumens, and is the most sparingly soluble of all the acid albumens in the solutions of neutral salts.

Les Mondes, Revue Hebdomadaire des Sciences.
No. 8, February 24, 1881.

Method of Distinguishing Spurious Honey.—A solution of 20 parts of honey in 60 parts of water mixed with alcohol gives a heavy white precipitate of dextrine if glucose has been added, whilst genuine honey if treated in the same manner merely becomes milky.

No. 9, March 3, 1881.

Source of Selenium.—At Cachenta, in the Province of Mendoza, in the Argentine Republic, there occurs an ore containing 28·8 per cent of selenium along with silver, copper, lead, iron, tellurium, sulphur, silica, and alumina. The proportion of tellurium is higher than that of sulphur.

Ten pages are devoted to an article on the alleged liquefaction of the blood of St. Januarius at Naples,

which it is maintained is a miracle not to be explained by science!

No. 10, March 10, 1881.

True Chemistry.—E. Maumené.—The author sums up his paper in the following words:—"Eight new acids in an operation which was believed to be known because it had already furnished a ninth." Everyone knows that barium hyposulphite and iodine gave Fordos and Gélis the tetra-sulpheate (tetra-thionate) of barium. These chemists thought this the only possible compound produced by the two bodies. The real action is not what Fordos and Gélis thought, and is accompanied or followed by other reactions, according as an excess of iodine or of disulphubate (hyposulphite) is employed. The new acids are said to be S_2O_3, S_6O_8, S_8O_{11}, S_3O_3, S_3O_2, S_6O_9, S_4O_6, and S_3O_4.

Revue Universelle des Mines, de la Metallurgie, &c., Tome 9, No. 1, January and February, 1881.

This number contains no chemical matter.

MISCELLANEOUS.

Royal Polytechnic Institution.—Mr. W. Mattieu Williams, F.R.A.S., F.C.S., author of "The Fuel of the Sun," "Through Norway with a Knapsack," &c., has been appointed to the management of the above Institution, and commences his duties forthwith.

The Stevens Institute of Technology.—At this establishment there has been recently opened a new workshop for the practical study of mechanical engineering. It occupies a building 80 feet by 50 in width, with a high open roof and double galleries. It has been fitted up, at his own cost, by Professor H. Morton, the President of the Institute, and is well filled with the finest specimens of steam-engines, lathes, planers, drills, grinding machines, &c., and is well illuminated with the electric light. The new workshop was formally opened on the 14th of May last, when speeches were delivered by President Morton, Mr. Coleman Sellers, and others. Mr. Sellers spoke of former efforts made for the training of mechanists, when it was thought sufficient to add shop practice to the regular school-course, and referred to a so-called "Russian system" which "seeks to instruct without trying to construct," but which he did not define or explain, though he declared that by its means skilled workmen are trained in a shorter time than by any other method with which he was familiar. President Morton explained that the object of the Stevens Institute was to train, not journeymen mechanics, but mechanical engineers, and gave a sketch of the educational curriculum requisite.

WOLVERHAMPTON.

MINERAL OIL REFINERY.

TO BE SOLD, as a Going Concern, a Works producing first class Lubricating Oils for Spindles and other purposes, Paraffin Scales, &c., which have obtained a high standard in the market, and for which there exists a good selling connection in London, Manchester, and other districts. The Works adjoin the North Staffordshire Railway, with siding accommodation, and are also conveniently situated for water carriage by canal. The plant consists of steam engines, boilers, stills, agitators, modern filter-presses, double freezing machine, hydraulic press, complete laboratory, &c., and is capable of working about fifty tons of raw material per week. Satisfactory reasons given for disposing of business.—For cards to views or further particulars apply to Mr. J. R. Wain, Tunstall, Staff.

IRISH HILL BAUXITE (Alum Clay).

THE IRISH HILL MINING CO. are now, and always have been, the LARGEST PRODUCERS OF THIS CLAY, of Superior Quality, and supply the Manufacturers of Alum, Sulphate of Alumina, and Alum-Cake, of the United Kingdom, America, and the Continent, almost exclusively.

ANALYSIS BY JOHN PATTINSON, ESQ.

Carr's Patent Paint and Drug Mill.

Approved by some of the most eminent Chemists, and awarded the Silver Prize Medals of the Manchester and Liverpool, and the Middleton Agricultural Shows.

From Messrs. E. H. SMYTH & Co., 21 Duke Street, Edinburgh, and 69, Coleman Street, City, London.—The small Levigator Mill we recently got from you works most efficiently, and is a great economiser of time.

The chief feature in this machine is, that although it can be turned with ease by a boy, it has immense frictional power for levigating purposes. This is caused by the runner being driven at a much greater speed, but in the same direction, than the bowl. The surfaces being Minton ware, they are clean, smooth, and durable.

Testimonials on application.

£11 nett cash, delivered in Manchester.

The diameter of the bowl is 18 ins., and it and the runners are made of Minton ware. It is useful for Painters, Chemists, Grocers, and Cooks, for triturating and mixing Medicines, Vegetable Powders, Ointments, Paints, Sugar, Salt, Spices, Herbs, Meat for Potting, and will grind the COARSEST EMERY INTO A NEARLY IMPALPABLE POWDER in a few seconds. The pan can be tilted for emptying, as shown in the dotted lines; it can be worked by hand or power.

COLLIERY EXPLOSIONS.*

By F. A. ABEL, C.B., F.R.S., President of the Institute of Chemistry, Chemist to the War Department, &c.

(Continued from p. 18.)

II.

The influence which may be exerted by deposits of coal-dust in mines upon the magnitude of fire-damp explosions, to which attention appears first to have been directed by the observations of Faraday and Lyell in 1845, was made the subject of some experiments in France in 1867 by M. Verpilleux, who came to the conclusion that coal-dust plays an important part in coal mine explosions. The subject was further and more fully examined into in France by the aid of experiments on a small scale by M. Vital in 1875, in connection with an enquiry into the nature and cause of an explosion which occurred the preceding year in the Campagnac Colliery, and in a part of that colliery where no fire-damp had ever been detected On this occasion an examination for gas had been made by the overman with the Mueseler lamp just before firing a shot. After the first shot a scond hole was charged: the fuze having been ignited, the men then retreated, when, after a few seconds, a violent explosion occurred, and the men saw a *large body of red flame* advancing upon them. After examining the nature of dust collected in the mine, and instituting some special experiments upon a very small scale for the purpose of ascertaining whether, and to what extent, the flame from a small charge of powder was lengthened, when projected, like the flame from a blown out shot, into air containing fine coal-dust in suspension, M. Vital concluded that very fine coal-dust, very rich in volatile (inflammable) constituents, will take fire when raised by an explosion, and that portions of the coal are successively decomposed, yielded explosive mixtures with the air, whereby the fire is carried along; the intensity or violence of the burning being much influenced by the physical characters (fineness, &c.) of the dust. He also pointed out that an explosion of fire-damp, while taking place almost instantaneously, inflames or decomposes a small quantity of coal-dust raised by its explosion, and that explosive action is thus propagated when the fire-damp explosion ceases. Soon after M. Vital's investigation of the subject Mr. W. Galloway commenced a series of valuable experiments upon a larger scale, with the view of investigating the influence of coal-dust in colliery explosions, and the results were communicated by him to the Royal Society in two papers, in 1876 and 1879. The conclusions to which Mr. Galloway was led by the experiments described in his first paper were to the effect that a mixture of air and a particular coal-dust which had been made the subject of chemical examination and practical experiment, was not inflammable at the ordinary pressure and temperature, but that the presence of a very small proportion of fire-damp in the air, the existence of which could not be detected with the Davy lamp by the most experienced observer, rendered this dust inflammable, and caused it to burn freely with a red smoky flame. From this it was inferred that an explosion, when originated in any way whatever in a dry and dusty mine, may extend itself to remote parts of the workings, where the presence of fire-damp was quite unsuspected.

In his second paper Mr. Galloway demonstrated that the return air of a mine in which a considerable quantity of fire-damp is emitted by the coal, as in the Llwynypia Colliery (where the air-return was estimated to contain approximately 2 to 2½ per cent), may be rendered inflammable by the addition of coal-dust. He also described experiments by which it appeared to be demonstrated that the flame developed by an explosion of fire-damp in a particular part of a mine might be propagated, at any rate to some extent, by coal-dust raised and suspended by the explosion in the air travelling through a mine, even in the complete absence of fire-damp in this air.

The apparatus devised by Mr. Galloway for the latter experiments was very ingenious, but it appears open to question whether small quantities of fire-damp did not find their way, before the explosion, from that part of the apparatus where the gas-mixture was prepared and fired, into the channel where coal-dust was raised and into which the flame of the explosion was projected.

Extensive experiments have been carried on, and are still in progress, at Harton Colliery, under the direction of Mr. Lindsay Wood and Professor Frere Marreco, and also at the Broad Oaks Iron Works by a committee of the Chesterfield and Derbyshire Institute of Engineers, upon the behaviour of air containing coal-dust in suspension, and moving at different velocities, when exposed to the effect of a lamp or gas-flame, or of the flash produced by firing a small charge of gunpowder from a pistol or cannon in the dust-laden atmosphere. The apparatus used in these experiments and in some of those of Mr. Galloway are alike in general construction, differing, however, in regard to dimensions and some other details. They consist of long wooden boxes, channels, or galleries, fitted with windows to serve as observing stations; with relief doors, flaps, or other suitable arrangements for minimising damage to the apparatus from explosions; with appliances for maintaining air currents at different velocities, and supplies of air and of coal-gas or fire-damp in fixed proportions; with arrangements (in some instances) for raising the temperature of the air which passes through the box or channel, and means of admitting supplies of coal dust into the apparatus in such a way that they shall be readily carried forward in suspension in the current of air and gas. Attempts have also been made, in connexion with these apparatus, to obtain some comparative records of the force exerted by different explosions. The height and width of the channels or galleries used by the different experimentors have varied from 12" × 6" to 18" × 15". Their length has differed greatly: Mr. Galloway employed channels about 19 feet and 80 feet long; in the Harton experiments the length of the gallery was 42 feet from the dust hopper, and it had a parallel return gallery 39 feet long; in the Chesterfield apparatus the length of the gallery from the hopper was nearly 62 feet.

It does not appear that in the numerous experiments made at the Harton Colliery by exposure of naked flames in currents of air laden with coal-dust, and by firing small cannon (representing blown-out shots), placed in various positions in such air currents, any decisive indication has been obtained of a propagation of flame by the coal-dust. On the other hand, I believe that the Chesterfield Committee consider they have obtained unquestionable evidence that flame will travel in a mixture of coal-dust and air in the absence of any trace of fire-damp.

At the Garswood Hall Colliery of Messrs. Smethurst, Hoyle, and Grime, at Brynn, near Wigan, a copious and continuous supply of pit-gas is brought to the surface, and has been utilised by Mr. William Smethurst in many valuable experiments on the behaviour of different safety lamps in explosive gas mixtures, with the employment of apparatus similar in general construction to those just described.

The Royal Commission on Accidents in Mines have availed themselves of this supply of gas, and of special conveniences and personal aid kindly placed at their disposal by Mr. Smethurst, to institute extensive experiments on the comparative merits of different safety-lamps. For

* Report on the Results of Experiments made, with Samples of Dust collected at Seaham Colliery, in compliance with the request of the Secretary of State for the Home Department, conveyed by letter dated November 4th, 1880.

this purpose they had an apparatus constructed of the kind above referred to. The particular purpose for which it was needed rendered it only necessary to provide a comparatively short channel or gallery, and the general fittings were of a simple nature, but great pains were taken to secure accuracy and uniformity in the velocity of the air-currents employed, in the proportions of gas used with the air, and in the intimacy of their mixture. The Commission satisfied themselves that, in these important respects, the apparatus used by them left little to be desired.

Into this apparatus various modifications have been introduced for the purpose of rendering it suitable for the experiments which I desired to carry out with the samples of Seaham dust, and for the more extended experiments with coal-dust upon which the Commission are now engaged.

The gallery or channel (one foot length of which has a capacity of about one cubic foot) has been increased in length so that the distance between the hopper, or drum-sieve, used for delivering the dust, and the vertical shaft at the end, into which the steam-jet passes, whereby the current is established and maintained at the desired velocity, is 28 feet. In order to raise the air-current in the gallery to a temperature similar to that of the atmosphere in colliery workings, the air supply is drawn through the tubes of a large tubular boiler, which are heated by steam so as to obtain the current, passing at velocities which have ranged from 100 to 1000 feet per minute, at temperatures of 75° to 85° Fahrenheit, even in the severe winter weather during which a portion of these experiments have had to be carried on.

The following sources of heat and flame were employed in the experiments made in this apparatus with the dust samples from Seaham Colliery :—

1. An uncovered Davy or Mueseler lamp, with a long wick, so as to furnish a large flame, which, when exposed to the more rapid currents, was protected from extinction by a low screen of sheet metal.
2. A wide gas jet, supplied with pit-gas and furnishing a broad flame, from 3 to 5 inches long. This was also protected by a shield reaching just above the gas-jet.
3. A small cannon, fitted with an electric fuze in the breech, and loaded with charges of 80 grains of fine grain powder. A simple plan of confining the charge or closing the muzzle of the cannon was employed, by which uniformity in the force of explosion of the powder-charges was secured. In some instances the muzzle of the cannon was opposed to the current, in others its position was reversed. In some experiments these little cannon were employed singly, in others, two cannon were placed in the gallery at some distance from each other, their muzzles facing, and were fired one after the other, either in quick or in slow succession.
4. A charge of 400 grains of powder, unconfined, and placed on the floor of the gallery, the charge consisting of 390 grains of compressed mining powder and 10 grains of sporting powder for the purpose of inflaming the former rapidly. The charge was ignited electrically.
5. A charge of 200 grains of compressed powder, including a small quantity of sporting powder, arranged as No. 4.
6. A charge of 400 grains of sporting powder, arranged as No. 4.
7. A charge of 300 grains of loose gun-cotton, placed upon the floor of the gallery and fired electrically. This particular explosive agent was employed because its ignition suddenly developed a large volume of flame similar in character to that produced by the ignition of an explosive mixture of fire-damp and air.

The pit-gas which issues from the Wigan 9-foot mine, and with which the experiments at Garswood Hall Colliery were made, is what is commonly called a sharp gas, and of the kind known as *silver gas*. Its presence in air, when in sufficient abundance, is indicated by a lengthening of the flame of a safety lamp, but lower proportions, such as would be indicated by the production of small blue caps upon the flame of a Davy lamp with some descriptions of fire-damp, afford no such signs of their existence with this gas. The effects upon the lamp-flame of as much as 2·5 per cent of the gas, in air, can only be detected by the most experienced observers.

In experiments made in currents which ranged in velocity from 200 to 1000 feet per minute, mixtures containing 3·5 per cent of this gas were ignited (producing feeble explosions) by a naked Davy lamp flame, sometimes almost immediately upon reaching that part of the gallery where the flame was placed, at others after the gas-mixture had been passing the flame from 5 to 10 seconds, the general ignition of the mixture being preceded by flares which travelled forward from the lamp-flame. In two or three experiments a gas-mixture containing only 3 per cent of firedamp inflamed throughout after the current had been passing some time, but in these instances there appears little doubt that other conditions, to be presently mentioned, determined the inflammation of the mixture. With a current travelling only at a velocity of 100 feet per minute, no effect beyond some elongation of the lamp-flame was produced by a mixture containing 3 per cent of gas; when increased to 3·25 per cent a very faint flickering flame was observed, which was lengthened when the gas was further increased to 3·50 per cent. With 3·75 per cent the lamp-flame became occasionally prolonged into a lambent flame, which increased in size when the gas was increased to 4 per cent, and with a further increase to 4·25 (in one experiment, and 4·5 in another), the flame increased in size rapidly, filling the gallery in front of the lamp-flame, and finally a general ignition of the gas mixture in the whole gallery occurred.

In an apparatus arranged (at Woolwich) for the exposure of mixtures of coal-gas and air, with or without dust, but *perfectly still*, to the effect of flashes of flame (produced by igniting small quantities of gun-cotton electrically), no result was obtained with mixtures of 3 and 4 per cent of gas, and a feeble explosion was obtained with a mixture containing 4·25 per cent. It appears, therefore, that in currents of considerable or moderate velocity, a mixture containing 3·5 per cent of the particular pit gas employed becomes ignited by the flame of a safety lamp, the flame travelling against the current with feeble explosive effect, while, at a low velocity, or in a still atmosphere, from 4 to 4·5 per cent of coal-gas, or of this pit-gas, are required to produce a similar result.

A series of experiments, as nearly as possible comparative in all respects, was made with the 10 samples of dry Seaham dust, conveyed in suspension in currents having in each experiment a velocity of 600 feet per minute, and a temperature of about 80° Fahrenheit. A naked Davy lamp, the flame protected by a screen, was placed in the gallery at a distance of 12 feet from the point where the current met the supply of dust. The latter was always maintained as far as possible at the maximum which could be delivered by the feeding arrangement used. In two or three instances the quantity of dust was comparatively small, and could, therefore, not be maintained for as long a period as in other experiments, but the general results obtained were sufficiently marked to admit of a classification of the dusts as regards the readiness with which they promoted the ignition of such a gas mixture as the naked lamp flame did not exhibit any tendency to ignite before the dust was allowed to mingle with it; or, in other words, as regards the proportion of fire-damp required to impart explosive properties to the mixture of air and dust. What may be termed the *order of sensitiveness* of the dust samples, in reference to the latter point, is represented in the accompanying tabular statement, in which the samples of dust are indicated by their distinctive letters; in the same table are shown the order of richness in coal, and of

fineness of the dust samples as well as their relative position in regard to the extent to which they had been affected by exposure to heat, so far as could be ascertained by the microscopic examination of small specimens.

O.—Old incline floor.
T.—No. 1, travelling road.

The most sensitive dusts, which were also the richest in coal and the finest, produced explosives mixtures with air containing only 2·5 per cent of fire-damp. The next to these in order of sensitiveness, and not greatly different from them, also followed next in order, both as regards richness in coal and fineness, but the one next following, and differing but little in sensitiveness from the preceding one, was the dust which chemical examination showed to be poorest in coal (containing nearly half its weight of non-combustible constituents). This dust, though not so uniformly fine as the preceding samples, was very uniformly suspended throughout the air current which conveyed it; 2·75 of fire-damp sufficed to produce with it a mixture which was exploded by the lamp-flame. Of the other six samples, four ranked closely together, being less sensitive than those already referred to. It will be seen that these differed from each other in regard to richness in coal and the proportions of very fine dust which they contain. Lastly, there were two samples decidedly less sensitive than these; they did not present any very marked difference from or other of the preceding four samples in point of richness in coal, but they could not be so plentifully and uniformly suspended in the air current as the others. These six samples all formed more or less readily explosive mixtures when suspended in air containing 3 per cent of fire-damp.

It will be seen from the tabulated comparative statement that the circumstance of some of the samples having been more or less affected by heat, while others were unaffected, does not appear to have borne any definite relation to the comparative sensitiveness of the different samples. An examination of the specific gravities of the several samples of dust showed that those which were the most sensitive had the lowest specific gravities, containing as they did the lowest proportions of heavier metals foreign to coal (the specific gravity of X was = 1·41, of K = 1·50, and of S = 1·47. But with respect to the other samples, their specific gravities did not show any definite relation to their sensitiveness. Thus, of the two least sensitive dusts, O had a specific gravity of 1·53, while that of T was 1·72, and the sample N, which contained so large a proportion of non-combustible matters, and was third in order of sensitiveness, had the highest specific gravity of all the samples (1·89).

On submitting dusts from other collieries to the same comparative experiments as were applied to the Seaham dust, it was found in the first place that the most sensitive of the latter were somewhat less so than two samples from the Madeley and Leycett Collieries (Fair Lady Pit). A copious flow of one of these in air containing only 2 per cent of gas, and travelling at a velocity of 600 feet per minute, caught fire almost immediately it reached the lamp-flame, and a general ignition of the mixture in the gallery followed very rapidly upon the first flare produced in front of the lamp. Another sample furnished a similar result when the fire-damp amounted to 2·25 per cent. Samples of dust from Blantyre and Newport, Abercarn Collieries, were found to be as sensitive as the most sensitive Seaham samples, while some samples from Penycraig Colliery corresponded in this respect to the second in order of the Seaham samples, but produced sharper explosions than any of those samples, when mixtures of the dust with air containing 2·75 and 3 per cent of fire-damp were inflamed.

Although great pains were taken to render the discharge or flow of the several samples of dust into the gas- and air-mixture uniform in different experiments, some variations unavoidably occurred in the rapidity with which the dust was delivered, and such variations no doubt affected in some instances the rapidity with which the dust- and gas-mixture was inflamed; but repetitions of experiments with one and the same sample of dust showed that the results were generally reliable, and this was confirmed by the close correspondence of those obtained with dust-samples of similar character.

The Leycett samples corresponded closely in chemical character and specific gravity to the Seaham dust collected from the screens; their somewhat greater sensitiveness was, therefore, possibly ascribable to their travelling better and more uniformly in the air-current, and, perhaps, also to physical peculiarities. Indeed, while the richness of a dust in coal, or its greater inflammability, influenced the rapidity and consequent violence of the explosion of dust- and gas-mixtures containing corresponding quantities of fire-damp, the physical characters and mechanical condition (lightness, porosity, and state of division) evidently contribute more than the richness in coal or combustibility of the dust-sample, to determine the comparative readiness with which it brings about the inflammation of a gas-mixture not susceptible of ignition *per se* under otherwise similar conditions, and to regulate the proportion of gas required to produce, with it, a mixture which will ignite and *convey* flame, when coming into contact with flame. This is strikingly illustrated by the fact that the sample of Seaham dust containing the smallest proportion of coal, and consisting, indeed, of nearly half its weight of non-combustible matter, ranked next in sensitiveness to the samples which consisted almost entirely, or chiefly, of coal.

The results obtained with this particular dust led me to try whether the ignition by a lamp-flame of a mixture of fire-damp and air, not inflammable *per se*, would be brought about by suspending it in a fine readily-floating dust which was *quite non-combustible*, and not susceptible of any chemical change by exposure to a high temperature. The powder answering to these conditions which was most readily procurable when this experiment suggested itself was calcined magnesia. A gas-mixture having 3 per cent of fire-damp was allowed to pass a lamp-flame, at a velocity of 600 feet per minute for some time; no result was produced, but on causing it to convey calcined magnesia in suspension long flares of flame were produced within a few seconds of the mixture first passing the lamp, and the inflammation speedily spread throughout the gallery with feeble explosive effect. With only 2·75 per cent of gas, results quite similar were produced, the *general* ignition following, however, less rapidly after the first production of the flares in front of the lamp-flame. With another sample of calcined magnesia, which was not quite so light as the first one, a corresponding result was obtained with a mixture containing 3 per cent of fire-damp.

In a still atmosphere, containing 2·5 per cent of coal gas, one of the most sensitive of the Seaham dusts (K), when suspended in it, produced ignition of the mixture, with no explosive effect. A corresponding result was produced by suspending calcined magnesia in a still atmosphere containing 3 per cent of gas.

It will be seen from these results that the perfectly non-combustible powder, magnesia, is, in its power to bring about the ignition of an otherwise uninflammable mixture of fire-damp or coal gas and air, little inferior to the most inflammable and sensitive of the Seaham dust-samples.

These remarkable results led to the trial of a number of other non-combustible powders or dusts, which are not chemically affected by such heat as they would be exposed to in the flame of a lamp (such as kaolin, powdered flint and other forms of silica, pumice, slate dust, &c.) with results similar to those furnished by the magnesia-dust, but more or less affected by variations in the density and other physical properties of the dusts. In experiments with currents of 1000 feet velocity, the effect of any one of the powders being deposited on the bottom and sides of the gallery, was to cause the *instantaneous* ignition of a 3·5 per cent gas mixture on its reaching the lamp-flame, through the influence of dust particles carried along by the current, and in some instances a like result was obtained with 3·25 and 3 per cent gas-mixtures. From these results it appears that the ignition, after longer or shorter intervals, of currents of gas-mixtures of this kind, when passing a small lamp-flame (as noticed in an earlier part of this Report), is most probably ascribable to the influence of a few dust-particles which become accidentally suspended in the current and are carried into the flame. The instantaneous raising of such small dust-particles to incandescence by the flame must have the effect of localising and consequently intensifying the heat at those points, and the ignition of the gas, greatly diluted with air, may thus be brought about. That such an effect must be magnified when a *cloud* of very fine dust suspended in the gas-mixture passes through the flame, is obvious, and is demonstrated by the fringe of incandescent particles which surround the lamp-flame under these conditions, and thus the action of the dust in promoting the ignition of mixtures of very small quantities of fire-damp with air may perhaps be sufficiently accounted for. From certain phenomena observed in the experiments with non-combustible powders, it appears not improbable, however, that another quite distinct mode of action of the finely-divided and heated solid may operate very importantly, and at any rate contribute, in determining the ignition of gas-mixtures which are not susceptible of inflammation by the application of flame alone.

This subject will receive at the hands of the Royal Commission on Accidents in Mines the further investigation which it demands, but the experiments which have been instituted by me in fire-damp mixtures with the Seaham dusts, and with other dusts (consequent upon the results which the former have furnished), have fully confirmed the facts, already, in part, well established by the experiments of M. Vital and Mr. Galloway, that coal-dust in mines importantly promotes, extends, and aggravates explosions due to fire-damp, by reason of the rapid inflammability of the finely-divided combustible, and of the readiness with which it becomes and remains suspended in air-currents; and that it may also be itself readily brought into operation as a fiercely and rapidly burning, or even as an exploding, agent in mines, through the medium of fire-damp when existing even in a proportion which, in the case of the fire-damp *per se*, would not be attended by danger. The experiments have further demonstrated that *dust* in coal mines, quite apart from any inflammability which it may possess through consisting partly or chiefly of coal (and by which it operates more or less seriously in increasing the magnitude of explosions and the heat and fire developed by them), can operate distinctly, as a finely-divided solid, in determining the ignition of mixtures of only small proportions of fire damp and air, and consequently in developing explosive effects, which, though mild in the first instance, may be increased in magnitude by the coal-dust which the first ignition of the gas-mixture raises and brings into action.

In the experiments with coal-dust, the results of which are given in this Report, it has been shown that as small a proportion as about 2 per cent of fire-damp in air, in currents travelling at a moderate velocity (600 feet per minute) may be brought to ignition by coal-dust, or, what amounts to the same thing in regard to the result, *that small proportions of fire-damp may be instrumental in determining the ignition of, and the propagation of flame by, coal-dust.*

In some experiments made in currents of very low velocity (100 feet per minute) with the most sensitive of the coal-dusts used in these experiments (from Leycett Colliery) it was found that when a mixture containing only 1·25 per cent of gas, charged with the dust, reached the naked lamp-flame the latter became surrounded by a large fringe of flame, filled with incandescent dust particles. When the proportion of gas was increased to 1·5 per cent a long flare was at once produced which soon increased to a large flame, and after a short interval the mixture of dust and air with this small quantity of fire-damp burned from end to end of the gallery.

In his earlier paper communicated to the Royal Society, Mr. Galloway describes a series of careful observations on the effect of various mixtures of fire-damp of a particular kind upon the flame of a safety lamp (which notwithstanding the persevering efforts of many intelligent workers who have endeavoured to establish a practicable and accurate method of determining *underground* the proportion of fire-damp in air, still remains the only expedient by which fire-damp is searched for, and its amount roughly estimated). Those observations demonstrate that it is, to say the least, extremely difficult to detect so small a proportion as 2 per cent of fire-damp in the atmosphere of a mine, and this conclusion has been quite recently confirmed by Mr. Galloway in his evidence at the inquest upon the Penycraig disaster, in which he stated that "it is impossible for any but the most practised eye to detect so small a proportion of fire-damp (as 2 per cent) in the air, and then it is only with the aid of a glass lamp well cleaned, and with a good wick and good oil. The great majority of mining men and all ordinary workmen would pronounce the return air of such a colliery to be *quite free from gas.*"

The correctness of these statements of Mr. Galloway has been confirmed by others having great experience in coal mines, of whom I have made inquiry on this subject.

It appears, therefore, that the proportion of fire-damp which is required to establish the ignition of what may be termed sensitive coal-dust, by means of a naked Davy-lamp flame, and *to promote the propagation of flame* by it, is below that which can, with the means at present employed, be detected in the atmosphere of a mine by most experienced and careful observers. Even with less sensitive dusts (such as those from Seaham) the proportion of gas needed for the *initiation* of such a result is so small that its detection might be doubtful, especially with particular descriptions of fire-damp which do not produce "caps" in the safety lamp.

It may be objected that in such special experiments as those which have been conducted with coal-dust by Mr. Galloway, by the Chesterfield Committee, by the Harton Experimentors, and by myself, the amount of coal-dust which was suspended in air was considerably in excess of that which would exist even in very dusty coal-mine ways, at any time when the explosion may be originated by the combined action of fire-damp and small quantities of dust. But many observations made in the course of these experiments have indicated that even minute quantities of dust may, under favourable conditions, serve as the inciting cause of the ignition of fire-damp mixtures of such a nature that, in the absence of that cause, they would escape ignition. Moreover, the inflaming agency in the experiments which have been described was simply the

naked flame of a safety lamp, whereas the disasters which have been attributed to so-called coal-dust explosions, and which may have been due to the combined action of dust and of fire-damp existing in very small proportions, have, at any rate in several instances, been clearly connected with the firing of shots. It has been demonstrated by the small-scale experiments described in this Report that the sensitiveness to ignition of a mixture of a *small* proportion of fire-damp with air, even in the supposed absence of dust, is very considerably increased if the source of heat or flame to which the mixture is exposed be increased. It has also been demonstrated that the existence of a proportion of fire-damp very much below the smallest specified in the experiments described, in air in which coal-dust is suspended, will suffice to bring about the slow *propagation* of flame by the coal-dust, if the flame from a small cannon charged with *only* 80 *grains* of powder, and representing a blown-out shot upon a very small scale, be projected into it in the gallery used in these experiments. This being the case, there is no doubt that the large body of flame produced in a working by a blown-out shot, or even by a somewhat too heavily charged shot, could produce a similar result in localities where dust is readily and abundantly raised by the firing of a shot, and where very small quantities of fire-damp exist in the air.

ON WILKINSON'S PROCESS FOR THE MANUFACTURE OF ILLUMINATING GAS FROM WOOD.*

By CHARLES A. DOREMUS, M.D., Ph.D.

Though many substances have from time to time been suggested as proper materials from which to procure illuminating gas when subjected to destructive distillation, none seemed to equal coal, either in the quality of gas yielded or in the economy of manufacture. Fats, factory refuse, oil, petroleum have all even now a more or less extended use, and wood is frequently resorted to.

Practical difficulties, however, have always stood in the way of its more general employment. The moisture even in the harder varieties of wood causes a lowering of the temperature of the retorts to such a degree as to largely increase the yield of tar, pyroligneous acid, and gas liquor generally. Besides this, the water, by diminishing the heat, renders the amount of gas produced very small, while the oxygen it contains goes to augment the carbonic acid, the quantity of which may even exceed 25 per cent of the gas. This large amount of carbonic acid necessarily diminishes the illuminating properties of the gas, or as it is commonly expressed, "kills the light." Its removal is therefore requisite, and the cost of purification increased. Except, therefore, in few cases, wood as a source for gas has been practically abandoned.

For several years past it has been customary in some gas works to push the heat in the coal gas retorts, and obtain thereby 3000 or 4000 feet more gas to the ton of coal, but of a very low candle-power, however. This poor gas was then, after purification in the usual way, carburetted either by naphtha vapour or "fixed" naphtha vapour, or by cannel gas. A very excellent quality of gas was thus made, and at a low rate.

The first instance of the use of such a process in this country, we believe, was with the company working under Tessié du Motay's patents, in Buffalo. It was proposed by this company to manufacture water-gas, and enrich it by means of carburetters placed in each house. The danger of the oil (gasoline) was recognised by the insurance companies, and the "*binary*" process of making gas was then inaugurated by Dr. Wilkinson, at that time (1872) chemist for the company. With some alterations this process is in use in all works where gas is enriched.

But coal-gas manufacture was destined to a more radical change than this, in the adoption of the many processes for the production of water-gas subsequently enriched by naphtha. The cost of gas is hereby so greatly reduced that it seemed as if no better method could be suggested. Supplying a gas brilliantly white when burnt, of high gravity, affording great benefit, therefore, to consumers, the projectors of the new enterprises have already reaped, at least in New York, a goodly harvest.

But older companies could not abide such an invasion of their territories without remonstrance, and though, naturally, the competition at first caused fierce disputes, it ended as usual in a coalition.

It was during the heat of battle that the method we are to describe was invented. From an intimate acquaintance with all the methods in use, and especially those of coal- and water-gas, and the advantages and disadvantages of the several processes, Dr. A. W. Wilkinson, chemist of the Mutual Gas Light Company, devised the following plan, which was first tried experimentally at the works, then operated with several benches, and finally adoped on a large scale.

The ordinary clay retort of the gas works, but slightly modified, answers, though in subsequent experiments a somewhat different shaped retort was used, the retort being provided with a fall or "boot."

The essential feature of the process consists in reducing the carbonic acid to carbonic oxide, and at the same time of getting rid of all tar, acids, and waste products. This is accomplished by forcing the gas through a bed of red-hot charcoal. After the first charge of wood has been carbonised, the charcoal, instead of being drawn as with coke, is shoved back in the retort. The gas made from the second charge is therefore obliged to pass through this layer of red-hot coal to reach the stand pipe at the rear of the "through" retort. The heat is pushed to get as large a yield of gas as possible, and the reduction of the carbonic acid correspondingly facilitated.

The water in the wood is also an active agent, since in this superheated state it forms water-gas with the aid of the charcoal. The gas needs but slight purification. Nitrogen in the form of ammonia is virtually absent; little sulphur exists in any form, neither sulphuretted hydrogen nor carbon bisulphide being found, except in traces, while of tar there is not a trace.

To prevent too great an accumulation of charcoal, the retorts are drawn twice a day.

53,832 cubic feet of gas are produced from a cord of wood costing 5·25 dols. per cord of 3300 lbs., as computed from the average of six months.

The quantity of gas alone is thus four times as great as that which can be obtained from coal, costing an equal sum per ton as does wood per cord.

The crude gas has the following composition, as analysed at the works by myself:—

Hydrogen	44·10
Marsh gas	5·40
Carbonic oxide	33·75
Illuminants	none
Carbonic acid	10·50
Nitrogen	6·00
Oxygen	0·25
Ammonia	none
Sulphuretted hydrogen	none
	100·00

It is still customary with the Mutual Company to manufacture a poor quality of coal-gas, which is, along with the wood-gas, afterwards carburetted, and in which form it is termed "commercial" gas, and has a high candle-power. An analysis of the coal-gas, taken from the company's records from an analysis made at the works, shows it to be composed of—

* From the *Journal of the American Chemical Society*, vol. ii. An abstract of this Paper appeared in the Chemical News, vol. xliii., p. 57.

Hydrogen	30·50
Marsh gas	41·00
Carbonic oxide	6·00
Illuminants	2·00
Carbonic acid	3·00
Nitrogen	16·00
Oxygen	1·50
Ammonia	trace
Sulphuretted hydrogen	trace
	100·00

The yield of coal-gas is 14,645 cubic feet per ton of coal, costing 5·00 dols. From this sum we must deduct the price received for coke, tar, and gas liquor.

Prior to admixture with naphtha vapour, the coal- and wood-gases are purified and passed to the storage holder. From this the gas enters an illuminator, so constructed that the naphtha running in is converted into vapour by steam heat, and thoroughly mixed with the gas. From the illuminator, the mixture of gas and vapour passes into superheated retorts to be "fixed." 4·5 gallons of naphtha are used for every thousand feet of "commercial" gas.

As the naphtha is of good quality, no purification of the resulting gas is needed other than passing it through a coke box to remove any liquid naphtha.*

100 volumes of the "commercial" gas of the Mutual Company consists, at present, of 21 volumes of wood-gas, 37·4 volumes of coal-gas, and 41·6 volumes of naphtha gas.

An analysis of the "commercial" gas showed it to contain:—

Hydrogen + Marsh gas	56·75
Carbonic oxide	11·25
Illuminants	15·25
Carbonic acid	1·00
Nitrogen	15·00
Oxygen	0·75
Ammonia	none
Sulphuretted hydrogen	none
	100·00

This analysis shows, also, how closely the composition can be determined by separate analyses of its components, and how, by the speedy method of gas analysis introduced by Dr. Wilkinson, in use not only in the Mutual but other gas works, a complete control of each and every step in the process of manufacture is obtained. As the method has been fully described in the *London Gas Light Journal* for August, 1877, but this brief allusion to it seems required. An addition was made in 1879 to the process, whereby nitrogen could be determ ined and an account published in the *American Gas Light Journal* of that year. The rapidity with which an analysis can be made, and the simplicity of the various steps, give it a decided advantage over other methods.

No new process of manufacture stops with the application of any single scientific discovery; the adoption of wood, therefore, instead of coal, required several changes in the manag ement of the retorts.

The want of coke for firing was the first requirement that made itself felt. Coke might, of course, be purchased from gas works, manufacturing by the older methods, but wood-gas could only thus be manufactured in one or two of the larger cities.

The furnaces were at the Mutual Works, therefore, supplied for a time from the coal benches; but, finally, grates were constructed, to allow the use of "pea" anthracite. The employment of hard coal was only feasible by an increased draught; but to obviate the use of a blower, yet accomplish this result, the following device was adopted.

At the base of the fire pot, an iron tube is inserted, having a blind end. This serves, on being heated red-hot, by the fire, as a superheater for a jet of steam driven in through a central iron pipe, and passing nearly to the blind end of the exterior tube. The steam thus superheated passes next through a small injection pipe into the fire. A draught of air is drawn into the fire by this injector, and the combustion greatly accelerated. The steam also decomposes in presence of the coal, water-gas is formed in abundance, and an intense heat, under absolute control, is attained.

The heat is greatly increased, too, by another ingenious device. Over the benches stretches a long wrought-iron tube, some 2 feet in diameter, and open at each end. The hot gases from the furnaces impinge upon this, heating the contained air. By means of suitable pipes this heated air is drawn down by the steam injectors, and forced into the fires. A hot blast is thus procured. The saving of a dollar per diem for each fire results from the combined use of anthracite and hot blast, over the old system of coke fires.

As regards the relative cost of "poor" coal- or wood-gas, it can be stated at 20 cents per thousand for coal to 9·9 cents per thousand for wood. Not only the four times greater amount of gas yielded enters in this calculation, but the large decrease in expense thereby caused in the less number of hands employed, and also the less cost of purification of wood-gas made by this method. In the calculation of cost of coal-gas the drawbacks in ammonia, tar, &c., have been considered. With wood there are none of these. But the Mutual Gas Light Company contends that it is a gas manufacturer, and therefore does not base its business on side issues.

After this brief outline of the special features of the mode of manufacture, we desire next to call attention to some rather remarkable facts developed in the chemical analysis of the "commercial" product. We have already detailed the analyses of the several constituents of the "commercial" gas, and shown how closely the analysis of the merchantable article agrees with what would be the theoretical result of mixing them in the proportions actually carried out on an enormous scale at the Mutual Works.

In a paper read before the American Association in Boston, August, 1880, Dr. E. G. Love, City Gas Examiner, reports the composition of the various gases sold in New York city.

Besides these, four other analyses of the Mutual gas are given; three made by Dr. Love, and one by Mr. H. C. Bowen, intended to show that there is no material difference in the quality of the gas made by the use of wood from that of coal. These were reported in the *American Gas Light Journal* of October 2, 1880. We insert both tables:—

TABLE I.

Constituents.	Manhattan Co.	Harlem Co.	Metropolitan Co.	N.Y.Mut'l Co.	N.Y. Co.	Municipal Co.
Hydrogen	45·79	46·53	35·41	10·57	27·14	26·25
Marsh gas	39·01	42·38	42·66	41·75	25·35	28·91
Carbonic oxide—	6·31	3·14	9·17	9·53	26·84	27·12
Illuminants	6·38	6·31	7·41	15·41	14·63	15·80
Nitrogen	2·51	0·50	5·35	20·69	2·87	1·92
Carbonic acid	—	1·08	—	1·51	3·02	—
Oxygen	—	0·06	—	0·54	0·15	—
Sulphuretted hydrogen—	—	trace	—	trace	—	—
	100·00	100·00	100·00	100·00	100·00	100·00

Table No. I. differs quite widely in its statements, as published in the *Gas Light Journal*, from the way it was reported in the daily press at the time of the Boston meeting, four of the six analyses being much modified—two, however, being retained in exactly their original shape.

Thus with the Mutual gas the hydrogen, from being 28·87 per cent, falls to 10·57 per cent; marsh gas rises

* Traces of SiH_4 are sometimes observable.

Table II.

	100·00	100·00	100·00	100·00

from 22·95 to 41·75; carbonic oxide falls from 27·19 to 9·53, and nitrogen rises from 3·24 to 20·69 per cent. We are at a loss to explain these variations, especially as the quantity of illuminants is not modified. The gravity also remains as fluctuating between 0·703 and 0·808. The sulphur is 7·28 grs. per 100 cub. ft., and the ammonia 82 grs. per 100 cub. ft., in both analyses.

These discrepancies are, in comparison with the analyses of the commercial products of other companies, particularly noticeable. Yet Dr. Love has taken pains to show, by Table No. II., that analyses of the Mutual gas, ranging over a long interval, demonstrate its composition to be nearly constant. Thus, in comparison with other gases, the carbonic oxide was first stated to be 27 per cent, an amount in excess of that in any water-gas enriched by naphtha, and a fact which does not accord at all with the process of manufacture of the Mutual gas, since we have shown that at least one-third is of a low grade of coal-gas, which would contain about 6 per cent carbonic oxide, and another third wood-gas, with 30 per cent. Were these two gases mixed and distributed in equal proportion, there could only be 18 per cent carbonic oxide, while as they form but 60 per cent of the "commercial" gas, there would at most be but 10 8 per cent of carbonic oxide. The analyses of Tables I. and II. agree to this state of things.

We are surprised also that a coal-gas, such as that sent out by the Manhattan Company, should only contain 1·19 per cent, as in the first report. In Table I. it stands 6·31 per cent. Though in a foot-note Dr. Love states:—"I find considerable variation in composition, especially in those gases enriched by naphtha," we can hardly imagine them to take such curious fluctuations, since the process of manufacture precludes them.

However accurate such a method of analysis as Bunsen's may be, can it not be replaced with advantage by one which, though less correct, allows by the rapidity of execution, duplicate analyses, and thus gives a knowledge of the average composition of a commercial product? From personal experience, we know how tedious an analysis is, and how liable to error from mistakes, not only in the various steps of the method, but the subsequent calculations regarding temperature, pressure, moisture, &c., when carried out as indicated by Bunsen.

In "Watts's Dictionary of Chemistry," 2, 1036, we find the following:—

"The effect of continuing the distillation too long is that gases of a very feeble illuminating power are evolved together with nitrogen, which, when once mingled with the combustible gas, cannot be removed by any known method, and must seriously impair its illuminating power." We have shown, not only by our own analysis, but by Dr. Love's, that the Mutual "commercial" gas contains about 15 to 20 per cent nitrogen. That this is not present as air is seen from the only trivial quantity of oxygen. The nitrogen must have gained access in great measure from the fires around the retorts, as well as in small quantity from the leakage of air, the oxygen in the latter case being consumed in the retorts.

By an adjustment of the exhaust, the company attempts to keep the proportion of nitrogen in the "commercial" gas at 15 per cent, and there is not much variation from this figure.

No other New York company furnishes street gas with so high a percentage of a neutral gas.

According to Dr. Love's analysis, and his statement of the various candle-powers, as given in Table III., the Mutual ranks as containing ten times as much nitrogen as the Municipal: yet, both having the same amount of illuminants, it is only three candle-power lower. From photometric measurements at the College of the City of New York, the Mutual gas was found, on November 27th, to stand 25·5 candle-power, and had 17 per cent nitrogen.

According to these facts, the old impression that the presence of nitrogen is destructive to the light-giving properties of street gas, must fall, or whatever holds good for coal-gas is not found to follow in coal-gas enriched by naphtha. Never before has gas been furnished in New York of such brilliancy as at present. Each company charges 2·25 dols. per thousand. Let us suppose the Mutual Company delivers 3,000,000 cubic feet per diem; 15 per cent of this, or 450,000 cubic feet, is nitrogen, which, at 2·25 dols. per 1000, gives 1023·50 dols. per diem clear profit. This percentage of nitrogen does not seem to cause any smoking of the flame; the company receives no more complaints on this score than do others. The consumption of naphtha is always about 45 gallons per 1000 cubic feet of "commercial" gas, a quantity below that required in other gas works.

We specially desire, therefore, in connection with the description of the wood-gas process, to point out these peculiarities regarding nitrogen, trusting new experimentation will develop more clearly the reasons for these phenomena.

LONDON WATER SUPPLY.

Report on the Composition and Quality of Daily Samples of the Water Supplied to London, from May 20th to June 30th, 1881.

By WILLIAM CROOKES, F.R.S.,
WILLIAM ODLING, M.B., F.R.S., F.R.C.P.,
Professor of Chemistry at the University of Oxford;
and C. MEYMOTT TIDY, M.B., F.C.S.,
Professor of Chemistry and of Forensic Medicine at the London Hospital; Medical Officer of Health for Islington.

To the Right Honourable the President of the Local Government Board.

July 4th, 1881.

Sir,—Our present report has reference to the quality of the water supplied to the Metropolis, from the 20th of May to the 30th of June inclusive, and relates to the examination during this period of 245 samples which have as usual been collected by a man in our employ, at times and places determined by us. In future, our reports wil

Table III.

Company.	Hydrogen.	Marsh Gas.	Carbonic Oxide.	Total Non-Illuminants.	Illuminants.	Nitrogen.	Carbonic Acid.	Oxygen.	Candle-Power.
Manhattan ..	45·79	39·01	6·31	91·11	6·38	2·51	—	—	19·76
Harlem	46·53	42·38	43·14	92·05	6·31	0·50	1·08	0·06	17·59
Metropolitan ..	35·41	42·66	9·17	87·24	7·41	5·35	—	—	20·33

relate to the analyses of samples obtained from the 1st to the end of each month.

In 10 only of the 245 samples examined were we able to detect by examining the water in large bulk with the naked eye the minutest trace of matter in suspension.

In Table I. we have recorded the analyses in detail of samples, one taken daily between May 20th and June 30th. The purity of the water in respect of organic matter has been determined by the Oxygen and the Combustion processes, and the results of our analyses by these methods are stated in columns XIV. to XVIII.

We have recorded in Table II. the tint of daily samples of the water as determined by the colour-meter we have described in a previous report. Practically the waters differ very little in their appearance (even when examined in large bulk) from distilled water. If complaints of inferior colour and of turbidity arise, it is manifest to us that the contamination and impurities complained of, are to be traced to the condition of the receptacles, rather than to the want of care on the part of the Water Companies in providing a proper supply.

For several months we have been experimenting on a method whereby the slight amount of clayey matter occasionally present in the waters could be determined with a nearer approach to quantitative accuracy than is possible by classifying the samples under the headings "clear," "very slightly turbid," slightly turbid," and "turbid," and we hope to make known our results in this direction in our next month's report.

Of the 35 samples supplied by the New River Company, the whole were found to be clear, bright, and efficiently filtered.

Of the 35 samples from the mains of the East London Company, 2 were noted as "very slightly turbid." The remainder were bright, clear, and well filtered.

Of the 35 samples from the mains of the Chelsea Water Company, 2 were noted as "very slightly turbid." The remaining 33 samples were bright, clear, and well filtered.

Of the 35 samples from the mains of the West Middlesex Company, 1 was found "very slightly turbid." The remainder were clear, bright, and well filtered.

Of the 35 samples from the mains of the Lambeth Water Company, 4 were found to be "very slightly turbid." The remainder were clear, bright, and well filtered.

Of the 35 samples from the mains of the Grand Junction Company, the whole were clear, bright, and well filtered.

Of the 35 samples from the mains of the Southwark and Vauxhall Company, excepting one, the whole were clear, bright, and efficiently filtered.

In Table III. we have recorded the oxygen required to oxidise the organic matter, and the quantities of free oxygen in the whole of the samples collected.

Judged by our daily examinations, the water supplied to London is, in our opinion, whether considered as to its efficient filtration or as to its proper aëration, or as to its purity and wholesomeness, unimpeachable. The result of our six months' work, and the examination during this period of 1,127 samples, enable us to state that as an excellent drinking supply it leaves nothing to be desired.

We remain, Sir,

Your obedient Servants,

WILLIAM CROOKES,
WILLIAM ODLING,
C. MEYMOTT TIDY.

The Part and the Origin of Certain Microzymas.—M. Béchamp.—The author examines the microzymas of swamps, of different kinds of earth, and of the street-dust of Montpellier, &c. He holds that the microzymas found in chalk, rocks, soils, &c., have no other origin than the microzymas which form an integral part of every living organism, the physiological function of which is the total destruction of the organism after its death.—*Comptes Rendus.*

OBITUARY.

DEATH OF PROF. SAINTE-CLAIRE DEVILLE.

SCIENCE has recently sustained a heavy loss in the death of one who for the past thirty years has had few equals and no superior in the fields of mineral chemistry and of inorganic analysis.

Etienne Henri Sainte-Claire Deville was born March 18, 1818, in the island of St. Thomas, in the West Indies. At an early age he manifested an ardent passion for the study of chemistry, which at that time found in France so many of its most distinguished professors. His abilities were manifested so early that at the age of 26 he was commissioned to organise the Faculty of Science, newly created in Franche Comté, and to preside over it as its dean. Here he undertook the analysis of the waters of the Doubs and of the springs around the town of Besançon, and greatly improved the methods then known for water analysis. Shortly after, he succeeded in preparing nitric anhydride, which previously had been attempted in vain. Toluol was another of his discoveries. In his 33rd year he succeeded Balard in the chemical chair at the Ecole Normale Supérieure, at Paris. Here, his emoluments only reached the modest sum of 3000 francs, chemistry in France, as well as in England, being supposed to be its own reward. His next researches related to the properties and the industrial preparation of aluminium—discoveries which attracted public attention throughout the world. He then turned his attention with signal success to the metallurgy of platinum, and its separation from its associated metals. His investigations on boron and silicon are also well worthy notice, and his production of sodium at a cheap price has placed a powerful reagent in the hands of chemists, and has led the way to valuable results both in the laboratory and in industrial establishments. His highest achievement, from a strictly scientific point of view, was the establishment of the laws of dissociation. Previously, decomposition was regarded as a simple phenomenon, effected and completed, in the case of every substance, at a fixed temperature. Deville showed that in some cases it is effected within certain limits of temperature, being arrested at a given heat by the equilibrium established between the decomposing body and its products of decomposition.

A most admirable characteristic of the deceased *savant* was his strict accuracy—an attribute all the more deserving of honour in a man of his ardent and impetuous temperament. Among his pupils may be counted not a few of the most meritorious among the younger French chemists, such as Debray, Troost, Hautefeuille, Grandeau, Gernez, and others.

M. Deville died on July 1st, at Boulogne-sur-Seine, and was buried on the 5th. His old friend, M. Pasteur, pronounced an eloquent and impressive *éloge* at the funeral. All honour to his memory, and may his experimental accuracy, which M. Pasteur aptly calls the "probity of the chemist," find abundant imitators.

Detection of Nitro-benzol in Oil of Bitter Almonds.—Enrico Pegna.—The oil is mixed with a little alcohol, a solution of pure potash, and a few drops of ferric chloride. The mixture is allowed to stand for some hours, shaken, and distilled, avoiding with great care bumping or spitting, and the direct action of the flame upon any part of the oil. A portion of the distillate, dehydrated, is heated in a test-tube with a few fragments of pure potash. If the oil was pure the mixture remains colourless. If nitro-benzol was present there is produced a dark colouration from the formation of azo-oxy-benzol, and as a little aniline is also formed, a few drops of solution of chloride of lime added to the cold mixture produce a violet colouration.—*Zeitschrift für Analytische Chemie.*

CORRESPONDENCE.

REMARKS ON MR. TATLOCK'S CHALLENGE.

To the Editor of the Chemical News.

Sir,—A strange fascination has again led Mr. Tatlock to that corner of the field of chemical analysis devoted to the estimation of potash by platinum, wherein he stumbled some fourteen years ago.

Stranger still, as showing how a man may be, as it were "possessed" by a subject, is his elaborate challenge of May 1, 1880—"To the Manufacturers of Potash Salts in Germany," addressed, in duplicate, to them, and stipulating, among other somewhat vague conditions, that "Prof. Fresenius, of Wiesbaden, is to make experiments on myprocess," and to do so "in my presence, and in that of a representative chosen by the German manufacturers;" and that, "in the event of the mean result coming out above 99·50 per cent." What can be intended by this "ninety nine and one-half per cent?" However, should this result, be it what it may, "come out above 99½ per cent, the manufacturers will pay my travelling and hotel expenses from and back to Glasgow," there is a praiseworthy exactness here, "and that whatever the results may be, the manufacturers will pay Fresenius's fees."

The strangest incident in this odd affair is, it seems to us, the simplicity of the challenger, who persuading himself that his challenge would be eagerly caught at by a number of manufacturers, instead of being pooh-poohed, or utterly neglected by these gentlemen, has led him to say in a fractious and aggrieved tone that, "up to the present moment this challenge, for obvious reasons," fie! fie! Mr. Tatlock, "remains unaccepted." However simple-minded a man may be, it is well nigh incredible that he should also be so destitute of humour as to be blind to the absurdities on the one hand, and the serious imputation on the other, involved in a challenge, of which he is so enamoured, as to say "which every unbiassed person will admit is fairness itself;" a judgment we will not dispute, although we find it difficult to understand why the challenger did not discern the impracticable nature of his proposal, which demands negotiation and agreement between all the "manufacturers of potash salts in Germany," be they five or fifty, with their various tempers, interests, and views, to determine the just and proper *quota* each should pay, in a given event, towards the discharge of Mr. Tatlock's fare and tavern bills to Wiesbaden and back to Glasgow. It is further provided that these associated manufacturers pay certain fees to Dr. Fresenius, and also that they appoint a representative to watch the "experiments made by Dr. Fresenius or his assistant in his laboratory at Wiesbaden, in my presence." The fun of the thing, perhaps, reaches its climax here. The challenger quietly assumes Fresenius's consent to this preposterous suggestion, and leaves us with the picture on our minds of Dr. Fresenius experimenting away at Wiesbaden, watched by detective Tatlock on the one side, and detective Kalimacher on the other, to see fair-play. We have said the fun culminates here, and maybe it does, yet we do not know if the proposal that these manufacturers should band themselves together and organise an association so that each should pay his proper *quota* of Mr. Tatlock's travelling expenses, appoint a representative to watch Dr. Fresenius, and gain his assent to this programme; in order, that in a given event, Mr. Tatlock shall add a certain unspecified amount, called in the challenge "the difference," and which, so far as we can find, amounts, at the utmost, to 0·50 per cent of muriate of potash, does not transcend the single incident in absurdity:—*Montes parturient et nascitur ridiculus mus.*

There is a serious view, however, of this subject, which justifies our statement that Mr. Tatlock was "possessed," when issuing this challenge; *i.e.*, he must have been so carried away by his belief in its overwhelming importance, as to blind him to the utter want of courtesy, to speak mildly, of which he has been guilty. Else, how could he have conceived, much more how could he have given birth, to the unworthy thought, that in order to obtain the truth from Dr. Fresenius as to the result of any experiments made by him, the challenger should specify "that these experiments be made by Prof. Fresenius or his assistants, in his laboratory at Wiesbaden, *in my presence*, and in that of a representative chosen by the German manufacturers." The italics are ours. Of one thing we rest assured, that when Mr. Tatlock perceives the only obvious meaning of this proviso, he will publicly offer the most ample apology to one so deservedly honoured as is Dr. Fresenius, who, whilst unlikely to notice this untoward remark, should be assured that the imputation conveyed is distinctly repudiated by English chemists.

Mr. Tatlock is so much aggrieved by the ignoring of his challenge that he quarrels with and sneers at every one who crosses his path in this matter. Thus Drs. Zuckschwerdt and West, who have ventured, and who are quite within their right in so venturing, to examine and criticise his process, are always spoken of by him in an unpleasant tone, quite unprovoked by them, unless adverse criticism can be justly regarded a provocation. Of these gentlemen, who appear to us to be capable analysts and fair and just critics, he tells us "they make experiments privately upon my method, and tell us what results they got in this way when nobody was present to verify them, and affect to be simple enough to suppose that we shall credit their results," and much more in the same unwarrantable style, which almost induces us to repent of the favourable interpretation we gave to the same idea when applied to Dr. Fresenius. Mr. Tatlock always speaks of these gentlemen as "the two doctors," with a little "d," as if the Doctorate of a German University, achieved by a German, were not pretty certain to be an honourable title conferred by a recognised Authority, forgetful all the while that he had bedecked himself with a title derived from the "*Limited Liability Act*"!

We have read the memoir of Drs. Zuckschwerdt and West (Chemical News, vol. xliii., p. 251), which is both clear and inoffensive; nor do we think the method of analysis described by them open to any objection beyond the "balanced filter." We venture to doubt whether the solution of "0·3250 grm. of the double chloride" they speak of, is due to the chloride of platinum itself, regarding it as owing to the acid water in which the platinum salt is dissolved, which constitutes an obvious and constant defect in Mr. Tatlock's method—a method which they have permitted themselves to say "should be completely rejected." These "two doctors" have not had the fear of Mr. Tatlock before their eyes, a hardened state in which we also find ourselves, and thus we requested our principal assistant, Mr. Beverley, to examine Mr. Tatlock's present method and report to us. He states that the double chloride of platinum and potash is almost one hundred times more soluble in Mr. Tatlock's 7 per cent of platinum solution than in alcohol of 95 per cent. That his solution of "muriates," is nearly three and a half times stronger than that we are accustomed to employ, which greatly augments his liability to error. That his great excess of platinum is not only unnecessary but injurious. That in other respects his method is ours, and that Mr. Tatlock's process has been recently criticised by Drs. Zuckschwerdt and West, Mr. Tatlock's "two doctors," who published nearly 40 determinations of potassium by his and Fresenius's method, which latter is almost identical with our own, and show that Mr. Tatlock's is liable to a loss of 0·30 per cent. After detailing his mode by preparing pure KCl, Mr. Beverley subjoins his results from six analyses of 10 grains of salt = 8 grs. of KCl and 2 grs. NaCl. (See table next page.)

These results are more in Mr. Tatlock's favour than are the German ones, but plainly point to the defect inherent in his method to which he still fondly clings, the use of

Tatlock's Method.

	Pt salt	=	p.c. KCl agst. 80 p.c. used.
A.	26·19	=	79·898
B.	26·20	=	79·928
C.	26·17	=	79·837

A shows a loss of 0·102 per cent; B, of 0·072 per cent; C, of 0·163 per cent.

Teschemacher and Smith's Method.

	Pt salt	=	p.c. KCl agst. 80 p.c. used.
D.	26·22	=	79·989
E.	26·22	=	79·989
F.	26·19	=	79 898

D and E are each 0·011 per cent too low; and F, 0·102 per cent.

an aqueous solution of platinic chloride, of which we have before spoken. When he discards this, and consigns it to the limbo of forgetfulness, wherein repose his old coadjutor, Mr. Chalmers, and the former "key-stone of their entire process" "perfectly pure platinum," and further uses a far more dilute solution of his sample of German muriate, he will employ a method with which he is perfectly well acquainted, but which, as other of our readers may be pardonably ignorant, may be found in the CHEMICAL NEWS, vol. xvii., p. 244.

We may here, perhaps, be allowed to say the "key-stone" of our process, the obtaining the potassio-platinic chloride in *brilliant orange coloured crystals* which permits of the most rapid and complete washing, is the discovery of the late Mr. Teschemacher the younger. An improvement, so great on the former process, that we regard the determination of potash and also of ammonia by platinum, as being among the most perfect of analytical processes when these double chlorides are obtained by gentle evaporation of the acid aqueous solutions in brilliant clusters of crystals.

As respects German makers and English buyers of muriate of potash, we take leave to say that if these gentlemen can transact their business, selling and buying within a quarter per cent of the actual value, they will be contented. Whilst as to the challenger, we would hope the next time Mr. Tatlock appears in print, respecting the estimation of potash by platinum, he will bear in mind that as both his manifestations have been signalised by error, a more modest demeanour and a greater courteousness in tone, would befit him better than the assumption and imputations which characterise his challenge and his communication of the 17th ult. to the CHEMICAL NEWS, vol. xliii., p. 273.—We are, &c.,

E. F. TESCHEMACHER and J. DENHAM SMITH.

CHEMICAL NOTICES FROM FOREIGN SOURCES.

NOTE.—All degrees of temperature are Centigrade, unless otherwise expressed.

Comptes Rendus Hebdomadaires des Séances, de l'Académie des Sciences. No. 23, June 6, 1881.

Researches on Nitrogen Sulphide.—MM. Berthelot and Vieille.—This compound is formed with absorption of heat like all the binary compounds of nitrogen, except ammonia. Hence it can only be obtained by indirect methods.

New Analyses of Jade and certain Sodiferous Rocks.—A. Damour.—The author gives analyses of certain Asiatic and Mexican specimens, and of certain European minerals, which do not differ widely from the former in composition. He thinks it probable that a deposit of jade will be found in the Alps.

Study on Electricity as Manifested on Board Modern Ships, with Remarks Concerning the Method of Soldering in Complex Electric Circuits, and the Principle of an Electric Hygrometer and a Fire Alarm.—A. Ledieu.—The author shows that when the immersed portions of an iron-clad are sheathed with wood, above which is a copper coating, fixed to the iron by metallic connections, we have a complex battery, the nature and the functions of which he has studied. From his results there "may be deduced the principle of an electric hygrometer, especially useful for measuring dew," which, however, he does not describe. The fire alarm consists of a piece of wood, connected to the wires of a constant battery by means of strong copper screws sunk up to the head. This piece of wood is kept slightly moist by means of a coating of spongey material kept in communication with a receptacle for water. The instrument is placed in the interior of the compartment (powder magazine, or coal room), the temperature of which is to be observed. The battery is placed outside, and a very sensitive galvanometer is introduced into its circuit. This galvanometer indicates by the movements of its needle the variations in the dryness of the wood. The needle may be arranged to set in action an electric bell on reaching zero.

The Part Played by Phosphoric Acid in Volcanic Soils.—P. de Gasparin.—A superabundance of phosphoric acid counts for nothing in the phenomena of vegetation. An exceedingly fruitful garden between Catania and Nicolosi contains merely two parts of phosphoric acid per thousand. The soils of the plain of the Vistre at Nimes, of St. Contest at Caen, and of Castro-Giovanni, in Sicily, do not contain more than one-thousandth, whilst the alluvial soils of l'Ardèche and of the Rhone fall still lower.

The Liquid and the Gaseous State.—J. B. Hannay.—From an English source.

Sodium and Barium Cyanides.—M. Joannis.—A thermo-chemical study.

Compounds of Lead Iodide with the Alkaline Iodides.—A. Ditte.—The decomposition of lead potassium iodide by water is effected according to ordinary laws, that is, at every temperature the solution which floats over the double salt without decomposing it must contain a minimum and well-defined quantity of alkaline iodide.

Non-existence of Microzyma cretæ.—MM. Chamberland and Roux.—The authors consider that the experiments of M. Béchamp have not been conducted with the requisite precautions.

Biedermann's Central-Blatt für Agrikultur-Chemie, Vol. ix., No. 9.

The Source of the Atmospheric Carbonic Acid.—Dr. M. S. Meunier.—The author maintains that the interior of the earth contains large beds of carboniferous cast-iron, which, coming in contact with water at high temperatures, yields hydrocarbons. These, on their subsequent combustion, give rise to the carbonic acid exhaled from the earth.

Fluctuations in the Proportion of Carbonic Acid in Underground Waters.—Dr. M. Popper.—The proportion of carbonic acid varies at different depths of one and the same well, decreasing upwards. There is no relation between the amount of carbonic acid in the water and its level, but its percentage increases with a fall of the barometer. The variations in the proportions of chlorine and carbonic acid do not correspond.

Researches on the Drainage Water of Reclaimed Moors.—Dr. R. Schiller.—The waters were found very rich in soluble matter.

Researches on the Application of Manure to Vineyards.—Drs. P. Wagner and H. Prinz.—The authors recommend that the present practice should be inverted, and

that farm-yard manure should be chiefly applied to arable lands, and chemical manures to the vineyards.

Behaviour of Different Phosphates with Carbonated Waters, both when alone and when Distributed in Different Soils.—H. Albert and R. Wagner.—The author concludes that on barren calcareous sands phosphoric acid is more efficacious in the state of bibasic calcium phosphate and of aluminium and iron phosphates than when soluble. He infers that the phosphorites from the Lahn, with a high percentage of iron and aluminium phosphate, are better than superphosphates made from minerals free from alumina and iron.

Manurial Experiments on Certain Root-Crops.—J. Godefroy and A. Doudonz.—Not suitable for abstraction.

Is Glycerin a Nutritive Matter?—Dr. Munk, Dr. Lewin, and N. Tschirwinsky.—The authors decide that glycerin has little or no nutritive value.

Re-absorption of Fats and Fatty Acids in the Intestine and their Utilisation in the Organism.—A. Will and Dr. Munk.—Not suitable for abridgment.

Comparative Experiments on the Value of Linseed Cake and a Mixture of Indian Meal and Cotton-seed Cake for Oxen.—From an English source.

Experiments on the Consumption and Purification of Lupins.—MM. Puttkammer, Glaser, Schlæger, and Schmidt.—Not suitable for abstraction.

Composition of Oats.—L. Grandeau and A. Leclerc.—The mean composition of oats, as ascertained from 120 analyses is:—

Moisture	12·01
Nitrogenous bodies	9 80
Non-nitrogenous extractive	59·09
Fat	4·58
Cellulose	11·20
Ash	3·32

Chemical Composition of Linseed.—A. Ladureau.—The total percentage of ash, the proportion of its soluble and insoluble constituents, and the residue insoluble in acids are nearly constant. The phosphoric acid in the ash ranges from 40 to 15 per cent.

Occurrence of Ammonia in Plants, Muscular Juice, and in Yeast.—H. Pellet.—In plants ammonia is widely distributed. In the juice of 100 grms. beef the author found 0·15 ammonia, and in yeast an average percentage of 0·059.

The Alleged Conversion of Albumen into Fat during the Ripening of Cheese.—Dr. O. Kellner and N. Sieber.—The authors do not admit this supposed conversion. The absolute proportion of fat in cheese decreases slightly during ripening.

A Cheap and Rapid Process of Obtaining Sugar from Treacle.—Dr. Jünemann.—The author obtains a saccharate of lime by treatment with caustic lime, water, and steam, at 8 atmospheres; frees the compound thus obtained from mother-liquor by pressure and by washing at a high tension, and when brought to 99·3 decomposes it. Dr. Scheibler doubts the value of the process, as the temperature employed (172°) destroys sugar, especially in presence of lime.

Disease of Apple Trees due to Alcoholic Fermentation in their Roots.—Ph. van Tieghem.—The presence of alcohol was proved beyond doubt. The author ascribes the cause to a deficiency of oxygen, due to wet weather, and recommends drainage.

Diastase and the Influence of Foreign Bodies on its Efficacy.—J. Kjeldahl.—Small proportions of acid augment the action of diastase, but a slight increase proves injurious. The smallest proportions of alcohol check the effects of the diastase. The action of alcohol is injurious.

NOTES AND QUERIES.

*** Our Notes and Queries column was opened for the purpose of giving and obtaining information likely to be of use to our readers generally. We cannot undertake to let this column be the means of transmitting merely private information, or such trade notices as should legitimately come in the advertising columns.

Bright-Plating.—For some time past I have been endeavouring to form a solution technically termed "bright," composed of bisulphite of soda and hyposulphite of soda. It is known as the French system by Roseleur, now used practically by electro platers in place of bisulphide of carbon. I have also tried the addition of ammonia to the solution, but have failed to get a deposit of "bright" metal. My object is bright-plating by the above preparations of soda.—W. H. S.

BRITISH ASSOCIATION FOR THE ADVANCEMENT OF SCIENCE.

22, ALBEMARLE STREET, LONDON, W.

The NEXT ANNUAL GENERAL MEETING will be held at YORK, commencing on WEDNESDAY, AUGUST 31.

President Elect:—
SIR JOHN LUBBOCK, Bart., M.P., D.C.L., LL.D., F.R.S., F.L.S., F.G.S.

NOTICE TO CONTRIBUTORS OF MEMOIRS.—Authors are reminded that, under an arrangement dating from 1871, the acceptance of Memoirs, and the days on which they are to be read, are now, as far as possible, determined by Organising Committees for the several Sections *before the beginning of the Meeting*. It has therefore become necessary, in order to give an opportunity to the Committees of doing justice to the several Communications, that each Author should prepare beforehand an abstract of his Memoir, of a length suitable for insertion in the published Transactions of the Association, and the Council request that he will send it, together with the original Memoir, by book-post, on or before August 1, addressed thus:—"General Secretaries, British Association, 22, Albemarle Street, London, W. For Section . . . . ." Authors who comply with this request, and whose papers are accepted, will be furnished *before* the Meeting with printed copies of their Reports or Abstracts. If it should be inconvenient to the Author that his Paper should be read on any particular days, he is requested to send information thereof to the SECRETARIES in a separate note.

G. GRIFFITH, Acting Secretary, Harrow, Middlesex.

INTERNATIONAL MEDICAL AND SANITARY EXHIBITION.

OPENING CEREMONY, ROYAL ALBERT HALL SATURDAY NEXT, JULY 16TH.

The President, THE RIGHT HON. EARL SPENCER, K.G., will take the Chair at 4.30 p.m., supported by The Right Hon. Earl Granville, K.G.; The Right Hon. J. G. Dodson, M.P.; Sir James Paget, Bart., F.R.S.; George Godwin, Esq., F.R.S., F.R.I.B.A.; and John Eric Erichsen, Esq., F.R.S.

HUNGARIAN BAND FROM 5.30 TILL DUSK.

Admission—Opening Day, by Season Ticket, Five Shillings. After Opening Day, One Shilling. From 10 till 7.

MARK H. JUDGE, Secretary.

All communications to be addressed South Kensington, London, W.

Vol. XLIV. No. 1130.

COLLIERY EXPLOSIONS.*

By F. A. ABEL, C.B., F.R.S., President of the Institute of Chemistry, Chemist to the War Department, &c.

(Concluded from p. 31.)

III.

A series of experiments, variously modified, has been instituted with the most sensitive of the samples of dust from Seaham Colliery, and also with the specially inflammable dusts from Leycett Colliery, for the purpose of ascertaining whether evidence could be obtained of a tendency of coal-dust, when suspended in the air, *in the complete absence of fire-damp*, to become ignited and to convey or propagate flame.

It was observed in the first instance that the travelling of a dust-cloud past the naked flame of a safety lamp merely produced a fringe of scintillations round the flame; but when the latter was replaced by a large flame produced by a jet of the pit-gas, a very decided elongation of the flame took place when the cloud of dust reached it, travelling at a velocity of 300 feet per minute, and a small flare was occasionally produced. The lengthening of the flame was increased by increasing the velocity of the air-current, so that its length eventually was three or four times that of the gas-flame in the absence of the dust (Seaham, K).

With a view of exposing coal-dust suspended in air to a flash of flame of considerable volume, and of thus producing conditions similar to those which might exist if an explosion of fire-damp occurred in contiguity with coal-dust suspended in air free from fire-damp, heaps of loose gun-cotton (300 grains) were placed on the floor of the gallery, and fired by electricity, the length to which the flash of flame extended, both with and against the current, being noted in the first instance when no dust was present, and afterwards when dust clouds were travelling at the time at different velocities.

At the lower velocities (200 and 300 feet per minute) the volume of flame was decidedly increased when the dust-cloud was passing, and the increase became more marked when the dust was travelling at a higher velocity (1000 feet per minute), it being then specially noticed (what was observed also, though to a less marked extent, at low velocities) that the flame extended considerably further in the direction of the current, but less far *against* the current, when dust was passing, than when the gun-cotton was fired in the absence of dust. Thus in some parallel experiments when the gun-cotton heap was fired at a distance of 20 feet from the far end of the gallery, the following results were obtained :—

Air current 1000 ft. per min.	Length of Flame.				
Gallery free from dust	9 ft.	with current	6 ft.	against	
,, ,, ,,	9	,,	,,	6	,,
Seaham (K) dust passing	14	,,	,,	3 ft. 6 in.	,,
,, ,, ,,	14	,,	,,	4	,,
Gallery free from dust	10	,,	,,	5	,,
Leycett dust passing	15	,,	,,	3	,,

It will be observed from these numbers that the *total* length of the flame produced was not greatly increased, but that the dust showed a tendency to carry the flame in the direction of the current, and appeared to check the flame where it met the current.

Experiments similar to these with gun-cotton were made with freely exposed charges (400 grains) of blasting-powder and sporting powder, placed in heaps upon the floor of the gallery and fired electrically. The most readily inflammable of the Seaham coal-dusts, and the still more inflammable dust from Leycett Colliery, were passed through the gallery at a velocity of 100 feet per minute, and the total distance to which the flame extended on firing the powder-charge while dust was travelling, was not found to be greater than when the powder-charges were exploded under the same conditions, but in the absence of dust, as shown by the following examples :—

Air current 100 feet per minute.	Powder Charge.	Length of Flame. With current.	Against.
	Blasting.		
Gallery free from dust	400 grains.	7 feet	5 feet
,, ,, ,,	,,	7	5
Leycett dust passing	,,	6 ft. 6 ins.	2
Seaham (X) ,,	,,	6 ,, 6	1 ft. 6 ins.

When the dust was passed at a velocity of 500 feet per minute there were decided indications that the coal-dust increased the total distance to which the flame extended.

Air current 500 feet per minute.	Powder Charge.	Length of Flame. With current.	Against.
	Sporting.		
Box free from dust	400 grains	8 feet	3 feet
Leycett dust passing	,,	8	6

(Many sparks extended beyond the forward flame.)

	Blasting.		
Box free from dust	400 grains	5 feet	2 feet
Leycett dust passing	,,	7	3
,, ,, ,,	,,	7	2 ft. 6 ins.

At a velocity of 1000 feet per minute the increase of the flame by the dust cloud was much more marked when blasting powder was used, but not so with sporting powder, a difference which may perhaps be ascribable to the considerably longer duration of the flame produced by an explosion of the comparatively slow-burning mining powder. The actual heat developed would be greater with the sporting than with the mining powder.

The results obtained at this velocity with the two descriptions of powder are shown in Table III.

Numerous experiments, varied in several particulars, have been made with Seaham and other dusts by firing small charges of powder from either while dust was being carried through the gallery by air currents of different velocities, or with dust deposited upon the floor and sides of the gallery. In the latter description of experiments, two shots were sometimes fired in succession, and in different directions (with and against the air-current), so that dust raised by the concussion and rush of gas from the first shot might be exposed to the flame of the second. In all instances with different samples of dust from Seaham, Leycett, and Garswood Hall Collieries, in air-currents travelling at velocities 100, 200, and 300 feet per minute, the results were negative. At a velocity of 1000 feet per minute, a slight but decided indication was obtained in several experiments that dust particles were inflamed by those shots which were fired in the direction of the air-current. In these instances the volume of flame produced on firing the shot was certainly greater than when no dust was suspended in the air, but the duration of the flash was but slightly if at all prolonged. On one single occasion a long reddish flame was produced when a shot was fired, which travelled to the forward end of the gallery. Some fire-damp had been passed into the latter just previously, and it was evident that, although the apparatus had subsequently been ventilated, the exceptional result was due to the presence of some, though certainly a very

* Report on the Results of Experiments made, with Samples of Dust collected at Seaham Colliery, in compliance with the request of the Secretary of State for the Home Department, conveyed by letter dated November 4th, 1880.

small, quantity of fire-damp, for when the experiment was very carefully repeated, all conditions, except the possible presence of gas, being identical with those previously existing, the only effect observed was a slight increase in the volume of the flash of flame produced by the shot, which has been described.

Some experiments made with these cannon in air-currents containing small quantities of fire-damp, with or without the presence of suspended coal-dust, afforded instructive corroboration of the results described in the second part of this report. Two or three illustrations will suffice. Cannon were fired in a mixture of air and 2·5 per cent of fire-damp passing at velocities of 100 and 200 feet per minute, and in an atmosphere containing 3·75 per cent, travelling with a velocity of 300 feet per minute, without any effect. With only 1·75 per cent of gas (at 100 feet velocity), coal-dust being abundantly suspended in the air, the portion of the gallery immediately in front of the flash produced by the shot was filled with flame, which did not, however, travel further; corresponding results were obtained by firing the shot against and with the current. With a slight increase in the proportion of gas (2 per cent and 2·25 per cent), the dust being freely passed, the gas- and dust-mixture was inflamed throughout, with explosive effect. On one occasion air containing 2 per cent of gas was passed at a velocity of 100 feet per second through the gallery in which there was only a very small quantity of coal-dust deposited upon the bottom and sides; when a shot was fired in the direction of the current a reddish flame was produced which extended to a distance of four feet, and which rolled along the floor of the gallery a further distance of three feet. This result illustrated the influence of a few dust-particles in promoting the ignition and propagation of flame by a gas-mixture which otherwise would not have inflamed; an effect which corresponds to the influence exerted by an exceedingly small proportion of gas in determining the ignition and propagation of flame to some distance by a cloud of coal-dust, as demonstrated by an experiment just now described.

Summary.

The principal facts which appear to have been more or less conclusively demonstrated by the results obtained in the experiments with dust from Seaham Colliery and other sources, which form the subject of this report, may be summarised as follows:—

1. Several of the samples of dust collected in Seaham Colliery in November, 1880, exhibited signs of having been affected by heat; those indications were very slight in some instances, and considerable in only three samples, viz., in Q (scraped off stones on return side of Polka doors), R (from No. 1 engine plane at long turn), and T (from floor of No. 1 travelling road).

2. The two samples taken from the floor and off timbers at the curve in the stone drift (in proximity to where the shot was fired at the time of the explosion), as also the sample from near Maudlin engine, exhibited no signs of having been affected by heat.

3. The samples of Seaham dust exhibited considerable differences in regard to richness in coal, fineness and uniformity in this respect, density, &c.; the proportion of coal ranged from about 96 to below 54 per cent in the dry sifted samples.

4. The chemical and microscopical examination did not furnish any data to lead to conclusions as to the extent to which the dust may have taken part in the production or augmentation, and transmission, of the explosion at Seaham Colliery.

5. But there was evidence of the existence of partially burnt dust at a number of points very distant from each other, and in different directions in the colliery.

6. The several samples of dust differed from each other considerably in sensitiveness, *i.e.*, in the readiness with which they promoted the ignition of a mixture of air and fire-damp in such proportions that it was not inflammable *per se* when brought into contact with the flame of a lamp, or, in regard to the proportion of fire-damp required by the several samples to impart explosive properties to them, when suspended in air.

7. The most sensitive of the Seaham dusts were found to be those which were the richest in coal, and those which also contained the highest proportions of very fine dust.

8. Comparing the samples of Seaham dust with dusts obtained from other collieries where disastrous explosions have recently occurred, it was found that the most sensitive of the former was somewhat less sensitive than samples of dust obtained from Leycett Colliery (Fair Lady Pit), which ranked highest in this respect among all the samples experimented with. The Leycett dusts corresponded closely in chemical character and specific gravity to the purest Seaham coal-dust; their somewhat greater sensitiveness was perhaps ascribable to their remaining more uniformly suspended in air-currents, but possibly also to physical peculiarities.

9. One of the Seaham dusts which ranked high (third) in order of sensitiveness contained the lowest proportion of coal of all the samples, and consisted of non-combustible matter to the extent of nearly half its weight.

10. Special experiments, which were instituted in consequence of the behaviour of this sample, demonstrated that some perfectly non-combustible powders, which are also not susceptible of any chemical change when exposed to the action of flame, are very little inferior to the most inflammable or sensitive of the Seaham dust samples in their power to bring about the ignition of an otherwise uninflammable mixture of fire-damp and air.

11. Mixtures of fire-damp and air, in proportions bordering on those which will ignite on the approach of flame, are inflamed instantaneously if they contain in suspension only few particles of such non-combustible dusts, or of the Seaham or other dusts from coal-pits.

12. This effect appears ascribable, at any rate in part, to the fact that these dust particles, when they pass through a lamp-flame, immediately become incandescent and thereby localise and intensify the heat at those points, and thus bring about the ignition of the mixture of air and fire-damp by which they are surrounded. But some phenomena observed in the course of the experiments with non-combustible powders favour the belief that finely-divided solids of particular descriptions may exert another quite distinct kind of action when heated in fire-damp mixtures, which may at least contribute importantly in determining the ignition of gas-mixtures which are not susceptible of inflammation by the application of flame alone. This subject is about to receive complete investigation.

13. The smallest proportion of the fire-damp experimented with (from the nine-foot Wigan mine) which became ignited and produced explosive effects, when passing a naked lamp flame at a velocity of 600 feet per minute, by having suspended in it the most sensitive of the Seaham dusts, was 2·5 per cent. The most sensitive coal-dust from Leycett furnished a mixture which exploded when passing the flame, under corresponding condition, with air containing only 2 per cent of fire-damp. A mixture of 2·75 per cent of fire-damp with air was ignited by the lamp through the agency of a perfectly non-combustible powder (calcined magnesia).

In a current moving at a velocity of only 100 feet per minute, the Leycett coal-dust, suspended in air containing only 1·5 per cent of fire-damp, became ignited by the lamp flame, the ignition extending throughout the mixture.

14. The accidental presence of a proportion of fire-damp which must have been considerably below the smallest above specified, caused one of the most inflammable of the coal-dusts (from Leycett) to become inflamed and to carry fire some distance, when a small powder-charge was fired from a cannon while the dust was travelling.

15. The sensitiveness to ignition of a mixture of air with a small proportion of fire-damp is considerably increased if the source of heat is increased.

16. The results of the experiments with Seaham and other dusts appear to have demonstrated—

(*a.*) That coal-dust in mines not only much promotes and extends explosions in mines by reason of the rapid inflammability of the finely-divided combustible, and of the readiness with which it becomes and remains suspended in air-currents; but

(*b.*) That it may also be itself readily brought into operation as a fiercely-burning agent which will carry flame rapidly as far as its mixture with air extends, and will operate even as an exploding agent, *through the medium of a proportion of fire-damp in the air of the mine, the existence of which, in the absence of the dust, would not be attended by any danger.*

(*c.*) That dust in coal-mines, *quite apart from any inflammability which it may possess*, can operate in a distinct manner, as a finely-divided solid, in determining the ignition of mixtures of only small proportions of fire-damp and air, and consequently in developing explosive effects.

(*d.*) That a particular dust in a mine (such as the Seaham N dust) may therefore be a source of danger, even though it contains only a small proportion of coal or combustible matter. Although the explosion which may occur through the agency even of a non-combustible powder, in the manner described, may be of very mild or feeble character in the first instance, it may be almost at once increased in magnitude and violence by coal-dust which the first ignition will raise and bring into action.

17. The proportion of fire-damp required to bring dust in a mine into operation as a rapidly burning or exploding agent, even upon a small scale, and with the application of a small source of heat or flame, is below the smallest amount which can be detected in the air of a mine, even by the most experienced observer, with the means at present in use, as has been already demonstrated by the experiments of Mr. Galloway. Indeed, with dusts of highly sensitive or dangerous character, under those conditions, and very possibly with dusts not more so than the least sensitive of the Seaham samples, *in the presence of a source of considerable heat and flame*, such as a blown-out shot or an overcharged hole would constitute, a small propor-

tion of fire-damp, the possible existence of which in the mine might not be in the least suspected, may serve as the inciting cause to the development of an explosion of coal-dust.

18. In the complete absence of fire-damp coal-dust exhibits some tendency to become inflamed when passing a very large lamp flame at a high velocity; if exposed to the action of a large volume of flame, such as produced by the explosion of freely exposed gunpowder or gun-cotton, it exhibits, in addition, a decided tendency to carry or propagate flame. But, so far as can be determined by experiments on a moderate scale, this *tendency* (which was exhibited by Seaham X, K, and S dusts, and still more by the more sensitive Leycett dust) is of limited nature, and very different indeed from the *property* of carrying or propagating flame, which even comparatively non-sensitive dusts possess, *in the presence of a very small quantity of fire-damp*.

In conclusion, it may be admitted as possible that, with the large volume of flame, and the great disturbing effect, of a blown-out shot, as the initiatory cause of the ignition of dust, and its suspension in the surrounding air, such inflammation may, in the complete absence of fire-damp, be propagated to a greater distance than the results of small experiments would warrant one in assuming. But it can scarcely be maintained that the air of a mine in which the coal gives off gas at all can be, at any time, *free* from fire-damp; and as the existence of very small and unsuspected quantities of that gas in the air of a mine may suffice to bring about the ready propagation of flame by coal-dust, and thus to develop violent explosive effects, it would appear needless to assume that coal-dust may, in the entire absence of fire-damp, give rise to explosions, even of only limited character, in coal-mines, in order to account for casualties which cannot be ascribed to the existence of accumulations or sudden outbursts of fire-damp.

F. A. Abel.

March 23, 1881.

Appendix II.

Memorandum of Points for Analysis and Experiments with respect to Coal-dust or other dust in Seaham Colliery.

(*Accompanying the Letter of the Under Secretary of State for the Home Department to Mr. Abel, dated November 9th*, 1880.)

A. Samples of *burnt dust* found in the mine after the explosion, to be analysed with a view to an opinion whether such burnt dust is—

(1.) The ash or product of dust burnt by an explosion of fire-damp; or

(2.) Is the remains or product of dust which has itself been explosively burnt (with or without fire-damp) whilst suspended in the air.

B. Samples of *unburnt dust* to be collected in the mine and analysed, and also subjected to experiments, with a view to try—

(1.) How far the presence of such dust suspended in the air or lying strewn upon the ground or timbers in an enclosed gallery intensifies an explosion of fire-damp or extends the area of the effects of such explosion; and

(2.) How far such coal-dust in suspension in the air is capable of mischievous explosion (*e.g.*, by a shot or by passing through a ventilating furnace without the presence of gas); and

(3.) What are the effects of a shot fired in a gallery (such as the air-ways of a colliery) in causing the disturbance and suspension in the air of such coal-dust lying on the floor or timbers of the gallery.

NOTE ON THE SPECTRUM OF CARBONIC ACID.*

By Charles Wesendonck, Berlin.

Communicated by Professor Helmholtz, For. Mem. R.S.

The well-known spectrum first observed by Mr. Swan at the inner cone of a number of flames produced by burning liquid and gaseous combinations of carbon, has been ascribed by Messrs. Attfield† and Watts‡ to the element carbon itself; while several other natural philosophers—amongst whom I only mention Messrs. Thalèn and Ångström,§ P. Smyth, Liveing‖ and Dewar¶—believe it to be due to some combination of carbon with hydrogen. The fact that the bands and lines of Swan's spectrum are seen even when oxide or binoxide of carbon is made luminous in a Geissler tube by means of an electric current, the last-named gentlemen explain as being caused by the gases not having been entirely deprived of all moisture when introduced into the vacuum tube. I therefore believed it to be not altogether without interest to make some experiments on carbonic acid dried with the utmost care. For this purpose I used a mercurial pump, as invented by Professor Toepler, with some slight changes in the original construction indicated by Dr. Hagen,** which enables us not only to obtain the most perfect vacua, but also to avoid every cock or junction by slided pieces, which must be greased in order to be hermetic, so that no vapours and gases containing carbonic matters arising from the grease, either by increase of temperature or by the electric current when passing the vacuum tube, would render impure the carbonic acid, as is the case with the common Geissler pumps. Carbonic acid was produced in the well-known manner from marble and diluted muriatic acid in a Pippian apparatus, well washed with water in a large Woolf's bottle, and then sent through concentrated sulphuric acid, three tubes of U form containing chloride of calcium and a double tube half filled with phosphoric anhydride. To this last tube were fastened, by means of sealing, two Geissler glass cocks, being on the other side fastened by sealing to a valve of sulphuric acid, that prevented all vapours coming from the cocks from entering the vacuum tube. After all air had been driven and pumped out of the whole apparatus, the spectrum tube was exhausted to the highest possible degree, in order to free it from all moisture adherent to the sides of the glass. This, however, was found to cause some difficulty, for the green hydrogen line was seen with great constancy in high vacua, even if not the least trace of it could be remarked when the carbonic acid spectrum could be seen brightly. I soon recognised that the more the gas had been deprived of moisture, the further had the exhaustion to be carried on to render the said line visible again, but for a long time I could not quite get rid of it. By repeatedly filling and exhausting the vacuum tube, in doing which the gas naturally was only permitted to pass very slowly through the phosphoric anhydride tube, and the spectrum tube was heated to the highest degree possible, I at last arrived at such a degree of perfect dryness as no more to give any trace of the fatal green line, not even if the tube was exposed to high temperature; this, indeed, always had the effect of driving into the vacuum some matter adherent to the sides of the glass, and causing the illumination of the tube, when this has been so far exhausted as no longer to permit any current to pass, to reappear. But the brilliant mercury spectrum seen under such circumstances showed nothing of a hydrogen line. Nevertheless, after this exceedingly high degree of dryness

had been obtained, when there was some gas admitted into the spectrum tube and this again exhausted, the fatal line was feebly seen, showing clearly that the gas had not been entirely deprived of its moisture by its passing through the system of drying apparatus. I therefore finally only experimented with such carbonic acid as had been in perpetual contact with the phosphoric anhydride during at least twelve hours, and it was not till then that I got rid of every trace of the hydrogen lines. When making the experiments that I believe to be decisive, I always took care to convince myself, by rarefying, that not only the gas had remained perfectly dry, but also that the current had not introduced any trace of hydrogen or hydrocarbon when passing through the tube, for both would have been discovered in the high vacuum by the appearance of the green line, the spectrum of hydrogen being by no means suppressed by that of carbon in such a vacuum, as I most clearly observed when experimenting with olefine gas, which in a very rarefied state shows from the beginning of the current's passage a very distinct spectrum of the first order of hydrogen, besides the one of carbon. If the bands and lines observed by Swan really belonged to hydrocarbon only, they could not have appeared in our case, but they did appear very distinctly, and clearly, as soon as the density of the gas became great enough to oblige the current to pass a spark through the vacuum tube; and even not less brightly was Swan's spectrum seen at much lower pressures by using a Leyden jar. The capillary tube in which the said spectrum alone was seen was then wholly filled by the luminous discharge; no real spark appeared in this case, while the wide parts of the spectrum tube showed Mr. Watts's second carbon spectrum. It is these last-mentioned experiments only, made by use of a Leyden jar, that I believe to be decisive, and to prove irrefutably that Swan's spectrum cannot be ascribed solely to hydrocarbon. As to the phenomenon shown by sparks, it is not quite so convincing; for, accepting Mr. Wuellner's* ideas, one could object that the spark affecting but a set of molecules of infinitely small transverse section could have carried forth from the electrodes an exceedingly small quantity of hydrogen, which would quite escape observation when expanded throughout the whole vacuum tube, but would be sufficient to induce the hydrocarbon spectrum in the line of the spark, which explanation, however, I do not think to be at all probable. The tube used in these experiments was of common size; the ends of the electrodes, which were of aluminium, had a distance of about 15 centims. from one another. Some results, differing from those just mentioned, were obtained in a wide spectrum tube without capillary tube, the ends of its electrodes being distant about 3 centims. from one another. The spark, then, no more gave appearance to Swan's spectrum, even when the carbonic acid was not dried with the utmost care, as in the above-mentioned researches, but there were seen the enlarged maxima of Watts's second spectrum, which I have shown by some researches, of which a short account has been published in the *Monatsberichte der Berliner Academie*, October heft, 1880, to be generally due to the continuous form of discharge according to the nomenclature of Messrs. Thalèn and Ångström. If the density of the gas be still increased, there flashes a very brilliant line spectrum, never before observed by me, in a tube of common size. These facts, at all events, show that there exists some relation between the different orders and forms of spectra and the conditions of discharge, probably, as is my opinion, the quantities of electricity sent through the unit of space in the unit of time, till now unknown to us, and that will doubtless become clear as soon as the causes governing spark discharges shall be better recognised—a subject on which Sir W Thomson† says that it is difficult even to conjecture an explanation.

DETERMINATION OF CHROMIUM IN CHROME IRON ORE.

By H. N. MORSE and W. C. DAY.

WHEN a determination of the chromium only is sought, the decomposition of chrome iron ore, according to our experience, can be best accomplished by fusing the material with potassium hydroxide in a wrought-iron crucible.

The method here described has, without exception, given us satisfactory results. From 6 to 10 grms. of potassium hydroxide are placed in a wrought-iron crucible (having the form of the ordinary porcelain crucible and a capacity of about 100 c.c.) and gently heated until the evolution of steam ceases and the fused mass becomes tranquil. After cooling, the finely pulverised material, weighing not more than 0·5 grm., is placed upon the potassium hydroxide and evenly distributed over the surface. A flame just sufficient to thoroughly fuse the alkali is applied to the uncovered crucible, and the contents, as long as they remain in a fluid condition, frequently stirred with a piece of iron wire, which is allowed to remain in the crucible. The decomposition progresses rapidly, and the potassium hydroxide together with the soluble products of the decomposition soon begins to rise upon the sides of the crucible, where it deposits itself in forms somewhat resembling the cauliflower. Within two or three hours the decomposition is complete, and the bottom of the crucible becomes dry. The crucible is then turned upon its side and the temperature of its under surface raised to a dull red heat. The incrustation on the interior of the crucible does not fuse at this temperature, but becomes rapidly yellow, owing to the oxidation of the chromium to chromate. At the end of two or three hours the oxidation is perfect. Portions of the incrustation retain a greenish colour, however long the heating is continued; but this is due to the presence of iron or manganese and not to unoxidised chromium.

After cooling, the crucible is placed in a porcelain evaporating dish and the contents removed by means of hot-water. The solution, which at first has a greenish appearance owing to the presence of iron dissolved in the caustic potassa, is heated for some time in order to effect complete precipitation of the iron. The filtrate, which has a clear yellow colour, is rendered slightly acid with pure dilute nitric acid, the aluminum precipitated with ammonia and washed by decantation. The chromate of potassium is then reduced and the silica rendered insoluble by evaporating to perfect dryness with an excess of hydrochloric acid. The residue is moistened with hydrochloric acid and treated with water.

It only remains to separate the chromium in the filtrate from magnesium and to determine it as chromic oxide. To do this we have preferred in each instance to first precipitate with barium carbonate.

We give here the data of twelve determinations upon material whose origin is unknown to us. Four of these (1 to 4) were made by ourselves, four (5 to 8) by Mr. A. G. Palmer, and the remainder (9 to 12) by Mr. W. S. Bayley, both students in this laboratory. The analyses reported were in each case made consecutively.

	Wt. of Ore Taken.	Wt. of Cr_2O_3 Found.	Percentage.
1.	0·3250	0·1343	41·32
2.	0·3465	0·1433	41·35
3.	0·3248	0·1343	41·36
4.	0·3383	0·1392	41·14
5.	0·2723	0·1120	41·12
6.	0·3955	0·1629	41·19
7.	0·3311	0·1358	41·02
8.	0·3285	0·1290	41·23
9.	0·3387	0·1392	41·10
10.	0·2995	0·1235	41·25
11.	0·3606	0·1478	41·00
12.	0·3007	0·1236	41·11

In order to assure ourselves that complete decomposition and oxidation had been effected, the same method of treatment was applied to the iron and aluminum precipitates as to the original material. This was done in the case of nine of the analyses here reported. But in no case was there any trace of chromium obtained from them. The average loss of the iron crucibles is about 0·2 grm. Much coarser material can be successfully analysed by this than by the other methods in use. Its simplicity and economy also recommend it.

The only method on record, so far as we know, involving the use of potassium hydroxide for the decomposition of chrome iron ore, is that proposed by H. Schwarz,* who recommended fusion with potassium hydroxide in a silver crucible and addition of potassium chlorate to the fused mass. The decomposition by this method is doubtless easy and complete, but the rapidity with which the crucible is destroyed renders the method wholly impracticable.—*American Chemical Journal.*

Johns Hopkins University, May, 1881.

NOTE ON SULPHURETTED HYDROGEN.

By P. CASAMAJOR.

In 1873, Mr. William Skey, Analyst to the Geological Survey of New Zealand, published some interesting observations† on the production of sulphuretted hydrogen when a voltaic couple is formed with zinc as the positive, and a metallic sulphuret as the negative plate. When placed in contact with zinc or in communication with this metal, by means of a wire, many sulphurets give sulphuretted hydrogen very freely with sulphuric acid or hydrochloric acid, which alone would not give any in contact with these acids. This happens with galena and sulphuret of copper. I have had occasion lately to apply these researches of Mr. Skey to the production of sulphuretted hydrogen from sulphuret of iron, which refused to give it in presence of sulphuric acid diluted with ten times its volume of water. I believe that the greater part of the sulphuret of iron sold to chemists possesses this resistance to acids. I have lately found none that gave sulphuretted hydrogen easily, and I had accumulated several pounds possessing this undesirable quality.

After a few trials I was able to obtain an abundant supply of sulphuretted hydrogen from any sample of sulphuret of iron by proceeding as follows:—

Enough mercury is put in a bottle to cover the bottom entirely. Over this, diluted sulphuric acid is poured, and some pieces of zinc are thrown in, which immediately sink into the mercury, forming a zinc amalgam with great excess of mercury. No action takes place between the zinc and the acid. If, now, a few pieces of sulphuret of iron are thrown in the bottle, they will sink to the mercury, and a copious production of sulphuretted hydrogen will take place from the surface of the sulphuret. This production will continue with remarkable regularity until either the zinc, the sulphuret of iron, or the sulphuric acid is exhausted. As to the mercury, it only intervenes indirectly in the reaction, and it does not require to be renewed.

In place of sulphuret of iron, I have tried galena, iron pyrites, and copper pyrites. These all give sulphuretted hydrogen, but very slowly. With galena, the action soon ceases, as the mineral becomes coated with sulphate of lead. By leaving galena in contact with liquid zinc amalgam for several hours, the surface of the mineral becomes coated with a bright coat of lead amalgam.

With iron and copper pyrites, comparatively little sulphuretted hydrogen is given off, but there is a considerable production of hydrogen. In this case the sulphurets act mainly as conductors, in the same manner as a piece of retort carbon.

† CHEMICAL NEWS, vol. xxvii., p. 161.

ON MICROLITE FROM AMELIA CO., VIRGINIA.

By F. P. DUNNINGTON.

The mineral which is the subject of this examination was collected at the mica mines, two miles north of Amelia C.H., by Prof. W. M. Fontaine of this University, who gives the following notes of its occurrence and associations:

"This mineral occurs with others imbedded in a vein of 'Gigantic Granite' (so called because of the essential minerals of the granite being crystallised in large masses), which is enclosed in gneiss and mica schist, with the general characters of the Montalban series. Schorl is very abundant in the adjoining wall-rock.

"The associated minerals are as follows:—

"Beryl, abundant, sometimes in large crystals eight to ten inches in diameter; fluorite and columbite not uncommon; amethystine quartz, occasional; apatite, rare. In addition to which are the large crystal masses composing the vein, quartz, orthoclase,* and mica (of which last the sheets are frequently three feet across, and for which the vein is worked)."

Prof. Fontaine presumed the mineral in question would prove of interest, and handed it over to me for further examination, the result of which is as follows:—

It is found in single crystals varying in dimensions from one-tenth to three-quarters of an inch, and in larger crystalline masses of which one was obtained weighing *eight pounds*. It occurs crystallised in octahedra of the isometric system, some of the edges of which measure two centimetres; the face 1 is principally developed, and with it are the truncations made by O, 3-3 and *i* (Dana).

It has the following properties:—Hardness a little less than 6; specific gravity, 5·656; lustre, glistening resinous; colour, wax yellow to brown; streak, pale ochreous yellow, subtranslucent; fracture conchoidal and very brittle.

Heated in a closed tube it decrepitates and gives off a little water. When ignited it glows momentarily as if taking fire. Before the blowpipe it colours the flame a reddish yellow, is infusible, and on cooling is coloured pale yellow, and is without lustre. With the borax bead, and also with that of salt of phosphorus, in both flames it gives a glass yellowish when hot, colourless when cold. In both flames the saturated bead of salt of phosphorus is yellow when hot and greenish yellow when cold. It is not attacked by strong hydrochloric acid, but is decomposed slowly by concentrated sulphuric acid and also by fusion with caustic potash. It is readily decomposed by fusion with acid potassium sulphate. Fused with potassium nitrate and sodium carbonate, it does not give the manganese reaction. The moist metallic acids boiled with hydrochloric acid and tin afford a pale blue colour.

The finely pulverised mineral was fused at a low red heat in a platinum crucible with eight parts of acid potassium sulphate. Four portions of about two grms. each were thus fused, and all the constituents except the acids, alkalies, and water, were then determined from the sum of these = 8·3370 grms. of the mineral.

The metallic acids, insoluble in dilute hydrochloric acid, were well washed and then digested with yellow ammonium sulphide and washed, and then *separately* washed with dilute hydrochloric acid, and finally washed with water. The oxides of tin and tungsten obtained from the ammonium sulphide solution were weighed together, then fused with sodium carbonate and a little potassium cyanide and washed. The tin dissolved out by hydrochloric acid, re-precipitated by hydrogen sulphide, washed, ignited, and weighed, the tungsten being obtained by difference.

The insoluble metallic acids were treated with hydrofluoric acid and acid potassium fluoride, HKF_2, and the double salt, $2KF,TaF_5$, crystallised out according to Marignac's process; the crystals obtained were washed free of niobium and then dissolved and re-crystallised. The washings and mother-liquors were evaporated to a small bulk

And from another portion :—

Ta_2O_5,† 5·189

Nb_2O_5, 0·577. Sp. gr. 4·20, and after prolonged ignition = 4·23.

giving the ratio 9 to 1.

The mean of these determinations gives the ratio by weight :—

Ta_2O_5 to Nb_2O_5 = 8·84 to 1.

If these oxides when mixed do not change their volume on ignition, the mixed acids as separated should have had sp. gr. = less than 7·6, whereas after prolonged ignition they had sp. gr. = 7·86. I propose therefore to further examine this apparent combination of so closely related elements.

All the above specific gravities were taken between 11° and 14° C., and referred to water at this temperature.

The cerium metals proved to be present in too small amount to admit of accurate separation; they consist in about equal portions of cerium and didymium, and probably entirely of these, as lanthanum was not identified.

None of the lines attributed to erbium were found with the earths of the yttria group.

A portion dissolved in sulphuric acid under carbon dioxide decolourised a very little potassium permanganate, corresponding in amount to and probably due to the cerium as cerous oxide (C_2O_3); therefore the uranium and iron are taken as Ur_2O_3 and Fe_2O_3.

Fluorine was estimated by the volumetric method of Mr. S. L. Penfield,‡ and since, in order to decompose the mineral, the sulphuric acid was heated to 175° C., and for many hours, I took special precautions to condense the volatilised sulphuric acid and then deducted the minute amount of sulphuric acid found in the titrated liquid.

The water was given off below a red heat.

No trace of lead or of manganese was found.

The analysis gave the following results :—

Ta_2O_5	68·43
Nb_2O_5	7·74
WO_3	0·30
SnO_2	1·05
CaO	11·80
MgO	1·01
BeO	0·34
U_2O_3	1·59
Y_2O_3	0·23
Ce_2O_3 } Di_2O_3 }	0·17
Al_2O_3	0·13
Fe_2O_3	0·29
Na_2O	2·86
K_2O	0·29
F	2 85
H_2O	1·17
	100·25
Deduct O replaced by F	1·20
	99·05

Considering the bases as replacing equivalent amounts of calcium and neglecting the water, we have the following atomic relations :—

Ca.	Ta.	Nb.	Sn and W.	F.	O.
32·9	30·9	5·8	0·83	15	118·6

If we exclude the Fe_2O_3 and Al_2O_3 as uncombined, as they most probably are, the following formula may be deduced :—

$$\begin{cases} 3(Ca_2Ta_2O_7) + NbOF_3 \\ m(CaWO_3) \end{cases}$$

It may be remarked that in *most* of the reported analyses of pyrochlore the fluorine and alkaline metals nearly correspond in number of atoms, which is clearly not so in this case, while the relation between the niobium and fluorine points to the association of these elements under the familiar form of $NbOF_3$.

To some of the analyses of pyrochlore, considered by Prof. C. Rammelsberg in his extended paper* on tantalates and niobates, he assigns the formula :—

$$\begin{cases} m(R_2Nb_2O_7) \\ n(RTiO_3) \\ o(NaF) \end{cases}$$

From the results of the above analysis and also from its crystalline habit, it therefore appears that this mineral is the one which has been described by Prof. C. U. Shepard as microlite, although it proves to have a composition different from that originally supposed by him, and corresponding to that suggested by Prof. Brush, viz., essentially a calcium tantalate.

The minute size of the crystals in which it was previously found fully warranted the name microlite, but in view of the present facts it appears rather inappropriate.† —*American Chemical Journal*, May, 1881.

University of Virginia, April, 1881.

* Containing some Ta_2O_5. † Containing some Nb_2O_5.
‡ *American Chemical Journal*, i., 27.

* *Journal Chem. Soc.*, Series 2, x., 203.

† A private communication from Prof. E. S. Dana informs me of a recent analysis by Nordenskiöld, of a mineral from Utö, in size of crystals a true microlite, who found in it :—$Ta_2O_5(Nb_2O_5)$, 77·3; SnO_2, 0·8; CaO, 11·7; MuO,FeO, 7·7; MgO, 1·8; total, 99 3.—F.P.D.

NOTICES OF BOOKS.

Annual Report of the Board of Regents of the Smithsonian Institution for the Year 1879. Washington : Government Printing Office.

This volume contains in addition to a number of memoirs dealing with ethnological and archæological subjects, a biography of James Smithson, whose merits as a chemist, physicist, and mineralogist, the friend and associate of such men as Davy and Wollaston, have been remarkably overlooked in this his native country. He is often considered to have been an Englishman who had become naturalised in the United States. The fact is, on the contrary, that his long life was pased in this country and on the Continent, and that he had not a single correspondent in America. Like his friend Cavendish, he had, at one time, intended leaving his fortune to the Royal Society, but some slight difference with the Council led him to alter his determination.

Perhaps the most important paper in this volume, from our point of view at least, is the course of lectures on "The Present Fundamental Conceptions of Physics," as delivered by Prof. Pisko, at Vienna. On the statement that "one single natural force, or rather one single original universal motion, is recognised, which manifests itself as cohesion, adhesion, chemical affinity, gravitation, heat, &c.," the editor remarks, "This hypothesis is a remarkable instance of premature generalisation. In the Smithsonian Report for 1876 (pp. 275 to 279) reasons were given for believing that gravitation cannot be resolved into any form of *motion*, and further, that without an inscrutable "force" underlying all motion and antecedent to it, no rational conception of dynamics is possible. Without the ultimate fact of elasticity in material elements, neither transformation of motion nor conservation of energy could have any conceivable basis."

Spon's Encyclopædia of the Industrial Arts, Manufactures, and Commercial Products. Division IV. Edited by Charles G. Warnford Lock. London: E. and F. N. Spon.

This division includes not a few heads of great importance to the industrial chemist, such as inks, leather, manures, matches, mordants, oils and fats, perfumes, &c.

The article on inks includes black writing ink, copying-ink, coloured inks, sympathetic ink, marking ink, printing, engraving, and lithographic inks. Under the head writing inks it might have been useful to point out the distinction between such as are perfect solutions, and such as contain more or less insoluble matter in a state of suspension. In the latter class, gum, or some similar body, is necessary to prevent the colouring-matter from subsiding. In those inks, on the contrary, which are true solutions, gum is, to say the least, absolutely useless.

Under "Jute" we find reference to recent improvements in the methods of dyeing, which, however, are not described.

The article on leather and its manufacture is carefully and elaborately compiled; the morphology and the chemical composition of hides are treated at some length, and with the aid of several illustrations. We do not, however, find any mention of the respective parts played by tannin and by phlobaphene; nor is the newly-introduced system of chrome-tannin discussed.

Manures, natural and artificial, are very fully described. The fish guanos of Norway are stated to contain 25 to 30 per cent tricalcic phosphate, and 7 per cent of nitrogen. We have met with samples containing 10 per cent and upwards. Concerning blood, the writer pronounces it "difficult to remove even a portion only of the water."

An excellent and elaborate account is given of the phosphates occurring in commerce, with their localities, and their percentages of phosphoric acid.

The article on matches deals chiefly with the mechanical part of the manufacture. We find no reference to the use of amorphous phosphorus, recommended as preferable to ordinary phosphorus on sanitary grounds, nor to the still better proposal to dispense with phosphorus altogether, thus preventing the waste of plant food.

The section on "mordants" is of a practical character, and gives as much sound information as the space will allow.

Under the head "Narcotics," we find much interesting matter. It is singular to find what a prodigious quantity of soil and of plant food is taken up in the production of articles which can scarcely be said to supply any real want of the human system, and none of which were consumed by the most civilised nations of antiquity.

It is an unfortunate circumstance that the cultivation of narcotics is more remunerative than that of food-plants. In India, wheat and other cereals in the best soils pay 3 rupees per beegah of land, whilst poppies pay from 10 to 20 rupees, and even higher sums. The peasantry engage in the culture of their own free will, and are well remunerated. Both the people and the government must, however, look forward to the loss, or the great curtailment, of this trade in no distant future. Persia has entered the Chinese market as an eager competitor, and exports to that country an increasing quantity of opium, which in 1879 had already reached the value of five millions sterling. China herself, which we are sometimes told is anxious to put a stop to the importation of opium, produces five million lbs. weight annually, importing from India and Persia about 12 million lbs. The writer observes: "Though the abuse of the drug leads to evil consequences—by no means equalling, however, those of the abuse of alcohol in this country—its moderate use is extremely beneficial, if not absolutely necessary, in the malarial climate of China, where almost the whole is consumed, and the immunity of opium smokers from diseases of the bronchial tubes and lungs, so common among non-smokers, is remarkable. The real remedy for excessive opium smoking in China lies in the development of the resources of the country, enabling the inhabitants to occupy healthy houses and consume wholesome food; the abuse of opium would then die out of China, as the abuse of laudanum died out of Lincolnshire after the fens were drained. An antidote for opium smoking is the use of coca."

We must add the remark that the abuse of laudanum still flourishes in some districts of Lincolnshire, *e.g.*, Horncastle, unless a great change has taken place within the past ten years.

The article on oils and fats is exceedingly elaborate and valuable. We have only space to make the suggestion that a trifling addition of salicylic acid—too small to affect the flavour—would very probably enable palm oil to be brought over to this country free from rancidity. Nothing more is wanted to enable it to rank as an article of diet decidedly superior to the mixtures of animal fats now so largely used as a substitute for butter.

We are very happy to testify to the value of Spon's Encyclopædia as a work of reference.

CORRESPONDENCE.

ON A NEW METHOD FOR THE ESTIMATION OF NITRATES IN POTABLE WATER.

To the Editor of the Chemical News.

Sir,—Your correspondent, Mr. William Johnstone, does not appear to be able to distinguish between a qualitative test and a quantitative estimation.

In my paper, read before the Society of Public Analysts in March last, I described a method of estimating nitric acid in water by means of the brucine reaction, and so far as I am aware, the brucine reaction has never previously been made quantitative. If Mr. Johnstone will carefully read the paper of Mr. E. Nicholson (Chemical News, vol. xxv., p. 89) that he quotes from, he will find that it is nothing more nor less than a qualitative test, well known to analysts. The author does indeed state that he hopes before long to give a process for the quantitative estimation, but such process has never been given, until the appearance of my paper. In what way, then, my process is only a slight modification of Mr. Nicholson's, I am at a loss to conceive.

I am perfectly aware that many analysts have been in the habit of using the brucine test daily in water analysis, as giving a rough indication of the amount of nitrates present, but that in no way affects my method, which is, in fact, the only one that has been devised for estimating nitric acid, based on the brucine reaction.—I am, &c.,

J. West Knights.

Camtridge, July 13, 1881.

BETA-NAPHTHOL-SULPHONIC ACID.

To the Editor of the Chemical News.

Sir,—In the Chemical News, vol. xliii., p. 288, there is an account of an interesting description, given by Dr. Armstrong to the Chemical Society on June 16th, of a new isomeric beta-naphthol-sulphonic acid, obtained by Dr. Armstrong and Mr. Stallard, by dissolving beta-naphthol in cold concentrated sulphuric acid, and of the derivatives obtained from it by the action of bromine and nitric acid. Will you allow me to state that on March 21, 1881, I filed a Provisional Specification, and on June 21 obtained Letters Patent, dated March 21, 1881, for "Improvements in the Manufacture of Colouring Matters suitable for Dyeing and Printing, and in the Preparation of a New Mono-sulfo-acid of Beta-naphthol and its Salts and Derivatives," a communication to me from abroad from Mr. Carl Rumpff, of Elberfeld (senior partner of Messrs.

Friedrich Bayer and Co), to whom this Patent, together with a subsequent one following up the invention, has been assigned. The Specification describes the preparation of the new acid by the action of strong sulphuric acid on beta-naphthol at ordinary temperature, the mixture heating spontaneously with great rapidity, and requiring to be kept down to below 50° to 60° C., as, if the temperature rise only a few degrees higher, and there be an excess of sulphuric acid present, the new mono-sulpho-acid passes with rapidity wholly over into Schaefer's acid (which is always produced along with it). The new acid is distinguished in the Specification from Schaefer's by the temperature of formation; by the difference of its behaviour to nitric acid (giving, as Schaefer's does not, separable nitro products, the potassium salts of which are crystallisable compounds, dyeing wool and silk of a beautiful yellow); and by the different solubilities of the neutral soda salts of the two acids in spirits of wine at 90°, the salt of Schaefer's acid being nearly insoluble therein, while that of the new acid, on the contrary, dissolves with great facility, settling, as the alcohol cools, in fine large and extremely hygroscopic crystals, which contain spirit. The new acid gives with the diazo and tetrazo bodies a series of colouring matters fast against soap and light, the shades of which are, on the whole, yellower than those of the azo and diazo-azo dyes prepared from the common beta-naphthol-mono-sulpho-acid. The new acid also forms dyes in a variety of other combinations analogous to those in which the isomeric beta-naphthol-disulpho-acids have already been employed.

I do not doubt the identity of the new acid patented by me with that independently (but subsequently) discovered by Dr. Armstrong and Mr. Stallard. I mentioned to Dr. Armstrong some time ago, when he told me of his discovery, that I had already patented the new acid and its nitro-products and colour-combinations, and I now wish, on behalf of Mr. Rumpff, to mention the prior discovery and the patents, in case colour manufacturers should suppose that the preparation and applications of the new acid are open to the world.—I am, &c.,

J. A. Dixon.

175, W. George Street, Glasgow.
June 16, 1881.

CHEMICAL NOTICES FROM FOREIGN SOURCES.

Note.—All degrees of temperature are Centigrade, unless otherwise expressed.

Zeitschrift für Analytische Chemie.
Vol. xix., Part 4.

Methods for Determining the Permeability of Soils.—F. Seelheim.—An illustrated memoir exceeding thirty pages in length, and not capable of abstraction.

Determination of Sulphur in Sulphur Ores.—G. Lunge.—The author considers the process of Fresenius (*Zeitschrift*, xvi., 339) too tedious except for use in disputed cases. He gives an experimental justification of his method as described in his "Treatise on the Manufacture of Sulphuric Acid and Alkali," i., p. 92, as sufficiently accurate for the laboratories of manufacturing establishments. He particularly recommends the funnels made by Oppermann, of Hohenbüchen, near Delligsen, and the filter-paper of Rieckmann, in Hanover, as economising time, and rendering the use of a water air-pump or a Piccard's filtering arrangement superfluous.

Determination of Ash in Coal and Coke.—A. Wagner.—If coal is heated at first very gently the residue may be perfectly incinerated in a platinum crucible in a few hours' time by the heat of a common gas-burner. Samples very rich in ash may require the use of the blast towards the end of the process. Coke requires to be ignited in a muffle furnace.

Trustworthiness of the Analyses of the Gases of Smoke.—A. Wagner.—The author points out several sources of error by which the results must be vitiated to an appreciable extent.

Analysis of Gunpowder.—A. Wagner.—The author considers that the fear expressed by R. Fresenius lest, on drying the residue at 100°, after dissolving out the saltpetre, a little sulphur may be volatilised, to be needless.

Gravimetric Method of Determining Phosphoric Acid.—Dr. B. Peitzsch, Dr. W. Rohn, and Dr. P. Wagner.—Already inserted.

A Simple Apparatus for Collecting the Nitrogen in Volume-Determinations.—W. Städel.

A Simple Aspirator.—Fried. Lux.

Flavescine; a New Indicator.—Fried. Lux.

Preparation of Hydrochloric Acid.—Dr. L. L. de Koninck.—These four memoirs cannot be reproduced without the accompanying cuts.

Solution of Bromine as a Reagent.—Dr. L. L. de Koninck.—Already inserted.

Method for the Qualitative Separation of Cobalt and Nickel.—Fr. Reichel.—Already inserted.

Extraction-Apparatus.—O. Scheibler.—This apparatus is destined for extracting beet-root with alcohol, for the determination of sugar. It agrees in principle with that of Tollens (*Zeitschrift*, 17, 329).

Self-acting Washing Arrangement.—Jean de Mollins.—This apparatus cannot be described without the accompanying illustration.

The Determination of Coloured Acids.—F. Salomon.—The author makes use of an apparatus resembling in principle Scheibler's calcimeter, the acid being allowed to act upon a bicarbonate, and the liberated acid being measured.

Determination of the Melting-point of Organic Compounds.—G. Röster.—Taken from *Berichte der Deutsch. Chem. Gesell.*, 13, 580.

An Improved Pinchcock.—MM. Knies and v. Jüptner.—From *Chem. Central-blatt*, 3rd Series, 11, 179.

Occurrence of Gold Chloride in Commercial Solutions of Platinum Chloride.—W. Gintl.—This impurity may amount to 3 per cent, and may occasion errors in the determination of potash. The author recommends that such solutions should be repeatedly shaken up with ether, which dissolves all the gold chloride and but little of the platinum salt. From the ethereal solution the gold is recovered by evaporation, and is then re-dissolved in chlorine water.

Impure Sulphuric Acid.—W. Gintl has found in acid purchased as "pure" as much as 5 per cent of ammonia. F. Selmi shows that for the entire removal of arsenic from sulphuric acid it is necessary to treat with hydrogen sulphide, to dilute the clear residue with half its volume of water, and to rectify over lead chloride.

Adulterations of Coffee.—H. Hager.—The author gives instructions for the detection of dyed, sea-dipped, and factitious coffee beans in the raw state, and for the recognition of chicory, lupines, acorns, &c., in roasted and ground coffee. The seeds of *Cassia occidentalis*, which have been recently introduced as an adulterant, are detected microscopically by their smooth, polished surface.

Determination of Ash in Gun-cotton.—M. Hess.—The author melts pure paraffin in a platinum capsule, adds a weighed quantity of gun-cotton, and ignites it when saturated from above. The contents of the capsule burn as quietly as pure paraffin. The carbonaceous matter remaining is then incinerated.

Examination of Morphine Hydrochlorate.—H. Tausch.—The pure salt can be heated without decompo-

sition or change of colour to 130°, at which temperature impure specimens turn brown.

Contributions to the Quantitative Spectral Analysis of Blood.—M. Hufner.—The quotient $\frac{Ao}{Ao'}$ has the same value for crystalline oxy-hæmoglobin and for diluted blood; Ao denoting the absorptive ratio for the region—

D 32 E – D 53 E,

and Ao' that for the region D 63 E – D 84 E.

Determination of Urea by means of Sodium Hypobromite.—M. Fauconnier.—In presence of grape-sugar urea yields the theoretical quantity of gas as stated by Méhu. The latter proposes to add to the urine, sugar equal to ten times the weight of the urea present.

Determination of Hippuric Acid in Urine.—M. Lœbisch.—An examination of the process of Cazeneuve.

Determination of Acetic Ether in Urine.—M. Quincke.—The author makes use of a calorimetric process based on the dark red colour produced by an addition of ferric chloride. He doubts, however, the identity of the compound found in urine with ethyl-diacetic acid.

Occurrence of Glycerin-phosphoric Acid in Normal Human Urine.—M. Sotnitschewsky.—This acid, though in very small quantities, belongs to the constant ingredients of urine.

Volatile Phenols in Urine.—M. Brieger.—These phenols are chiefly para-cresol with small quantities of phenol and traces of ortho-cresol.

Occurrence of a Reductive Agent in Urine after Ingestion of Sodium Benzoate.—M. Salkowski.

Demonstraion of Preformed Urobiline in Urine.—M. Salkowski.

Justus Liebig's Annalen der Chemie, Band 205, Heft 3.

Amidoid Derivatives of Hydroxylamin. — This memoir consists of three portions: on ethyl-hydroxylamin and the determination of the vapour-density of some of its derivatives, by Dr. O. Gürke; a paper by the same author on α- and β-dibenz-hydroxamic ethyl-ester, and α- and β-ethyl-benz-hydroxamic acid, being a contribution to the knowledge of so-called physical isomerism. On his results Prof. Lossen remarks that the existence of such bodies as the modifications of one and the same hydroxylamin derivative does not justify the assumption that metamerism, *i.e.*, difference of properties along with similar composition and identical molecular weight, may exist in such compounds in which the concatenation of atoms within the molecule is perfectly identical. The third portion of the memoir by Dr. Lassar Cohn treats on the conversion of phthalic acid into salicylic acid.

Examination of the Constitution of Certain Alkaloids of the Cinchona Barks.—O. Hesse.—Not capable of useful abstraction.

Propionyl-quinine.—O. Hesse.—This compound forms large, colourless, hexagonal prisms, belonging to the rhombic system, fusible at 129°; rather easily soluble in ether, alcohol, and chloroform, and very sparingly in water. The alcoholic solution on the addition of chlorine and ammonia takes an intense green colour, and if then boiled with potassa the base is resolved into quinine and propionic acid.

Australian Alstonia Bark.—O. Hesse.—The author has isolated and described the bases alstonine (chlorogenine), porphyrine, and alstonidine, and considers that other alkaloids are likewise present.

Gay-Lussac's Hypo-chloro-nitric Acid.—H. Goldschmidt.—It appears from the author's experiments that a compound $NOCl_2$ does not exist among the distillation products of *aqua regia*. What Gay-Lussac regarded as hypo-chloro-nitric acid is merely nitrosyl chloride, having absorbed free chlorine in variable quantities.

Biedermann's Central-Blatt für Agrikultur-Chemie, Vol. ix., No. 10.

The Solid Constituents of Sea-water. — Ludwig Schmelck.—In the mother-liquor obtained by evaporating down 20 litres of sea-water iodine was detected according to Kœtstorfer's method. The proportion of organic matter, as determined by permanganate, is 0·0025 per cent.

The Permeability of the Soil for Air.—G. Ammon.—If soil is slightly moistened it is rendered more permeable for air. Frost diminishes the permeability of the soil, the more in proportion to its degree of moisture.

The Pollution of the Soil in Paris.—H. Ste.-Claire Deville.—From the *Comptes Rendus*.

Manurial Experiments on Potatoes.—Dr. J. Fittbogen.—Not adapted for abstraction.

Experiments on the Relative Value of Precipitated Phosphoric Acid and Soluble Phosphoric Acid.—Dr. A. Emmerling.—In the loamy soils of Holstein phosphoric acid in the form of precipitated phosphate has approximately half the value of phosphoric acid in the form of superphosphate. On moor soils there is little difference.

Analysis of Cocoa-nut and Palm-nut Meal.—Prof. A. Petermann.—Cocoa-nut meal contains 19·16 per cent of proteine compound; palm-meal 14·98 per cent.

The New Milk-tester.—M. Mittelstrass and C. Jenssen.—This instrument determines the quality of milk by its opacity. The portion operated upon is a mixture of 2 c.c. of milk with 98 c.c. of water. The indications of the apparatus are said to agree with the results of analysis to 0·3 per cent of fatty matter.

Nutrition of the Lower Fungi by the Compounds of Carbon and Nitrogen.—Von Nägeli and O. Loew.—Liebig's assumption that the lower fungi can be nourished merely by albumenoid compounds has been already refuted by Pasteur. The authors find that they can assimilate nitrogen from all the amides and amines, the ammoniacal salts, and in some cases the nitrates. Free nitrogen and the nitrogen of cyanogen and the cyanides is not directly assimilated. Zygomycetes and schizomycetes assimilate nitric acid. Fungi can derive carbon even from certain antiseptics, such as alcohol, phenol, salicylic acid, and benzoic acid.

Vol. ix., No. 11.

Shot-ice in the Wiener Wald.—Dr. J. Breitenlohner.—An account of an incrustation of ice formed upon trees in the neighbourhood of Vienna, on Jan. 27, 1879.

Proportion of Ammonia in the Air and in Certain Waters.—A. Levy.—From the *Comptes Rendus*.

Researches on the Carbonic Acid in the Ground Air.—Prof. E. Wollny.—The proportion of carbonic acid as a rule rises and falls with the organic matter present in the earth.

Chemical Examination of the Arable Earth and the Sub-soil from Eight Places of the Black-Earth Region and the Adjacent District.—Prof. C. Schmidt.—Not adapted for abstraction.

Results of Manuring with Dicalcium Phosphate upon a Soil free from Humus.—H. Albert and Dr. Siegfried.—In such soils the plant prepares a solution of phosphoric acid from the neutral phosphate of lime by the action of its own roots. Manuring with dicalcium phosphate with or without potash improves the harvest both in quality and quantity. Potash and phosphoric acid increase the percentage of nitrogenous compounds.

The Acid of Milk.—E. Marchand.—The author ascribes the acid reaction of fresh milk drawn from healthy cows to the presence of 2 parts per thousand of lactic acid. For its observation he recommends the use of turmeric paper, or a tincture of logwood, Brazil wood, or cochineal. If litmus is used the caseine should be previously removed by the addition of 1½ to 2 vols. neutral alcohol at 90 per

cent, since caseine forms a light blue compound with litmus.

Decomposability of Nitrogenous Organic Manurial Matters.—Dr. A. Morgen.—A comparison between ground leather and ground horn, the former of which is much less easily rendered available for plant food. Ground leather is less suitable for manure and of lower value than horn powder.

The Albumenoids of Milk.—Dr. Danilewski and Dr. P. Badenhausen.—Already noticed.

Loss which Freshly-cut Grass Sustains from Moderate Rain.—Dr. A. Emmerling.—The mineral constituents are dissolved out in a much larger degree than the organic portions, and among the latter the non-nitrogenous extractive matters are removed more readily than the albumenoids.

Determination of Glycerin in Wines.—M. Raynaud.—In pure wines the separation of glycerin can be easily and accurately effected. In plastered samples the wine is concentrated to ⅛ of its volume, and treated with hydrofluosilicic acid, and then with alcohol in order to remove alkalies. Barium hydrate is then added in slight excess, the whole concentrated *in vacuo*, and the residue is exhausted with a mixture of alcohol and ether.

Vol. ix., No. 12.

Action of Water in Irrigation.—Dr. J. König.—This paper refers to irrigation with natural water. The action is said to consist in the supply of moisture, protection against the radiation of heat, the solution of plant food present in the soil, and the supply of fresh quantities of plant food.

The Absorption of Phosphoric Acid and Potash as Influenced by Chili Saltpetre.—H. Fiedler.—The absorption of phosphoric acid is promoted even by small doses of cubic nitre, whilst the absorption of potash is but little affected.

Turnip Sickness of Soils.—Prof. J. Kühn, Prof. v. Liebenberg, Prof. Marck, and Dr. G. Liebscher.—Turnip sickness is traced not to a deficiency of any ingredient of plant food, but to the multiplication of *Nematodæ*.

Researches on the Quantitative Determination of Proteine Nitrogen and the Separation of the Proteine Matters from other Nitrogenous Bodies Occurring in Plants.—Dr. A. Stutzer.—The author mixes the dissolved proteine compounds with perfectly neutral copper hydroxide free from alkali, and in this manner succeeds in precipitating the proteine compounds. Strongly diluted solution of copper sulphate is mixed with very dilute soda-lye till it reacts alkaline; the precipitate is thrown upon a large filter, washed quickly, the filter perforated, the precipitate is rinsed into a large bottle, which is filled up with cold water, and the hydrate washed by decantation till the supernatant liquid reacts perfectly neutral. The precipitate is then again placed upon a filter, let drain, pressed between blotting-paper till the greater part of the moisture is removed, and the pure blue copper hydroxide is rubbed up with water or alcohol.

The Use of the Lacto-butyrometer in Testing Milk.—Prof. G. C. Caldwell, MM. C. Jenssen, Friedländer, Schrodt, and Schmöger.—The results obtained by the use of this instrument sometimes agree with and sometimes differ from those given by direct analysis.

Philosophical Society of Glasgow (Chemical Section).—The Graham Medal, instituted in connection with this section for the encouragement of chemical research, and open to competition to all chemists, has, on the recommendation of Prof. Williamson, F.R.S., the adjudicator in the competition, been awarded to Mr. James Mactear, F.C.S., F.I.C., for a paper entitled "Some Researches on the Reactions involved in the Leblanc Process of Alkali Manufacture."

THE PURIFIED and GENERAL YEAST COMPANY (Limited).—Registered under the Companies' Acts, with limited liability.

CAPITAL £120,000 IN £1 SHARES,

Of which 38,000 Shares are taken by the Vendor, the remaining 82,000 Shares being now offered for Public Subscription, payable as follows:—1s. per Share on Application, 4s. on Allotment, and the balance when called up, but not more than 5s. per Share at one time, and at intervals between calls of at least one month. Where no Allotments are made the amount paid on application will be returned without any deduction. The expenses of the formation of the Company up to date of allotment will be borne by the Vendor.

DIRECTORS.—JOHN COWAN, Esq. (Director of the Wynaad District Gold Mining Company, Limited), 27, Walbrook, E.C.
R. H. WALLACE DUNLOP, Esq., C.B. (late Bengal Civil Service), 12, Kent Gardens, W., and E.I.U.S. Club.
Major-General H. N. HODGSON (late of the Bengal Army), 21, Maberly Road, Upper Norwood.
*THOMAS ELLIS, Esq., 80, Cornhill, London (the Vendor of the Patents).
**Will join the Board after the completion of the Assignment of the Patents mentioned below).*

BANKERS.—The Imperial Bank, Limited, Lothbury, E.C.
BROKER.—Henry Staples, Esq., 51, Threadneedle Street, E.C.

SECRETARY (pro. tem.).—Charles Akers, Esq.
Temporary Offices.—80, Cornhill, London, E.C.

ABRIDGED PROSPECTUS.

This Company is formed for the purpose of purchasing two Patents belonging to Mr. Thomas Ellis—one for purifying and extracting the bitter taste from Yeast; and the other, patented by Professor Charles Graham, D.Sc, the eminent Chemist, of University College, London, for stimulating and increasing the fermentative power of Yeast; and this Company proposes to work these Patents and to deal in purified and crude Yeasts.

By means of the joint processes, Brewers' Yeast is completely freed from the bitter taste of the hops, thoroughly purified, and its fermentative power and quickness greatly increased, and is thus converted into a substitute for the pure and powerful foreign Yeasts, but more especially German dried Yeasts, now imported into this country.

The Company's Purified and Stimulated Yeast has been tested by a large number of the principal London Bakers and Confectioners, including Messrs. Gunter and Co. (Berkeley Square), Birch, Stewart and Co., W. Buzzard, from whose Reports, given in full in the complete prospectus, it will be seen that, in their opinion, it is quite equal, if not superior, to any of the Foreign Yeasts.

The wholesale prices of the Foreign Yeasts vary from time to time, but are, as nearly as can be ascertained, equal to about £56 per ton in the cool months, rising, during the warm weather, to about £70 per ton, and even higher.

The Foreign Yeasts are re-sold by the Yeast merchants in this country to Bakers and Confectioners at from about ten to twelve pence per pound (equal to from £93 6s. 8d. to £112 per ton), and to cornchandlers and others, who retail them to the public at about one penny per ounce (equal to £149 6s. 8d. per ton).

The amount of Brewers' Yeast annually produced in this country is enormous, greatly exceeding the demand. The Company, will, therefore, always be able to obtain ample supplies of crude Brewers' Yeast at a very low price; and the cost of purifying and stimulating this Yeast is so small that, when prepared for the market, it can be sold, and with great profit, at so low a price as, it is believed, must defy competition.

The following Table shows the profits that may fairly be calculated on the Sale of Purified Yeast (wholesale) at any of the undermentioned prices:—

Cost of production of the Purified Yeast per ton.	Sold at per lb.	Equal to per ton.	Profit on each ton sold.	Equal to Per cent.
£ s. d.	d.	£ s. d.	£ s. d.	£ s. d.
14 0 0	3	28 0 0	14 0 0	100 0 0
,,	2¾	25 13 4	11 13 4	83 6 8
,,	2½	23 6 8	9 6 8	66 13 4
,,	2¼	21 0 0	7 0 0	50 0 0
,,	2	18 13 4	4 13 4	33 6 8
,,	1¾	16 6 8	2 6 8	16 13 4

The amount of the purchase money to be paid by the Company for the above-mentioned patents is £43,000, payable £38,000 in fully paid-up shares, and £5000 in cash.

The following documents can be seen at the Offices of the Solicitors of the Company:—The Agreement between the Company and Mr. T. Ellis; the Memorandum and Articles of Association; the Patents, and the Originals of the Reports, and of the Bakers and Confectioners above-mentioned.

Copies of the Prospectus, Reports, and Forms of Application can be obtained at the temporary offices of the Company, 80, Cornhill, London, E.C., or from the Solicitors, Bankers, or Broker of the Company.

IRISH HILL BAUXITE (Alum Clay).

The IRISH HILL MINING CO. are now, and always have been, the LARGEST PRODUCERS OF THIS CLAY, of Superior Quality, and supply the Manufacturers of Alum, Sulphate of Alumina, and Alum-Cake, of the United Kingdom, America, and the Continent, almost exclusively.

ANALYSIS BY JOHN PATTINSON, ESQ.

	Dried at 212° F.

A DIFFERENTIAL METHOD OF SPECIFIC GRAVITY DETERMINATION.

By W. DITTMAR.

To determine the difference in specific gravity between two liquids, the most obvious method is to determine the specific gravities themselves; and in most cases a convenient mode of doing this is to immerse a tared glass plunger successively in water Liquid I. and Liquid II., and ascertain in each case the loss of weight which the plunger suffers. But supposing the two liquids to be (say solutions) of the same kind, and of very nearly the same density (and this is the only case which I here propose to deal with), the desired difference can be obtained directly, and with a far higher degree of exactitude, by weighing a known volume of the one liquid within the other. The apparatus required are as follows:—

(1.) A cylindrical specific gravity bottle, provided with a narrowly perforated glass stopper, and a hook (above or below) for suspending it from the balance by a fine platinum wire.

(2.) A cylinder large enough to float the bottle, supposing it to be suspended in a mass of liquid within the cylinder.

(3.) A balance, so arranged that things can be suspended *below* the pans, and when thus suspended are at a convenient working height.

Modus operandi.—After having ascertained (once for ever) the capacity of the bottle for water, charge it with liquid I., suspend it from the balance within a mass of the same liquid, and ascertain its apparent weight (p' grms.)

Then repeat the experiment with liquid II. *inside*, and note down the result p''.

If the capacity of the bottle is $= v$ fluid grms., we obviously have $v(s''-s') = p''-p'$, or—

$$s''-s' = \frac{p''-p'}{v}.$$

In both weighings we must take care to give the inner liquid time to assume the temperature of the outer, *i.e.*, to postpone the final weighing until the weight has become constant.

One of the advantages of this method is that the result is relatively independent of errors in temperature. Supposing the bottle to be filled *successively* with the two liquids at intentionally the same temperature, and weighed in the ordinary way; then if the temperature of liquid II. (by error) is by (Δt), say too high, the error in weight is $-v(\Delta t)s''k$, and the error in specific gravity is $(\Delta t)s''k$, where k means the coefficient of expansion of the liquid. In our method the corresponding error (Δs) is equal to only $k(\Delta t)(s'-s'')$, *i.e.*, far less. For $\frac{s'-s''}{s''} = 0{\cdot}01$, for instance, it is only 1-100th of the error of the ordinary method.

In conclusion, I will quote a few experiments which I made for testing the method for its practical workability.

Expt. (1.)—I. = water; II. = centinormal hydrochloric acid, *i.e.*, an acid of about 0·036 per cent.

I. inside and I. outside; $p' = 5{\cdot}343$
II. ,, I. ,, $p'' = 5{\cdot}347$

$v = 23{\cdot}43$; $\therefore s'' = s' = \frac{4}{23{,}400} = 0{\cdot}00017$

The uncertainty in $p''-p'$ is about $\pm$ 1 m.grm.; $\therefore$ the uncertainty in the result is about 4 units in the 5th place.

Expt. (2.)—I. = water; II. = solution of tannin of sp. gr. 1·00336 at 21·6, as determined by a glass plunger of about 30 c.c. volume.

I. inside and I. outside; $t = 20{\cdot}4°$; $p' = 7{\cdot}267$
II. ,, I. ,, ,, $p'' = 7{\cdot}386$

The whole system left to itself for a night, next morning $t = 17{\cdot}3°$; $p'' = 7{\cdot}386$; *i.e.*, the same as before, which shows that the existing difference in the expansion, and the diffusion going on for about fourteen hours failed to tell upon the result. $v = 32{\cdot}8$; $\therefore s''-s' = 0{\cdot}00361 \pm 0{\cdot}00003$. The difference between this result and the excess over unity in the specific gravity 1·00336, as determined in the ordinary way (as far as it indicates errors), must be charged against the latter method.

Expt. (3.)—$v = 6{\cdot}3085$; 96 per cent alcohol, both inside and outside; $p = 4{\cdot}208$. Now a small quantity of water was mixed with the outer liquid, so that, by calculation, the percentage of alcohol there fell by 0·13 per cent. The bottle rose, and, after establishment of equilibrium of temperature, p'' was $= 4{\cdot}2045$. In this case, of course, the *outer* volume of the bottle must be substituted for v. The volume of the body of the bottle was estimated at about 1·67, whence v, corrected, $= 7{\cdot}98$, say 8; whence—

$$s''-s' = -0{\cdot}00044 \pm \text{about } 0{\cdot}0001.$$

$s''-s'$ by Fownes's table $= 0{\cdot}0004$.

The new method is susceptible of a number of useful applications, of which the following occur to me just now:—

(1.) Preparation of large supplies of standard solutions, supposing a small quantity of the correct solution to be at hand.

(2.) Determination of the specific gravities of waters in general, and sea waters in particular, as of dilute solutions generally.

(3.) Execution of *Hammer's* process for the determination of tannin in infusions of oak-bark, &c. (See "Fresenius's Quantitative Analysis," p. 673 of Ed. VI.) For this purpose, as I may note in passing, the method was originally invented. Experiments in this particular direction are in progress.

(4.) The examination of *butter* fat by Mr. Bell's method.

ON A CURIOUS ACTINIC PHENOMENON.

By J. CAWLEY, A.R.S.M.

ON reading a communication from Dr. Phipson upon the subject designated above (CHEMICAL NEWS, vol. xliii., p. 283), I was much struck with the great discrepancy between his results and those obtained by myself in experimenting with sulphide of zinc pigments. I should be disinclined to question his results but for the high probability that I, having been engaged in the manufacture of such pigments for several years, have made *hundreds* of experiments in connection with them where Dr. Phipson has made *one*. It will perhaps make the following remarks much more readily intelligible if I give a brief description of the method generally adopted in manufacturing sulphide of zinc containing pigments.

A solution of a zinc salt, *carefully freed* from iron, manganese, &c., is precipitated by means of a solution of an alkaline or alkaline-earthy sulphide. The resulting precipitate is dried, and ignited at a full red heat, and drawn into water, and afterwards levigated, filtered, dried, and ground.

Now, Dr. Phipson says that the sample analysed by him was *white*, but my experience has taught me that such a pigment containing over 2 per cent of protoxide of iron would be more nearly *black*. And I am really puzzled to understand how barium sulphide and protoxide of iron could exist side by side in *prolonged* contact with water

without any blackening taking place. And I am still more deeply puzzled to know how barium sulphide could *occur* in the finished pigment. In the process of manufacture care is *always* taken to have a slight excess of zinc salt. If barium sulphide were in even slight excess much trouble would ensue, and a pigment of *maximum* whiteness could not be obtained. Moreover, in the process of ignition—or, as it is improperly called, calcination—notable quantities of zinc sulphates, and in some cases chloride of zinc, are formed, and these on drawing the pigment into water, pass into solution. Now I must confess that I cannot imagine how barium sulphide can remain in *prolonged* contact with a hot solution of a zinc salt without being destroyed.

Dr. Phipson is of opinion that the discolouration is connected with the presence of barium sulphide in the pigment, but I have found that the pigment *may* be just as sensitive to light if no barium salt be used. So far, too, from the dark substance being soluble in acetic acid, I have found that it is readily formed in the presence of that acid. Under a given set of atmospheric conditions I find that a sheet of glass exerts no *sensible* protective action, while Dr. Phipson claims that such protection was complete.

In conclusion, let me say that I have made a large number of experiments on this interesting subject, and I shall be glad to give a brief account of them and the inferences drawn therefrom if our Editor will afford me the necessary space.

Newark, N.J., U.S.A., July 6, 1881.

ON SEWAGE IN OYSTERS.*

By CHARLES A. CAMERON, M.D., M.K.Q.C.P.I.

Large numbers of oysters collected by dredges off the coast of the county of Wexford are laid down in "beds" on the northern shore of the Bay of Dublin. When fully developed in these "Clontarf beds" they are removed for consumption to Dublin and other places. Formerly the Clontarf oysters were thriving molluscs, but during late years they have not done well, and great numbers of them die shortly after their translation from their native habitat.

Owing to the recent construction of many large sewers, the contents of which are discharged into the northern side of Dublin Bay, and also owing to the rapid development of the water-closet system in Dublin and its suburbs, the water of the Bay is yearly becoming more polluted with excrementitious and other offensive matters. These obnoxious substances are thrown up on the fore-shores of the Bay. The river Liffey, which is the chief carrier of filth to the Bay, is steadily becoming more and more polluted. It is only a generation ago when mullets and other edible fishes were numerous in the river, where now they are rarely seen. Near the estuary there were numerous beds of oysters, which have become extinct, partly owing to their sites being now the "berths" of ships, but also owing apparently to the great pollution of the river.

An examination of some oysters taken from Clontarf and of the water which covered them has afforded rather startling results. The oysters—a large and coarse variety—were taken from a place where the tide covers them to a height of about ten feet, and which during low water is nearly dry. In most of the oysters the brine had no peculiar odour, but in a rather large proportion there was a very slight, but distinctly fœtid odour, whilst in a few cases there was a strong and unmistakable odour of sewage. Examined microscopically the liquid in the oysters which had a fœtid odour was found to swarm with micrococci and other low organisms similar to those usually present in sewage.

* From the Report on Public Heath, July, 1881. Reprinted from the *Dublin Journal of Medical Science*.

The sea-water taken at the oyster beds when the tide was fully in was subjected to chemical analysis, and the following were the results arrived at:—

One imperial gallon (70,0000 grs. weight) contained, in addition to water—

	Grains.
*Volatile matter at a red heat	303·000
Fixed substances at ,, ...	2110·000
Total solid matters	2413·000
*Yielding—Albumenoid ammonia ..	0·009
Saline ammonia	0·010

One gallon of the water taken, when the tide was fully out, from little pools containing oysters, was found to contain the following, exclusive of pure water—

	Grains.
*Organic and volatile matters	242·000
Fixed mineral substances	1406·000
Total solid matters	1648·000
*Yielding—Albumenoid ammonia ..	0·090
Saline ammonia	0·300

Thus it will be seen that the albumenoid ammonia was ten times, and the saline ammonia thirty times, more abundant in the water taken when the tide was out, clearly proving that it was in great part composed of sewage.

The large amount of solids in the "low water" may be accounted for by the evaporation of the surface water—the weather at the time being warm—concentrating the saline matter in the remaining water. The water taken when the tide was out had a decidedly sewage odour, and teemed with low forms of life.

Marine crustacean and molluscous animals are amongst the most active scavengers of our coast; they devour not only animalcules, but also particles of dead animals and vegetable matter contained in the water. In the case of crustaceans, this decomposing organic matter becomes reorganised into living tissue, and, therefore, these animals furnish wholesome food to man. Lobsters and crabs are also always cooked before being eaten. Oysters, cockles, mussels, and other lamellibranchiate molluscs are often eaten uncooked, and their shells enclose a liquid which is more frequently drank uncooked than cooked. Although oysters when deserted by the tide instinctively keep their valves closed, they do not invariably do so, and, therefore, at low water, sewage trickling down the shore is likely to find its way into the interior of the open oysters. Now, if potable water and milk be vehicles in which it is possible that the germs of typhoid fever may exist, why may they not be sometimes present in the so-called juice of an oyster or cockle? Anyone may satisfy himself that sewage is constantly discharging over fore-shores, in which various edible molluscs have their abiding place; and it is in the highest degree improbable that animals can always resist successfully the entry of polluted brackish water into their calcareous dwellings. Under all the circumstances we confess that we prefer to eat oysters taken from the lonely shores of Clare and Kerry, rather than from the sewage-polluted estuaries of rivers like the Liffey and the Thames. It may be that the illness which so many persons have experienced after swallowing oysters, believed to have been stale, was really due to the presence of sewage matter in the juice of the molluscs.

Analysis of Milk.—Drs. N. Gerber, P. Radenhausen, H. Vogel, and L. Janke.—It is recommended not to measure, but to weigh the milk for analysis. For the determination of the dry matter, the writers prefer to coagulate the milk with alcohol or acetic acid, and dry without the addition of sand.—*Biedermann's Centralblatt für Agrikultur Chemie*, ix., 12.

INDIGO, AND ITS ARTIFICIAL PRODUCTION.*

By H. E. ROSCOE, LL.D., F.R.S., &c.
President of the Chemical Society.

More than eleven years ago the speaker had the pleasure of bringing before this audience a discovery in synthetic chemistry of great interest and importance, viz., that of the artificial production of alizarin, the colouring substance of madder. To-day it is his privilege to point out the attainment of another equally striking case of synthesis, viz., the artificial formation of indigo. In this last instance, as in the former case, the world is indebted to German science, although to different individuals, for these interesting results, the synthesis of indigo having been achieved by Professor Adolf Baeyer, the worthy successor of the illustrious Liebig in the University of Munich. Here, then, we have another proof of the fact that the study of the most intricate problems of organic chemistry, and those which appear to many to be furthest removed from any practical application, are in reality capable of yielding results having an absolute value measured by hundreds of thousands of pounds.

In proof of this assertion, it is only necessary to mention that the value of the indigo imported into this country in the year 1879 reached the enormous sum of close on two millions sterling, whilst the total production of the world is assessed at twice that amount; so that if, as is certainly not impossible, artificial indigo can be prepared at a price which will compete with the native product, a wide field is indeed open to its manufacturers.

Indigo, as is well known, is a colouring-matter which has attracted attention from very early times. Cloth dyed with indigo has been found in the old Egyptian tombs. The method of preparing and using this colour is accurately described by both Pliny and Dioscorides, and the early inhabitants of these islands were well acquainted with indigo, which they obtained from the European indigo plant, *Isatis tinctoria*, the woad plant, or pastel. With this they dyed their garments and painted their skins. After the discovery of the passage to India by the Cape of Good Hope, the Eastern indigo, derived from various species of *Indigofera*, gradually displaced woad, as containing more of the colouring-matter. But this was not accomplished without great opposition from the European growers of woad; and severe enactments were promulgated against the introduction of the foreign colouring-matter, an edict condemning to death persons "who used that pernicious drug called devil's food" being issued by Henry the Fourth, of France. The chief source of Indian indigo is the *Indigofera tinctoria*, an herbaceous plant raised from seed which is sown in either spring or autumn The plant grows with a single stalk to a height of about 3 feet 6 inches, and about the thickness of a finger. It is usually cut for the first time in June or July, and a second or even a third cutting obtained later in the year. The value of the crop depends on the number of leaves which the plant puts forth, as it is in the leaves that the colouring principle is chiefly contained. Both the preparation of the colouring-matter from the plant, and its employment as a dye or as a paint, are carried on at the present day exactly as they have been for ages past. The description of the processes given by Dioscorides and Pliny tally exactly with the crude mode of manufacture carried on in Bengal at the present day as follows:—

"The Bengal indigo factories usually contain two rows of vats, the bottom of one row being level with the top of the other. Each series numbers from fifteen to twenty, and each vat is about 7 yards square and 3 feet deep; they are built of brickwork lined with stone or cement. About a hundred bundles of the cut indigo plants are placed in each vat in rows, and pressed down with heavy pieces of wood; this is essential to the success of the operation. Water is then run in so as to completely submerge the plants, when a fermentation quickly ensues, which lasts from nine to fourteen hours, according to the temperature of the atmosphere. From time to time a small quantity of the liquor is taken from the bottom of the vat to see how the operation is proceeding. If the liquor has a pale yellow hue the product obtained from it will be far richer in quality, but not so abundant as if it had a golden yellow appearance. The liquor is then run off into the lower vats, into which men enter and agitate it by means of bats or oars, or else mechanically by means of a dash-wheel, each vat requiring seventeen or eighteen workpeople, who are kept employed for three or four hours. During the operation, the yellow liquor assumes a greenish hue, and the indigo separates in flakes. The liquor is then allowed to stand for an hour, and the blue pulpy indigo is run into a separate vessel, after which it is pumped up into a pan and boiled, in order to prevent a second fermentation, which would spoil the product by giving rise to a brown matter. The whole is then left to stand for twenty hours, when it is again boiled for three or four hours, after which it is run on to large filters, which are placed over vats of stonework about 7 yards long, 2 yards wide, and 1 yard deep. The filters are made by placing bamboo canes across the vats, covering these with bass mats, and over all stretching strong canvas. The greater part of the indigo remains under the form of a dark blue or nearly black paste, which is introduced into small wooden frames having holes at the bottom and lined with strong canvas. A piece of canvas is then placed on the top of the frame, a perforated wooden cover, which fits into the box, put over it, and the whole submitted to a gradual pressure. When as much of the water as possible has been squeezed out the covers are removed, and the indigo allowed to dry slowly in large drying sheds, from which light is carefully excluded. When dry, it is ready for the market. Each vat yields from 36 to 50 lbs. of indigo."*

The same process carried out in the times of the Greeks is thus described by Dioscorides: "Indigo used in dyeing is a purple coloured froth formed at the top of the boiler; this is collected and dried by the manufacturer: that possessing a blue tint and being brittle is esteemed the most."

The identity of the blue colouring-matter of woad and that of the Bengal plant was proved by Hellot, and by Planer and Trommsdorff at the end of the last century. These latter chemists showed that the blue colour of the woad can be sublimed, and thus obtained in the pure state, a fact which was first mentioned in the case of indigo by O'Brien, in 1789, in his treatise on calico-printing. Indigo thus purified is termed indigotin. It has been analysed by various chemists, who ascertained that its composition may be most simply expressed by the formula C_8H_5NO.

Indigo is a blue powder, insoluble in water, alkalies, alcohol, and most common liquids. In order to employ it as a dyeing agent it must be obtained in a form in which it can be fixed or firmly held on to the fibres of the cloth. This is always effected by virtue of a property possessed by indigo-blue of combining with hydrogen to form a colourless body, soluble in alkalies known as indigo-white, or reduced indigo, of which the simplest formula is C_8H_6NO. This substance rapidly absorbs oxygen from the air and passes into the blue insoluble indigo, which, being held in the fibre of the cloth, imparts to it a permanent blue dye. This reduction to white indigo may be effected in various ways. The old cold vat, or blue-dip vats as they are termed, consist of a mixture of indigo, slacked lime, and green vitriol. The latter salt reduces the indigo, and the white indigo dissolves in the lime water. This process of indigo dyeing is both expensive and troublesome, owing to loss of indigo and formation of gypsum, so that many plans have been proposed to remedy these evils.

Concerning the origin of indigo in the leaves of the *Indigofera*, various and contradictory views have been

* A Paper read before the Royal Institution of Great Britain, Friday, May 27, 1881.

* Crace-Calvert.

held. Some have supposed that blue indigo exists ready formed in the plant; others, that white indigo is present, which on exposure to air is converted into indigo-blue. Schunck has, however, proved beyond doubt that the woad plant (*Isatis tinctoria*), the *Indigofera tinctoria* of India, and the Chinese and Japanese indigo plant (*Polygonum tinctorium*) contain neither indigo-blue nor white indigo ready formed. It is now known that by careful treatment the leaves of all these indigo-yielding plants can be shown to contain a colourless principle termed indican, and that this easily decomposes, yielding a sugar-like body and indigo-blue. That white indigo is not present in the leaves is proved by the fact that this compound requires an alkali to be present in order to bring it into solution, whereas the sap of plants is always acid. The decomposition is represented by Schunck as follows:—

$$\underset{\text{Indican.}}{C_{26}H_{31}NO_{17}} + 2H_2O = \underset{\text{Indigotin.}}{C_8H_5NO} + 3\underset{\text{Indiglucin.}}{C_6H_{10}O_6}.$$

So readily does this change from indican to indigo take place, that bruising the leaf or exposing it to great cold is sufficient to produce a blue stain. Even after mere immersion in cold alcohol or ether, when the chlorophyll has been removed, the leaves appear blue, and this has been taken to show the pre-existence of indigo in the plant. But these appearances are deceptive, for Schunck has proved that if boiling alcohol or ether be used, the whole of the colour-producing body as well as the chlorophyll is removed, the leaves retaining only a faint yellow tinge, whilst the alcoholic extract contains no indigo-blue, but on adding an acid to this liquid the indican is decomposed and indigo-blue is formed.

Passing now to the more immediate subject of his discourse, the speaker again reminded his hearers that indigo was the second natural colouring-matter which has been artificially prepared; alizarin, the colouring matter of the madder-root being the first. As a rule, the simpler problems of synthetic chemistry are those to which solutions are the soonest found, and these instances form no exception to the rule. The synthetic production of indigo is a more difficult matter than the artificial formation of alizarin, and hence the speaker did not apologise for leading up to the complex through the more simple phenomenon.

When the ingenious Japanese workman who had never seen a watch had one given to him with an order to make a duplicate, he took the only sensible course open to him, and carefully pulled the watch to pieces, to see how the various parts were connected together. Having once ascertained this, his task was a comparatively easy one, for he then had only to make the separate parts, and fit them together, and he thus succeeded so well in imitating the real article that no one could tell the difference. So it is with the chemist; until he knows how the compound is built up, that is, until he has ascertained its constitution, any attempt at synthesis is more like groping in the dark than like shaping the course by well-known landmarks into harbour.

In the case of alizarin it was comparatively easy to reduce it to its simplest terms, and to show that the backbone of this colouring-matter is anthracene, $C_{14}H_{10}$, a hydrocarbon found in coal-tar. This fact being ascertained, the next step was the further process of clothing the hydrocarbon by adding four atoms of oxygen and subtracting the two atoms of hydrogen present in excess, and this was soon successfully accomplished, so that now, as we know, artificial alizarin has excluded the natural colouring-matter altogether.

$$\underset{\text{Anthracen.}}{C_{14}H_{10}} \qquad \underset{\text{Alizarin.}}{C_{14}H_6O_2(OH)_2}.$$

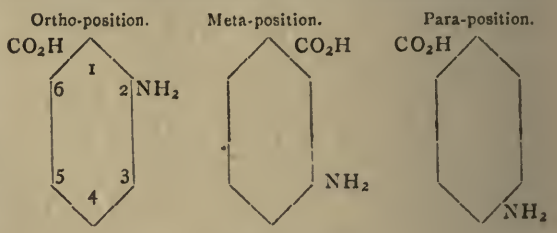
What now was the first step gained in our knowledge concerning the constitution of indigo, of which the simplest formula is C_8H_5NO?

Step No. 1.—This was made so long ago as 1840, when Fritsche proved that aniline, $C_6H_5NH_2$, can be obtained from indigo. The name for this now well-known substance is indeed derived from the Portuguese "anil," a word used to designate the blue colour from indigo. This result of Fritsche's is of great importance, as showing that indigo is built up from the well-known benzene ring, C_6H_6, the skeleton of all the aromatic compounds, and, moreover, that it contains an amido- group.

Step No. 2 was also made by Fritsche in the following year, when, by boiling indigo with soda and manganese dioxide, he obtained ortho-amido-benzoic acid, or, as he then termed it, anthranilic acid. The following is the reaction which here occurs:—

$$\underset{\text{Indigo.}}{C_8H_5NO} + O + 2H_2O = \underset{\text{Ortho-amido-benzoic acid.}}{C_7H_5NH_2O_2} + CH_2O_2.^*$$

What light does this fact shed upon the constitution of indigo? It shows (1) that one of the eight atoms of carbon in indigo can be readily separated from the rest; (2) that the carboxyl and the amido- group are in neighbouring positions in the benzene ring, viz., 1 and 2. For we have three isomeric acids of the following composition:—



(To be continued.)

ON THE CONDUCT OF FINELY-DIVIDED IRON TOWARDS NITROGEN.

By IRA REMSEN.

A recent writer† states that the method of Lassaigne for the detection of nitrogen in bodies containing carbon is not applicable to compounds in which sulphur is present. He claims that the sulphur gives rise to the formation of sulphocyanide, and that this is overlooked, as the solutions are strongly acid. A list of compounds is given in which nitrogen cannot be detected. It includes taurine, sulphourea, sulphocyanide of potassium, and the "amides of the sulphonic acids." In such cases it is recommended to fuse the bodies with sodium and pure iron, instead of sodium alone, as is customary. The sulphur forms sulphide of iron, and the nitrogen forms the cyanide, and can easily be detected.

As I have repeatedly used the ordinary method for the detection of nitrogen in compounds containing sulphur, and have in some cases relied upon the results reached, I undertook an examination of the subject thus opened, and I have been led to conclusions directly opposed to those of the writer referred to. At the same time certain interesting observations have been made on the conduct of pure iron, reduced by hydrogen, towards nitrogen.

As regards the statement that the method of Lassaigne is not applicable to compounds containing sulphur, I am prepared to give this an unqualified denial. I have examined every one of the substances mentioned by the writer, with the exception of cystine, and have in each case, without the slightest difficulty, obtained the precipitate of Prussian blue. I have also examined a large number of other substances, and have never experienced difficulty in getting the result looked for. Then, further, the fact that sulphocyanide of sodium or potassium itself breaks up under the influence of heat in the presence of an alkaline metal shows clearly that, even if this salt is

* Böttinger, *Deut. Chem. Ges.*, 1877, i., 269.
† *Ber. der Deut. Chem. Gesell.*, xii., 2316.

formed as is claimed and as is probable, the detection of the nitrogen cannot be interfered with by the presence of sulphur.

Having shown beyond a doubt that the conclusion I had drawn with reference to a certain compound, that it contained no nitrogen, is correct, I nevertheless fused a small specimen of this compound with sodium and iron by hydrogen, and was astonished to find that, on extracting the fused mass with water, filtering, and then adding successively ferric and ferrous salts and hydrochloric acid, the blue precipitate revealing the presency of nitrogen was distinctly formed. I repeated the experiments a number of times, but always with practically the same result. In every case the blue precipitate was formed, though in some cases it seemed to be formed in larger quantity than in others. The variations in quantity were, however, not striking.

I now took other non-nitrogenous organic substances than the one which was in question and tested these. The two purest specimens in this laboratory at the time were one of the double tartrate of potassium and sodium which had been re-crystallised a large number of times, and one of cane-sugar which had been repeatedly re-crystallised from alcohol. These two specimens may certainly be regarded as in the strictest sense chemically pure. Both of these substances gave the reaction for nitrogen distinctly. Of all the substances experimented upon, the pure double tartrate seemed to be best adapted to the purpose, and in continuing the experiments I have since always employed this particular pure specimen to furnish the carbon.

The question naturally suggests itself, whence comes the nitrogen in these reactions? I at first suspected the iron by hydrogen, and my suspicions were increased when, on enquiring into the history of the specimen used, I found that it had been made from ferric hydroxide precipitated by ammonia. To be sure the hydroxide had been washed with the greatest care, and had afterward of course been ignited in a current of hydrogen, and it did not seem probable that ammonia or any compound of ammonia and iron could be retained; but still, there was the nitrogen, and it appeared at least possible that it was actually contained in the iron. To test this point ferric hydroxide was precipitated from a solution of the pure chloride by means of sodium carbonate, and washed out until no test for sodium could be obtained. This precipitate was then divided into two parts, one of which was dried at once, and the other boiled for some hours with a solution of ammonium carbonate and ammonia. The latter was then washed out, no special precautions being taken to remove all the ammonium salts, and afterwards dried. Both specimens were separately reduced in a current of purified and dried hydrogen. *Both gave the test for nitrogen*, and indeed the one from which all ammonium compounds had been carefully excluded seemed to give the test better than the other.

Another specimen of iron by hydrogen, which has been in the collection of chemicals of this laboratory for five years, and which does not take fire by contact with the air, failed to give the nitrogen test. This led me to think that possibly the nitrogen is not contained in the iron, but is absorbed from the air, and that the power to absorb nitrogen in this way is connected with the active condition of the iron. Both the specimens above referred to, which in the active condition readily and invariably gave the test for nitrogen, were allowed to stand for a short time in contact with the air, and were then again tested. *Neither gave the reaction.* The same experiment was peformed with the specimen of iron by hydrogen first used, and which had been preserved under ether. A portion of this was allowed to stand over-night exposed to the air, and then gave no indication of the presence of nitrogen. These results make it appear extremely probable that the nitrogen detected when active iron is used is really absorbed from the air. But if this is so, then more thorough contact of the heated reagents with the air ought to increase the quantity of cyanide formed. All the experiments thus far mentioned were performed in test-tubes, and of course very little air came in contact with the substance at the bottom of the tube. On heating the necessary mixture in a crucible, however, violent combustion of the sodium took place, and no reaction for nitrogen was obtained. To prevent this combustion, a mixture of iron by hydrogen, double tartrate of sodium and potassium, and metallic sodium was placed in a hard glass tube, and dry hydrogen passed through while gentle heat was applied to drive off water. Then nitrogen was passed slowly over the mixture, while at the same time it was heated to redness. This process was continued for about ten minutes, when, on allowing the tube to cool, the contents were extracted with water, filtered, and treated in the usual manner. To my surprise, *a very large precipitate of Prussian blue was formed*, much larger in proportion than in any previous experiment. The result is so striking that the experiment is well adapted to serve the purpose of a lecture experiment, illustrating the formation of cyanogen from the nitrogen of the air. There can be no doubt that the nitrogen is really absorbed from the air. The quantity of the precipitate obtained in the last experiment was so great as to exclude the supposition that the nitrogen could have been present in the substances used. Then, further, the fact that the active iron, which readily gives the test for nitrogen, does not give the test after it has been exposed to the air and become oxidised, is a clear indication that the active condition of the iron is an important factor in the process, and that the nitrogen cannot be in combination with the iron. For if it were, it is difficult to understand how the spontaneous oxidation of the iron could remove it. The heat evolved can scarcely be sufficient to decompose any nitrogen compound present, for the iron is heated to a much higher temperature in the course of its preparation, and the possible nitrogen compound must have been decomposed by this first application of heat.

I have thus far performed no quantitative experiments, and there are obvious difficulties in the way of making these exact. As it is intended soon to continue the experiments, however, an attempt will be made to determine as near as possible how much nitrogen can be taken up and combined chemically by given weights of the reagents. Some other points of interest will also be taken up. Thus, in attempting to exclude the air from the vessels in which the reactions took place, hydrogen was used, and the nitrogen test was not obtained. But on testing a nitrogenous substance (hippuric acid) in the same way, very little evidence of nitrogen was obtained. It would hence appear that that the test cannot be applied in an atmosphere of hydrogen, or that the cyanide is decomposed when heated in hydrogen. On the other hand, Marchand* has stated that hydrogen does not interfere with the application of the test.

As a result of the experiments described in this paper, it may be stated with confidence that *when iron by hydrogen and certain non-nitrogenous organic substances are heated together with metallic sodium in an atmosphere of nitrogen a cyanide is readily formed.* The action is, of course, similar to that which takes place in blast-furnaces, and which gives rise to the formation of cyanide of potassium. In the latter case, the carbonate of potassium from the burning of the fuel furnishes the potassium. Nitrogen is always present in large quantity, and the iron is constantly passing from the state of oxide to that of the metal.

Marchand some years ago showed† that steel when heated with carbon and potassium can take up nitrogen. It had been previously stated by Schaufhäutl‡ that steel always contains nitrogen. The experiments of Marchand made this statement appear improbable, though they did not disprove it. Indeed, later a discussion arose in France on the same subject. Fremy claimed that not only is

* *Journ. Prakt. Chem.*, xlix., 355.
† *Loc. cit.*
‡ *Ibid.*, xix., 409.

nitrogen always present in steel, but it is the essential element of the steel. This discussion did not at the time lead to a satisfactory conclusion. Quite recently Müller* has found nitrogen in not inconsiderable quantity in the gases extracted from Bessemer steel by boring, but thus far he has not been able to determine whether the nitrogen is simply enclosed in the pores of the steel or is chemically combined with it.

I have made a number of experiments with Bessemer steel and with other forms of iron, and have obtained results in accordance with those already on record. It seems possible that as regards steel the nitrogen detected may be partly absorbed from the air and partly present in combination with the iron, though it would be difficult to prove the correctness of this supposition.—*American Chemical Journal.*

May, 1881.

THE OWENS COLLEGE COURSE OF TECHNOLOGICAL CHEMISTRY.

Most of our readers are aware that the Owens College is now duly constituted by Royal Charter a college of the New Victoria University. This University has the power to grant degrees to persons who have completed their studies in any of its colleges, and possesses many features upon which we cannot look without a feeling of lively satisfaction. It is not, like the University of London, a mere examining body. It contemplates actual research in the various sciences, and we have already had the satisfaction of seeing in *Liebig's Annalen* an article headed "Chemical Researches from the Laboratory of the Victoria University, Manchester." We find that in every department of science where such an arrangement is possible there is a practical course—"practicum" as it is called in the German Universities—and there are special facilities for students desirous of pursuing original investigations. There is also a most valuable latitude in the subjects to be studied. Thus, in the Faculty of Science the student during his second and third year has the choice of four distinct courses—the mathematical, the engineering, the experimental science course, and the biological.

We are particularly interested in the course of technological chemistry, which extends over four years, and which is very similar to the courses at the Polytechnic Schools of Aix-la-Chapelle, Zurich, &c., which have had such a powerful influence in promoting chemical industry in their respective countries. The first year's course consists of chemistry lectures, junior and tutorial classes, laboratory work two days weekly, and class work in analytical chemistry; pure mathematics, experimental mechanics *or* geology; the French *or* German language.

In the second year there are chemical lectures (junior, senior, and tutorial classes): laboratory work three days weekly; technological chemistry; experimental physics *or* mineralogy; German *or* French language. In the third year the course embraces chemistry lectures (senior and tutorial classes); lectures on organic chemistry and on chemical philosophy; laboratory work three days weekly; technological chemistry; and work in the physical laboratory, *or* in practical mineralogy, one day weekly.

In the fourth year there are lectures on organic chemistry and technological chemistry; four days' laboratory work, and the chemistry of colouring matters, dyeing and printing. In all four years there is also instruction in mechanical drawing.

The instructions in technological chemistry are conducted by Mr. Watson Smith, F.C.S., and embrace for the first year the sulphuric acid and alkali manufactures; bleaching-powder and liquor, potassium chlorate, and utilisation of burnt copper pyrites. The second course deals with the destructive distillation of wood and the products obtained; the destructive distillation of coal, the gas manufacture, ammonia and its salts, tar products, &c. In the third course will be explained the manufacture of pure tar products and derivatives; carbon bisulphide; turpentine, rosin, and rosin oils, and, if time allows, bleaching.

We are happy to learn that the students will through the courtesy of several manufacturers have the privilege of inspecting various chemical works where the processes described in the lectures may be seen in actual practical operation.

If this programme is ably carried out, the relative position of our chemical manufactures must before long show a marked improvement. But why could not the necessity of such arrangements be seen a quarter of a century ago?

* *Ber. der Deut. Chem. Gesell.*, xiv., 1.

PROCEEDINGS OF SOCIETIES.

AMERICAN CHEMICAL SOCIETY.*

June 3, 1881.

Dr. Albert R. Leeds, Vice-President, in the Chair.

The regular business of the Society was transacted, and Mr. A. P. Halloch, Ph.B., was duly elected a member of the Society.

After which the first paper of the evening, by Dr. Chas. A. Doremus, was read "*On the Analysis of Elephant's Milk.*" One sample of this milk gave 66·693 per cent of water; 33·303 per cent of solids; 22·070 per cent of fats; 11·233 per cent of solids not fats; 3·212 per cent of casein; 7·392 per cent of sugar; and 0·629 per cent of ash.

In discussing this paper, Dr. Leeds remarked that the ash closely approximated to that of human milk. He also further remarked that the difficulty of evaporating the milk, experienced by Dr. Doremus, could be overcome by using 10 c.c. of milk upon 30 c.c. of ignited sand, and this procedure caused no charring, the large excess of sand preventing the milk from touching the sides of the dish.

Dr. E. R. Squibb having taken the Chair, Dr. Leeds then read a paper "*Upon the Adulteration of Food, Drink, and Drugs, from the Chemist's Standpoint; and upon the Attitude of Chemists in the Matter of Appointment of Government Analysts.*" The subject of adulteration had not received that amount of attention from the chemists which its nature and amount, as at present practised in the United States, properly demanded. And in neglecting to assume control of the investigation of the subject, and of the information and education of the public mind as to the actual facts, they had left the field in the possession of scientific demagogues and pseudo-chemists, who, for the past four years, had been sending out through the daily press an unlimited amount of sensational literature, either in part or altogether false. The investigations as to the facts had been mainly fragmentary and sporadic in their character, instituted from time to time by various Boards of Health, but without much outcome in the arrest and prosecution of offenders. But this period of education had now gone by, and the time had come when the various States were about to pass laws upon adulteration. Some laws had been already enacted, and grave blunders had been committed. The experience in England had shown how difficult it was to secure wise and efficient legislation, and it was very important for chemists in America to avail themselves of that experience, and to control and shape the laws under consideration in the various State legislatures. Moreover, the duties of a public analyst required peculiar training and an accurate knowledge of certain topics not ordinarily studied by chemists. Finally, the analysts could not properly perform their labours

* Communicated by Arthur H. Elliott, Ph.B., F.C.S., Recording Secretary.

without the aid of suitably qualified inspectors, and as yet these two professions did not exist in the country, and would have to be in a sense created. Dr. Leeds who had been commissioned by the State of New Jersey to investigate the facts concerning adulteration, as a basis for future State legislation, then gave brief *résumé* of the results of his labours up to date. He had analysed a very large number of samples, and without claiming that the facts were universally true for the whole country, yet the examinations of so many articles of each kind, purchased at random from dealers in various parts of New Jersey, and in the city of New York, might justly be regarded as representing a reasonably close approximation to the true facts of the case. In regard to teas, three classes of adulterated samples had been found. The smallest class contained an amount of mineral matter in excess of that which should be present from facing materials alone, or from impurities which could properly be derived from the processes of preparation for the market. The largest class consisted of teas adulterated with exhausted leaves. Finally, in some samples, foreign leaves were present in such numbers as to denote intentional adulteration. But the percentage of adulterated teas was much smaller than was anticipated (10 p.c.), a majority of the teas being of inferior grade, their prices ranging from 30 cts. to 50 cts. per pound. Nearly all the coffees examined, both whole and ground, were pure, the adulterant in the other cases being chicory. The essences of coffee sometimes contained scarcely any coffee; one sample was composed almost entirely of chicory, caramel, and liquorice. The manufacture of mixed sugars, containing both cane-sugar and glucose, is now largely carried on in the United States, the product being sold under the name of "new process" sugar by the manufacturers. This fact had given rise to a popular belief that almost all varieties of sugar were more or less adulterated. Such was not found to be the case, most of the white sugars purchased at random being found pure, and of the brown sugars, which were the more adulterated, certain samples furnished by dealers as in their belief adulterated, were found to contain no more inverted sugar than might properly be present in a sugar of low grade. A similar remark applies to the syrups. Even the lowest-priced syrups were found, with few exceptions, to contain no more glucose than was to be expected in a non-adulterated article. No free sulphuric acid or excess of lime was present in any case. The specimens of flour examined, were uniformly pure, no other meal or alum being found in any instance. In bread, however, sufficient samples showing the employment of alum were obtained, to demonstrate its occasional use by bakers. Cream of tartar was found to be extensively adulterated, the adulterants being sulphate of lime, acid phosphate of lime, and starch. The first-named substance was likewise present in some samples of bicarbonate of soda. Some of the manufacturers of the baking-powders, now so extensively sold, use only bicarbonate of soda, cream of tartar, and starch. Others employ either partly or altogether in place of the cream of tartar, alum or acid phosphate of lime or a mixture of these two salts. Of the condiments and spices, very few were pure, though in no instance was any injurious metallic adulterant detected. Many of the samples of vinegar contained a much lower percentage of acetic acid than should have been present, but in no case were mineral acids present, and in only one instance a metallic substance—lead in traces. Some of the so-called white-wine vinegars had all the characters of ordinary cider vinegar, decolourised by filtration through animal charcoal. None of the *green* pickles examined were free from copper—one pickle containing 15 milligrms.—although the pickles prepared by the use of brine, and those imported with the Crosse and Blackwell label, were found unexceptionable. The employment of tin cans in the preservation of vegetables is reprehensible, both tin and lead being present in the canned tomatoes examined. The skimming and watering of milk was still very extensively practised in New York and New Jersey, although stringent laws had been passed for its repression. Condensed milk varied remarkably in composition, the percentage of water ranging from 25·5 to 59 per cent, and of fat from 3 to 11 per cent.

To a question from Mr. Elliot, Dr. Leeds remarked that he had not made any special tests for gelatine in condensed milk.

Dr. Doremus remarked that one of the first things to decide in this question of adulteration is "What is Adulteration?" and he discussed at some length the question of alum baking powders, claiming that at the present time there is no proof that they are unwholesome.

Dr. E. R. Squibb remarked that he looked upon the question from a different standpoint from most chemists, and would punish as a fraud anything that was sold and not found as represented. He condemned in strong terms the sale of quack medicines, and said that the American people take from five to six times as much medicine *per capita* as any other nation.

Mr. Eimer, of the firm of Eimer and Amend, wholesale druggists, corroborated Dr. Squibb's last statement as to the enormous amounts of patent medicines sold in the United States.

NOTICES OF BOOKS.

Profitable Clay Farming under a Just System of Tenant Right. By John Prout. London: E. Stanford.

The author of this work informs us that he "farms 450 acres of heavy land, all under the plough, and almost entirely devoted to corn," and finds it pay. He does not wish that his land were under grass, nor has he any "intention of replacing any portion of it by forage or root crops for live stock, or by vegetables for the market." Nineteen years' experience has convinced him that in "the present and prospective low state of the markets," it is still possible to secure an adequate return for the tenant's capital, and at the same time afford a satisfactory rent to the owner. This, it need not be said, is a very desirable conclusion. Mr. Prout's system is perpetual corn growing on heavy land by means of deep and cheap steam tillage, and plentiful applications of artificial manures. As preparatory requisites he mentions effectual sub-soil drainage, fields of considerable dimensions, straight and neat fences, sound headland roads, and convenient field water supply. On the question of large or small enclosures and of fences and hedge-row trees, he says: "The drying of the surface of the land and the crops is retarded by the excessive shading of numerous fences, while the produce is exposed to heavy damage by the depredation of infesting birds and vermin." But where the shading of trees and fences is done away with the crops suffer heavily from wind.

On the subject of vermin we fear the author has been guided by prejudice rather than observation. The insects hurtful to our field-crops, such as the Tipula, the wire-worms, the larvæ of the cock-chafer and its allies, the turnip-flea (*Haltica*), &c., do not harbour or breed in trees or bushes, but in the open fields. Nowhere has so much damage been suffered from insects as in the Western States of America, where the system of large fields, separated merely by wire or rail fences, is adopted. Trees certainly harbour birds, but the insect-eating species will suffer more from their removal than the chief grain-devourer, the sparrow. The expenditure for manure is at the annual rate of £2 10s. per acre. Dr. Voelcker, in an exhaustive report, based on analyses of the soil made at different times, states: "I can perceive no indications of incipient exhaustion, but, on the contrary, clear evidence of the great improvement effected in once unproductive land. I can see no reason why, with this system of manuring, and an occasional dead summer fallow, in order to give a

thorough cleaning to the land, Mr. Prout should not be able to grow wheat or barley profitably for an indefinite number of years without injury to his land." Lime has been experimentally applied to some of the fields, but, as Dr. Voelcker attests, without beneficial results. The store of potash in the soil may ultimately become exhausted if no provision is made for its supply. Small quantities of kænite have accordingly been used. The principal manures consumed have been of the phosphatic class, bone meal, mineral superphosphate, and Peruvian guano, both raw and dissolved. According to Dr. Voelcker's analysis, 6 inches of soil from the "Broad Field"—a portion of the farm in question—contain as much phosphoric acid as 118 good crops of wheat, as much potash as 212 such crops, as much sulphuric acid as 215 crops, as much magnesia as 1120 crops, and as much lime as 2256 crops. The restoration of silica Dr. Voelcker thinks needless, there being not a single instance on record showing that silica, even in the soluble form, has ever been applied with advantage to grain crops.

Both the author and Dr. Voelcker question whether bone manures have not been applied with somewhat too great liberality. The results of the nineteen years' farming are considered to prove the necessity of supplying grain-crops with ammoniacal manures, or such as otherwise contain nitrogen in a readily available condition. The profits of the undertaking have been on an average £1142 yearly, or about £3 per acre.

The question now arises why should not other farmers do as Mr. Prout has done and is still doing? The reply involves political considerations into which the Chemical News cannot enter. We quote merely the author's words: "I could not have stirred a step in my career of success at Sawbridgeworth if I had been hampered by estate rules, written consent to works proposed, restrictions as to fences or water-courses, lopping of timber, understanding about game, &c."

We commend this little book to the careful examination of all our readers.

Alcohol Tables, giving for all Specific Gravities from 1·000 *to* 0·7938 *the Percentages of Absolute Alcohol by Weight and Volume, and of Proof Spirit.* By Otto Hehner. Reprinted from the *Analyst*. London: J. and A. Churchill.

These tables, for which no originality is claimed, and the nature of which will be apparent from the title, are founded upon the tables of Fownes, the general accuracy of which, according to the author, all later investigators have confirmed—a statement which is by no means universally accepted. The results of Fownes differ at certain points from the earlier determinations of Gilpin to ½ per cent of proof spirit. We cannot help considering it as unfortunate that the notion of "proof spirit" should still be retained. It would be assuredly far simpler to speak of spirit as containing such or such a percentage of absolute alcohol.

Inorganic Chemistry: Adapted for Students in Elementary Classes of the Science and Art Department. By Dr. W. B. Kemshead, F.G.S., &c. Enlarged edition, revised and extended. London and Glasgow: W. Collins, Sons, and Co., Limited.

This book forms a member of the Science Series issued by Messrs. Collins. It is in its objects and tendencies avowedly examinational. The author is examiner in chemistry to the College of Preceptors, and the work, as we are told in the preface, was "originally issued for the first stage or elementary examination of the Science Department," whilst the present edition owes its origin to "a very generally expressed wish that the work might be extended in the same spirit, to include all the subjects required for the matriculation examination of the London University."

It is put forward as an important feature that the treatise before us is the only text-book in existence which combines the notation used by Prof. Williamson and his school with the graphic notation of which Dr. Frankland may be regarded as the chief teacher.

One of the author's reasons for bringing out a new edition of his work is the fact of many important discoveries having been made "within the last three years." Surely among the most weighty of recent discoveries—though made earlier than "within the last three years"—is the periodic law of Prof. Mendelejeff. It apparently "throws open to us a vista which may possibly revolutionise the whole science." Yet we do not find the slightest allusion in the work before us to this signal step in advance.

Under fuming sulphuric acid we find the erroneous assertion that ordinary sulphuric acid will not dissolve indigo. In practice by far the greater part of the extract of indigo used is made with ordinary oil of vitriol, and not with the fuming or so-called Nordhausen acid. The metallic elements are not here described, an acquaintance with their properties being probably not called for in the examinations for which the book is arranged.

The great bulk of the matter here laid before the student is, as might be expected from a teacher of Dr. Kemshead's standing and merit, strictly accurate in fact, unexceptionable in arrangement.

Lecture Notes for Chemical Students. Vol. II. *Organic Chemistry.* By E. Frankland, Ph.D., F.R.S., &c. Third edition. Revised by F. R. Japp, Ph.D. London: Van Voorst.

One of the most difficult tasks which a reviewer in these days can be called upon to undertake is to pronounce an opinion upon an elementary work on chemistry. The number of such manuals, treatises, &c., issuing from the English press is so great, and their subject matter necessarily so much alike, that it becomes scarcely possible to say anything which shall be acceptable to all the parties interested. The question is further complicated when, as in the present case, the author is a chemist of indisputable eminence, and when the work has already passed through several editions, and has not merely run the gauntlet of criticism, but stood the severer test of actual use. The search for errors, in fact, against which the reader should be warned, is here hopeless.

The chief merit of the book—and it is one of very high importance—is that it places before the eye of the student the apparently infinite and desultory array of organic compounds as reduced under definite groups, converting them, so to speak, from a mob into an army. By the classification adopted, the "description of the individual member" is, as remarked in the preface, "made subsidiary to that of the family to which they are attached." Hence the study of organic chemistry makes a less demand upon the memory—the faculty, too, exclusively and one-sidedly cultivated in the English system of education—and a greater call upon the understanding. Any agency tending in this direction we welcome with pleasure. From a truly scientific point of view nothing can be more unprofitable than the mere contemplation of a number of facts among which no connection can be traced. Whether everything laid down in these Lecture Notes, *e.g.*, on the "constitution" of certain compounds, is capable of demonstration is another question.

"Graphic formulæ" constitute, of course, an essential feature. We fully admit that there are minds who by means of this artifice are enabled to form a clearer idea of the composition of bodies; but our observation convinces us that there are other minds utterly incapable of profiting by or of remembering such formulæ, and whose only thought on meeting with them will be the demand for proof that the atoms are really arranged as represented. If told that this is more than the advocates of graphic formulæ contend for, they will ask why, then, is such

weight laid upon this mode of representation? Is there not too free play given to hypothesis? (See p. 53).

The work, after an introductory chapter, treats successively of organic radicles classified as positive and negative, of their hydrides, of the alcohols, the ethers, haloid ethers, aldehyds, acids, anhydrides, ketons, ethereal salts, organic compounds containing triad and pentad nitrogen, the organo-boron and organo-silicon bodies, and organo-metallic compounds. The indigo group, according to the latest researches of Prof. Baeyer, is given as an appendix.

The "Lecture Notes" may be regarded as a successful attempt to give a clear oversight of the field of organic chemistry in the briefest compass.

Text-Book of Practical Organic Chemistry for Elementary Students. By H. CHAPMAN JONES. London: Hughes.

THIS work is not put forward as a systematic treatise on organic chemistry. It does not give an account of all the various groups of compounds commonly known as organic, but is intended as a laboratory companion for students who are studying practically, and whose time for work is very limited. The experiments selected are such as can be performed without expensive appliances, whilst at the same time the author has sought to give them a representative character. A very considerable portion of the book—which, by the way, would have been all the better for a table of contents—is devoted to the recognition of the organic acids. For the purposes which the author has in view we are inclined to form a favourable opinion of this little treatise.

CORRESPONDENCE.

THE ACTION OF NITRIC ACID ON METALS.

To the Editor of the Chemical News.

SIR,—I feel as if I were dreaming on receiving the question of my friend D. Tommasi! I cannot imagine how a mind such as his can see "an obscure point" of "la Théorie Générale," in the fact, that 14Sn in *chemical presence* of nitric acid of a given strength, will leave 6Sn, not *useless*, but *inactive*, which is very different.

How would my friend D. Tommasi reply to the question?—

When you add 2 equivalents of KO and $(2+x)$ equivalents of SO_3HO, why can you only obtain $(SO_3)_2,KO,HO$; and why are the x equivalents left unemployed?

Why even in classical language are they absolutely useless?

What real difference can one find between this question and that which I am asked?

Is there anything more completely explained in my theory than this *non-employment* of 6Sn at a *given temperature*?

But may I be allowed to give a complete explanation. If we were to submit the mixture to 100° of cold (perhaps a lowwer temperature would be necessary), we should see all the 14Sn remain unemployed. Should we be astonished?

If, on the other hand, we submit the mixture at the ordinary temparature (or higher) to a very great pressure, we should see all the 14Sn take part in the reaction, and we should have:—

$$14Sn+NO_5(HO)_{10}=6Sn_2O+2SnO+NH_3+7HO$$

(I predict Sn_2O for abbreviation). Should we be any more astonished?

If my friend Tommasi will think over this theory, which merits more good will and attention than it has received, he will regret having asked so trivial a question.

Let him consider that the basis of this theory is *incontestable*—that of all reflections made concerning the explanation of chemical reactions, it is the only one which survives in this case; and he will be careful not to attack any of its consequences.

Perhaps I am wrong. Let my learned friend take the trouble to show it to me. I have often begged my *confrères* to do this service to science, but nobody has done it. All prefer to continue the use of an hypothesis which I have shown to be wrong, as clearly as one can establish a scientific truth. The shame of such a prolonged determination to remain in error, becomes altogether unpardonable in the eyes of those who seek the truth.

May D. Tommasi understand it!—I am, &c.

E. MAUMENÉ.

Lyons, July 11, 1881.

CHEMICAL NOTICES FROM FOREIGN SOURCES.

NOTE.—All degrees of temperature are Centigrade, unless otherwise expressed.

Comptes Rendus Hebdomadaires des Séances, de l'Académie des Sciences. No. 24, June 13, 1881.

Simple Law Relating to Natural or Magnetic Circular Double Refraction.—A. Cornu.—The author sums up the results of his experiments as follows:—1. In quartz the mean of the speeds of propagation along the optical axis of the circular waves of inverse directions is sensibly equal to the speed of the ordinary wave perpendicular to that axis. 2. In Faraday's heavy flint glass the mean of the speeds of propagation of circular waves of inverse directions separated by the magnetic action is sensibly equal to the common speed of these waves when the magnetic action is null. He proposes the following more general statement:—The splitting up of a wave polarised rectilinearly into two waves polarised circularly in opposite directions is effected in such a manner that the mean of the speeds of propagation of the split up waves is equal to the speed of propagation of the single wave, which exists in conditions where the causes of splitting up do not act.

Dialdanic Alcohol.—A. Wurtz.—The alcohol in question has the composition $C_8H_{16}O_3$, and is at once a primary and a secondary alcohol and an ether. It does not fix directly either bromine or hydrogen. It forms a white crystalline mass, deliquescent and soluble in all proportions in water and alcohol, and very soluble in ether.

Reproduction of Orthose in the Wet Way.—C. Friedel and E. Sarasin.—The authors have obtained this mineral by heating together gelatinous silica, alumina, and a solution of potash, in a strong steel tube, lined internally with a tube of copper or platinum, and heated to dull redness.

Summary Account of Experiments made at Pouilly-le-Fort, near Melun, on Vaccination for Splenic Fever.—M. Pasteur.—The experiments have proved decidedly successful. The new "verus-vaccine" for splenic fever can be cultivated at pleasure, transported without spoiling, and preserves the animals into which it is produced from a mortal disease. The method by which the virus is produced seems capable of generalisation.

Influence of Temperature upon Radiophonic Receivers of Selenium.—E. Mercadier.—The selenium radiophonic receivers constructed according to the author's description tend, in time, more or less rapidly to a state of stability as regards the effects of temperature. At ordinary temperatures, and even up to 100°, the resistance of these receivers varies inversely as the temperature. Between 5° or 6° and 35° these variations may be considered as approximately proportional to each other.

Certain Means and Formulæ for Measuring Electric Elements and Coefficients of Utilisation with the Dispositive with two Galvanometers.—G. Cabanellas.—A mathematical paper, not susceptible of useful abstraction.

Strontium, Calcium, and Zinc Cyanides.—M. Joannis.—A study of the formation- and solution-heats of these compounds. The author remarks that zinc cyanide, though insoluble in water and hydrocyanic acid, is slightly soluble in solutions of zinc sulphate and acetate.

Industrial Preparation of Crystalline Formic Acid.—M. Lorin.—The author sets out with mono-formine, which is obtained by heating glycerin with an equivalent proportion of dried oxalic acid, or from the product of glycerin submitted to the action of a quantity of 4 or 5 equivalents of dry oxalic acid, added successively, when it is partly decomposed. Too much time must not be left between the additions. The author has operated upon 560 grms. glycerin and has added the acid in quantities of 600 grms. each.

Researches on the Tertiary Monamines.—1. Action of Tri-ethylamine upon the Monobromised Propylenes.—E. Reboul.—Not adapted for abstraction.

No 25, June 20, 1881.

Preparation of Aldol.—M. Wurtz.—2 kilos. of aldehyd and 2 kilos. of water were introduced into 2 kilos. of hydrochloric acid, and the mixture was left to itself for 3 days at 15°. The liquid was then diluted, neutralised with sodium carbonate, and repeatedly exhausted with ether. The product was 497 grms. aldol, which distilled over between 85° to 105°. The aldol thus obtained, though perfectly fluid at first, became a thick colourless syrup, entirely soluble in water.

New Occurrence of Native Sulphur in the Soil of Paris.—M. Daubrée.—The deposit of sulphur seems due not to the escape of coal-gas, but to the reaction of organic matter upon gypsum. There is a bed of the bones of animals, mixed with the horns of oxen extending from the depth of 2·50 to 4·50 metres, and which has been traced for a length of 40 metres!

Thermic Laws of the Exciting Spark of Condensers.—E. Villari.—The author calls the "exciting spark" of the discharge of a condenser that which is produced against the exciter, whilst the "conjunctive spark" is that formed in an interruption. He finds that the heat evolved by the exciting spark alone is almost proportional to the square of the charges, and increases a little less rapidly than the charge when the potential is constant.

Formation-Heat of Calcium Oxychloride.—M. André.—The union of water with anhydrous oxychloride evolves more heat than the hydration of calcium chloride, which explains the formation of the oxychloride in the presence of water.

Action of Lead Protoxide upon the Alkaline Iodides.—A. Ditte.—This reaction may yield in one and the same liquid:—1. Decomposition of lead oxide by potassium iodide with formation of potash and oxyiodide, partly dissociated. 2. Decomposition of lead iodide by potash with the production of lead oxide and alkaline iodide. At a given constant temperature there are an infinite number of proportions of potassium iodide and potash capable of remaining in equilibrium with lead oxide and iodide.

Basic Calcium Carbonates.—F. M. Raoult.—The author obtains a bibasic carbonate by passing carbonic acid over dry calcium oxide at dull redness. The compound differs from a mixture of lime and of the neutral carbonate by certain properties. If exposed to the vapour of water it does not become hydrated, and if moistened with water it sets like a hydraulic cement without heating.

Influence of the Concentration of Hydrochloric Acid upon the Solution of Silver Chloride.—F. Ruyssen and E. Varenne.—The solubility of the salt decreases very rapidly with the dilution of the acid. An acid at 40 per cent dissolves 1-236th part of silver chloride; one at 5 per cent only 1-5626th part. The concentration of the salt also affects the solubility.

Action of Arsenic and Phosphoric Acids upon Sodium Tungstates.—J. Lefort.—With neutral sodium tungstate arsenic acid produces a double salt composed of sodium arseniate and tritungstate. On heating meta-tungstic acid is produced, which remains in the mother-liquor. With sodium bitungstate in the proportions of 4 parts of the salt to 1 of arsenic acid, there are formed sodium tritungstate and meta-tungstic acid. If the proportion of arsenic acid is doubled and the mixture heated to a boil for some time, renewing the water as it evaporates, the liquid acquires a yellowish tint, and there is formed an isomeric variety of meta-tungstic acid, which the authors name meta-luteo-tungstic acid.

Researches on Tertiary Monamines: Action of Heat on Allyl-triethyl-ammonium Bromide.—E. Reboul.—Allyl-triethyl-ammonium bromide, if heated in presence of a little water, yields triethylamine, diethyl-amine, and a primary ammonia (probably allylamine), also ethyl bromide, allyl bromide, and ethylen.

Microzymas of Chalk.—A. Béchamp.—The author refers to his former memoir (*Comptes Rendus*, lxiii., p. 453) to show that the necessary precautions to avoid error were not omitted, and that check-experiments were made with pure chalk, which gave negative results.

Justus Liebig's Annalen der Chemie,
Band 206, Heft 1 and 2.

Researches on the Non-Saturated Acids (Part 4).—Rudolph Fittig.—These consist of a memoir on the citraconic and mesaconic acids, by Paul Krusemark; a paper by H. Kast, on the atro-lactic, phenyl-lactic, and atro-glyceric acids; and a memoir by R. Fittig, on the isotropic acid.

Communications from the University Laboratory at Graz.—These comprise a memoir on the boiling-point of hypochloric acid, which the author, G. Schacherl, finds to be 9·9°. He observes, further, that the acid distils without explosion if it does not come in contact with any organic matter, such as caoutchouc or cork.

E. Fürst gives an account of the behaviour of hypochloric acid with potassium permanganate. Like hyponitric acid, the hypochloric acid is capable of acting both as an oxidising and a reducing agent. It reduces potassium permanganate very rapidly to manganese binoxide, potassium chlorate and hydrochloric acid being produced.

The same author has examined the behaviour of hypochloric acid with æthylen. The first result is the formation of mono-chlor-acetyl-chloride, water, and oxygen, the two former compounds being afterwards re-arranged as hydrochloric acid and mono-chlor-acetic acid.

The Condensation-Products of Aromatic Bases.—Otto Fischer.—The following general conclusions are drawn by the author from the numerous experiments described in this long and important paper:—In the products which arise from alcohols (benzyl-alcohol, benzhydrol) or aromatic acids (benzoic acid) with bases, the catenation takes such a form that water is separated and a molecule of the acid or the alcohol unites with each molecule of the base. In the compounds formed by aldehyds and bases water is formed and two molecules of the base combine with one molecule of the aldehyd. Anhydrides (benzoic, phthalic) behave like the aldehyds. In the fatty chlorides and the aromatised fatty chlorides the catenation with the bases is effected by the exit of hydrochloric acid. For every atom of chlorine there is introduced a phenyl residue, provided that the compound formed contains at most three phenyl residues combined with one atom of carbon. A single atom of carbon cannot retain more than three benzol residues. In the acid chlorides the process of condensation may be twofold;

either the catenation is attended with the exit of hydrochloric acid, keton-like bodies being formed, or it is accompanied with the elimination of water, as in the aldehyds.

Constitution of Arbutine.—H. Schiff.—The author considers that the substance analysed by Hlasiwetz and Habermann was a mixture of arbutine and methyl-arbutine.

Sulphamic and Oxy-Acids Derived from Mesitylen.—O. Jacobsen.—The author has examined in detail ortho-sulphamin-mesitylenic acid, the corresponding para-compound, sulphamin-uvitic acid, sulpho-uvitic acid, oxy-uvitic acid, sulphamin-trimesinic and oxy-trimesinic acids and their salts.

Researches on Levulinic Acid, or β-Aceto-propionic Acid.—These comprise a paper on the preparation and properties of levulinic acid, by A. v. Grote, Dr. E. Kehrer, and B. Tollens; memoirs on the production of levulinic acid from dextrose and milk sugar; an essay on its transformation into normal valerianic acid, and a paper on the hydrocarbons obtained as by-products during the reaction of hydrogen iodide upon levulinic acid.

Communications from the Laboratory of the University of Würzburg.—These consist of a memoir by Dr. R. Friedrich on dichlor-aldehyd-hydrate, and a memoir on the dry distillation of potassium dichloracetate, by the same author.

Band 206, Heft 3.

Researches on Lævulinic Acid or β-aceto-propionic Acid (Part 4).—This consists of an investigation on the oxidation of lævulinic acid, by B. Tollens. The author shows that the products of the action of dilute sulphuric acid are the succinic, acetic, carbonic, oxalic, hydrocyanic, and probably the formic acid, along with ammonia. Butyric acid is certainly not formed and the malonic acid could not be recognised.

The Naturally-occurring Mydriatic Alkaloids.—A. Ladenburg.—An account of the occurrence of these alkaloids in the Solanaceæ, and a description of a new base, hyoscine. Atropine occurs in *Atropa belladonna* and *Datura stramonium*, and resolves itself into tropic acid and tropine. Hyoscyamine is found in *Atropa belladonna*, *Datura stramonium*, *Hyoscyames niger*, and *Duboisia myoporoides*, and yields the same decomposition-products. Hyoscine occurs in *Hyoscyamus niger*, and yields tropic acid and pseudotropine. The three mydriatic alkaloids are isomers.

Communications from the University Laboratory of Würzburg.—These consist of a memoir by J. Wislicenus on the progress of the splitting up of polyvalent acetic esters by alkalies; a paper on two homologues of aceto-propionic acid, by C. Bischoff; an account of the synthesis of glyceric acid by means of mono-chlor-lactic acid, by E. Frank; a memoir on cetylacetester, cetyl, and dicetyl-malonic acid and their decomposition-products, cetyl- and dicetyl-acetic acids, by M. Guthzeit; and on the coal-tar oils whose boiling-points lie between that of naphthalin and that of acenaphthen, by F. Reingruber. The author commences with an account of methyl-naphthalin and the so-called diphenyl.

Moniteur Scientifique, Quesneville.
February, 1881.

The Odours of Paris.—Aimé Girard.—In this report we have a history of the processes by which the solid fœcal matters of Paris, removed on the pail system, have been treated in various suburban localities with a view to their disinfection and conversion into manure. The report recommends that all fœcal deposits in the open air, including the municipal cesspool of Bondy, ought to be totally suppressed, and the stock of fœcal matter accumulated there ought to be converted into dry manure with the least delay. All open-air deposits and manipulations of fœcal matters, liquid or solid, should be completely interdicted. All work-rooms, or tanks in which sewage-matters or their odorous derivatives are exposed to the contact of the air, and all apparatus in which such matters are treated should be inclosed with walls having only two openings, one for the entrance of the external air, and the other for the exit of the contaminated air, which should be connected with draught arrangements so constructed that the gases evolved cannot under any circumstances become diffused in the atmosphere. The treatment of the sewage-matters should include either the rapid desiccation of the whole refuse by means of artificial heat, or the drying up of the solids only, and the conversion of the liquids into ammoniacal salts. Before desiccation these substances should be mixed with a quantity of disinfectants sufficient to fix the hydrogen sulphide and the ammoniacal salts volatile at 100° F.

Coto-Barks and their Characteristic Elements.—J. Jobst and O. Hesse.—From the *Annalen der Chemie*.

Detection of the Accessory Alkaloids in Commercial Quinine Sulphate.—Dr. G. Kerner.—The author bases his method upon the following principles:—Among the neutral sulphates of the cinchona alkaloids quinine sulphate is the least soluble in cold water, and quinine hydrate is among all these bases the one most easily absorbed by ammonia. The solution, saturated in the cold, of chemically pure quinine sulphate contains always a constant quantity of alkaloid, which is precipitated from the solution by a constant quantity of ammonia, and redissolved by an unvarying excess of this liquid. The reaction of this re-solution may be observed with great precision.

Water and Air.—Dr. J. Tyndall.—From the *Journal of Science* for January, 1880.

Constitution of Ultramarine.—H. Endemann.—From the Chemical News.

Review of Chemical Researches Published in Germany.—Extracts from the *Berichte der Deutschen Chem. Gesell.*

Chemiker Zeitung.
IV., No. 20.

Retrospect of the Chemical Arts for the First Quarter of 1880.—Among the principal points brought forward is the failure of recent attempts to dispense with the lead chambers in the manufacture of sulphuric acid. Among the many new colours produced the only one for which success is expected is the red colour obtained by Grässler on treating sulphamido-azo-benzoic acid with β-naphthol. Anisol is now prepared on the large scale by means of methyl chloride, but the nitration of this body still presents serious difficulties.

Apparatus for the Volumetric Determination o Nitrogen.—Prof. H. Schwarz.—This paper cannot be intelligibly reproduced without the accompanying wood-cut.

Recovery of Old Vulcanised Caoutchouc.—The pieces are heated in contact with steam, when the sulphur is volatilised and the caoutchouc melts and is collected as a liquid, used in preparing water-proof covers, &c.

Meeting of the Industrial Society of Mulhouse.—A paper was read by Schmid on the direct preparation of cadmium sulphide upon tissues. It is proposed to print on a mixture of arsenious acid, sulphur, sodium acetate, and cadmium nitrate. A very fine yellow is obtained by steaming for one to two hours, and a bright orange is produced by increasing the proportion of sodium acetate.

Preservation of Meat.—In Vienna meat is prepared on the large scale for the Paris and London markets by exposure to cold and treatment with powdered borax.

Sodium Salicylate in Yellow Fever.—According to Dr. Freire hypodermic injections of this salt have been successfully used at Rio Janeiro in the earlier stages of yellow fever.

IRISH HILL BAUXITE (Alum Clay).

The IRISH HILL MINING CO. are now, and always have been, the LARGEST PRODUCERS OF THIS CLAY, of Superior Quality, and supply the Manufacturers of Alum, Sulphate of Alumina, and Alum-Cake, of the United Kingdom, America, and the Continent, almost exclusively.

Analysis by John Pattinson, Esq.

	Dried at 212° F.

VOL. XLIV. No. 1132.

ON SOME HITHERTO UNDESCRIBED SELENIUM COMPOUNDS.*

By CHARLES A. CAMERON, M.D., and EDMUND W. DAVY, M.D.,
The Professors of Chemistry, and of Forensic Medicine, Royal College of Surgeons, Ireland.

THE authors have succeeded in forming the different selenium compounds noticed in this abstract, which have not (as far as they are aware) been hitherto described.

Neutral Mercuric Selenate, $HgSeO_4$, is prepared by heating freshly precipitated mercuric oxide with selenic acid until a white compound is formed, filtering and evaporating to dryness, and heating to expel free acid. The salt may also be made by adding an excess of selenic acid to mercuric acetate, evaporating and heating the mixture to remove free selenic and acetic acids. It is a white salt, which dissolves in selenic acid, and from which solution it may be obtained in small crystals by its spontaneous evaporation. It is soluble also in sulphuric, nitric, and hydrochloric acids, but it is decomposed by water into a basic salt and free selenic acid, which latter retains a little mercuric selenate in solution.

Basic Mercuric Selenate, $HgSeO_4(HgO)_2$, may be prepared, as already stated, by the action of water upon the neutral salt, or more readily, by precipitating mercuric acetate by a soluble selenate or by selenic acid. It is a fine red salt, which is soluble in selenic, sulphuric, nitric, and hydrochloric acids; but it is very sparingly soluble in water, for even when freshly precipitated, it requires about 10,330 times its weight of that liquid for solution.

No acid mercuric selenate appears to exist, for the neutral salt treated with water produced, as already stated, the basic salt and free selenic acid, the reaction being as follows:—

$$3HgSeO_4 + 2H_2O = HgSeO_4(HgO)_2 + 2H_2SeO_4;$$

and on separating the acid liquid, and allowing it to evaporate *in vacuo* over sulphuric acid, crystals were obtained which proved to be the neutral selenate. The evaporation in the same way of a solution of the neutral mercuric selenate in selenic acid yielded only crystals of the neutral salt.

Mercurous Selenate, Hg_2SeO_4, is prepared by adding selenic acid, or an alkaline selenate to mercurous nitrate. It is a greyish white amorphous substance, which is very slightly soluble in water. It is insoluble in hydrochloric acid, and when boiled with nitric acid is converted into mercuric selenate, with the evolution of nitrogen dioxide. This salt is remarkably susceptible to the influence of light, a few moments' exposure being sufficient to cause darkening, even in diffused daylight.

Di-mercurammonium Selenate, $(NHg_2)_2SeO_4,2H_2O$.—Mercuric selenate forms with ammonia a compound analogous to the so-called ammoniacal turpethum, the dimercurammonium sulphate, $(NHg_2)_2.SO_4.2H_2O$. Thus, when the neutral, or freshly prepared and still moist, basic selenate is treated with a strong solution of ammonia it dissolves, but on the addition of water an abundant white precipitate appears, which is the compound in question. This salt dissolves readily in hydrochloric acid and in strong ammonia. It is blackened by exposure to the light, and when strongly heated it is decomposed, with the evolution of nitrogen, ammonia, and the vapour of water, basic mercuric selenate being left.

Action of Selenic Acid upon Mercury.—The authors have studied the action of selenic, as compared with sulphuric, acid on mercury. When the latter acid is heated with that metal a sulphate, with the evolution of sulphur dioxide, results, as is well known. When, however, selenic acid is heated with an excess of mercury, a selenite and not a selenate is formed. In this reaction a molecule of water is replaced in the acid by an atom of mercury, thus:—$Hg + H_2SeO_4 = HgSeO_3 + H_2O$. If an excess of acid, however, be used, the selenite first formed is decomposed and a selenate is produced. A mixture of mercurous and mercuric selenites is the usual product of the action of selenic acid upon an excess of mercury.

The authors have repeated the processes by which it is alleged an acid mercuric selenite is procurable, but they found that the compound described as biselenite of mercury is merely neutral selenite with a little selenious acid, and every attempt made to form an acid mercuric selenite failed.

Seleno-cyanides. — The authors succeeded in forming several hitherto undescribed simple and double seleno-cyanides; amongst the former the following were described:—

Mercuric Seleno-cyanide, $Hg(CySe)_2$, hitherto only obtained in the form of a double salt, was readily procured by adding potassium seleno-cyanide to mercuric acetate. It cannot be precipitated from mercuric chloride,—hence the previous failures to form it, as that salt had been used. From the acetate it is thrown down as a white felt-like mass, which must be dried over sulphuric acid, as the heat of the water-bath decomposes it. This salt is very sparingly soluble in cold water, but dissolves to a much greater extent in it when hot. It dissolves freely in alkaline cyanides, seleno-cyanides, and sulpho-cyanides, with all of which it forms double salts. In a hot solution of mercuric chloride it is likewise soluble, and the solution on cooling yields beautiful feathery crystals of the mercuric seleno-cyanide and chloride, the double salt already described by Mr. Crookes. Mercuric seleno-cyanide darkens on exposure to light, and when strongly heated it decomposes in a remarkable way, similar to that of its sulphur anologue, the combustion of which produces the intumescence known as Pharaoh's Serpents.

Mercurous Seleno-cyanide, $Hg_2(CySe)_2$, is prepared by adding a solution of an alkaline seleno-cyanide to one of mercurous nitrate. It is an olive-green compound, which must be dried over sulphuric acid, as it is decomposed by the heat of a water-bath. During combustion it intumesces, but only slightly. Nitric acid converts it into mercurous selenate, and hydrochloric into mercurous chloride, with separation of selenium.

Ammonium Seleno-cyanide, NH_4CySe.—This salt, though previously described by Mr. Crookes, is here noticed, as the authors prepared it by a new process, which consisted in digesting in alcohol a mixture of potassium seleno-cyanide and ammonium sulphate, which was found to be a very ready means of preparing this compound. Ammonium seleno-cyanide very closely resembles its sulphur analogue, but decomposes very readily. Its solution in water is attended by the production of great cold. Attempts to form selen-urea by heating ammonium seleno-cyanide gave unsatisfactory results, though it was probable that some selen-urea was thus formed.

Amongst the double salts which the authors succeeded in forming, the following are perhaps the most interesting:—

Potassium Seleno-cyanide and Mercuric Cyanide, $KCySe + HgCy_2$.—This salt is formed when to an aqueous —or, better still, alcoholic—solution of potassium seleno-cyanide mercuric cyanide in strong aqueous solution is added, when an immediate crystalline precipitate will be produced. This, on examination under the microscope, was found to consist of long fine prismatic crystals, which when dry have a white silky appearance, and seem to undergo no change even by prolonged exposure to the air. The salt dissolves but slowly and sparingly in cold water, and is still less soluble in cold alcohol, though in both

* Abstract of a Report read before the Royal Irish Academy, June 27, 1881.

liquids its solubility is much increased by heat. It is only to a very trifling extent dissolvable by ether, even when boiled in it. When heated with diluted hydrochloric acid its constituent selenium slowly separates, hydrocyanic acid being at the same time evolved.

Potassium Seleno-cyanide and Mercuric Sulphocyanide, $KCySe+Hg(CyS)_2$.—This salt is formed when an aqueous solution of potassium seleno-cyanide is heated along with mercuric sulphocyanide. The solution being filtered to separate the black matter that is formed, which appears to consist chiefly of mercuric sulphide, the filtrate on cooling yields long prismatic colourless crystals of this double salt, which when dry possesses a somewhat glistening appearance. This compound on being treated with a ferric salt develops the blood-red reaction of the sulphocyanides, and when heated with hydrochloric acid, selenium separates, whilst at the same time hydrocyanic acid is evolved; and, lastly, when heated in a tube, it yields, besides other products, a sublimate of metallic mercury. Like the double salt just described, it is sparingly soluble in both cold water and alcohol, but dissolves in either more readily on the application of heat, and these solutions on cooling or by evaporation yield long flat prismatic crystals, which possess considerable permanence; for some of the salt which had been exposed to the air for several months appeared to have undergone no change. This salt is soluble to some extent in ether, at least when boiled in it.

Potassium Seleno-cyanide and Mercuric Seleno-cyanide, $KCySe+Hg(CySe)_2$.—Mercuric seleno-cyanide dissolves readily in a solution of potassium seleno-cyanide, especially on the application of heat, and the solution on cooling or evaporation furnishes long prismatic six-sided crystals of the double salt, which remained unchanged on exposure to the air. This salt is readily soluble in water, even at the ordinary temperature, but dissolves slowly and sparingly in cold alcohol; in hot, however, it is soluble to a considerable extent. This compound was not quantitatively analysed, but there can be but little doubt that its composition is similar to the preceding salts, and that it consists of one molecule of the alkaline seleno-cyanide with one of the mercuric salt.

Potassium Seleno-cyanide and Mercuric Iodide,—

$KCySe+HgI_2$.

Mercuric iodide dissolves readily and completely in an aqueous or alcoholic solution of potassium seleno-cyanide, forming a colourless or faintly yellowish solution, which, if it is not too dilute, after a few moments yields colourless crystals of the above double salt. These when dry possess a pure white and somewhat pearly appearance, and when crystallised from an aqueous solution assume generally the form of thin plates, which are for the most part very irregular in their outline. The salt is sparingly soluble in water and in alcohol at the ordinary temperature, but dissolves readily in either on the application of heat. When this double salt is treated with diluted hydrochloric acid it immediately becomes yellow, then orange or scarlet, from the separation of its mercuric iodide, which subsequently dissolving in the excess of acid, the solution becomes perfectly colourless, whilst hydrocyanic acid is evolved, but this solution on being heated gradually becomes reddish brown from the separation of the constituent selenium of this salt.

An attempt was made to form a corresponding double salt with the green or mercurous iodide, but on treating it with a solution of potassium seleno-cyanide, metallic mercury separated, with the formation of the double salt just described.

Potassium Seleno-cyanide and Mercuric Chloride, $KCySe+HgCl_2$.—When to an aqueous or alcoholic solution of potassium seleno-cyanide, mercuric chloride in aqueous solution is added drop by drop, the white precipitate or effect at first produced instantly re-dissolves up to a certain point, when a colourless crystalline salt is formed, which remains. If, however, the addition of the mercuric chloride be continued, a light yellow compound will be formed after a certain amount of the chloride has been added. The white crystalline salt at first formed is a compound of potassium seleno-cyanide and mercuric chloride, a salt which is analogous to the double salts already described. This statement appears at first to be opposed to Mr. Crookes's results, who has stated that he obtained by the action of potassium seleno-cyanide on mercuric chloride a yellow salt consisting of mercuric seleno-cyanide and mercuric chloride. But in his experiments an excess of the mercuric chloride was employed in forming his double salt; whereas, in this case it was carefully avoided, and under these two opposite conditions two different salts are formed. This salt when quite dry has a very faint yellowish tint or shade, and like the double salts already described is sparingly soluble in cold water and alcohol, but is much more soluble in either solvent on the application of heat.

Potassium Seleno-cyanide and Mercuric Bromide, $KCySe+HgBr_2$.—Mercuric bromide acts in a perfectly similar manner to that of the mercuric chloride on potassium seleno-cyanide, and forms a corresponding double salt under the same conditions as those in the case of the chloride. The bromide salt crystallises in long flat prismatic crystals, which have a somewhat glistening appearance, and, like the other double salts, is sparingly soluble in cold water and in alcohol, though it dissolves more freely in both when heated.

It was ascertained that the different preceding double salts could be readily obtained by boiling together in water due proportions of potassium cyanide and precipitated selenium, and then adding the mercuric salt, and after continuing the heating for a short time, filtering the mixture whilst still hot, when the filtrate on cooling will yield crystals of the double salt. By this very simple means we may thus avoid the trouble of preparing, first, potassium seleno-cyanide by the process usually employed for its preparation.

In conclusion, the authors state that the formulæ which they have given for the different new salts they have described have been derived from the results of their chemical analyses of those compounds.

CONTRIBUTIONS TO THE CHEMISTRY OF BAST FIBRES.

Part III.

By E. T. BEVAN and C. F. CROSS.

A short time since we published a note upon the progress of our researches upon this subject, in which we announced our conclusion of the identity of the aromatic constituents of these fibres with the tannin group. Subsequently to this, we have examined the products of fusion of these bodies with potassic hydrate according to the usual method, and have obtained a considerable yield of protocatechuic acid together with phloro-glucin in small quantity, sufficient for qualitative identification. This fills up the only remaining gap in the evidence upon which our conclusion is based. It is likewise noticeable, that by the action of sulphuric acid upon the Esparto "resin," it is converted into substances resembling those obtained from digallic acid by the same treatment. Studying, in the next place, the action of the concentrated acid upon the jute fibre as a whole, we have obtained very interesting results, of which the following is a brief account.

On titrating the fibre in contact with the acid, it is dissolved to a viscous purplish solution; on heating this for a short time to 80° to 90°, and then pouring into water, the whole of the fibre substance is precipitated as a black spongey mass. This is converted by the action of Cl, in presence of water, into an orange coloured substance (or mixture), soluble in alcohol and in alkalies without residue, and closely resembling the aromatic chloro-derivatives

previously described by us. A large proportion of the black precipitated mass being evidently derived from the *cellulose* of the fibre, we proceeded to investigate the probability of *its* conversion into aromatic products, hereby suggested. Bleached cotton was titrated with the strong acid till dissolved, and heated to 80° to 90°. At this temperature the liquid effervesced copiously and gave off a strong smell of acetic acid; after a few minutes it thickened and swelled up to a voluminous black mass, which was purified by repeated treatment with water. Analysis showed it to contain 59 per cent C and 3·4 per cent H. On treatment with a mixture of potassium chlorate and hydrochlorate acid (dilute) in the cold, it was converted into a bright orange-coloured substance, entirely soluble in alcohol; soluble in alkalies to brown solutions, and in sodium sulphite solution with development of a red colour. Not only were its properties found to be closely similar to those of the chloro-derivatives above mentioned, but concordant analyses established its composition as that represented by the formula $n(C_{20}H_{16}Cl_4O_{10})$ and, therefore, as closely similar also. The original black substance, further, on treatment with nitric acid, specific gravity 1·4, at 30° C., was attacked and dissolved to a red solution, which on dilution, deposited a yellow nitro-body as a copious flocculent precipitate.

These results clearly show—(1.) That the black substances formed from the carbo-hydrates by the action of sulphuric acid (below 100°), while they have the external characteristics of charcoal, are not carbonaceous in any more special sense than alcohol is. (2.) That under this action, cellulose is so modified as to resemble (in its derivatives) the compound obtained from liquefied fibres, and, therefore, until we have proof to the contrary, we may regard *lignin* as derived from cellulose by a simple chemical modification (? dehydration). (3.) That the study of these compounds will throw light upon the relationship between the two great groups of the carbo-hydrates and the aromatic compound, and, lastly, may be expected also to elucidate several points in connection with the origin and nature of coal. These are the questions which are at present occupying our attention.

ON THE PREPARATION OF PURE NAPHTHALEN.

By G. LUNGE, Ph.D., F.C.S., Professor of Technical Chemistry, Zürich.

The manufacture of pure naphthalen on a large scale and at a cheap rate is still considered a secret process, and is not known to many tar-distillers. Hence, I may hope, that a communication of a convenient process for this purpose may be welcome to many of your readers, and I am fully entitled to publish it, as I have found it quite independently, and as I am, indeed, not even aware whether the same, or a similar plan, is in use at those tar-works where pure naphthalen is prepared.

Everybody knows that even very white naphthalen turns pink in the air after some time; this tendency can be overcome only by repeated crystallisations, washings, distillations, &c. Now the manufacturers of naphthol require naphthalen as nearly as possible chemically pure, and regard as a principal criterion its keeping *permanently* white. On the other hand, so much and so cheap pure naphthalen, made by "secret" processes, is in the market that evidently no purifying process has any chance which is not very simple and inexpensive. When working at a treatise (now in the press) on coal-tar and ammonia, my attention was necessarily drawn to the above gap in our public knowledge, and it became my task to try filling it up, in which I succeeded very soon.

I started from the assumption that the discolouration of naphthalen is analogous to that of phenol, and that it may be caused by the difficulty of removing the last traces of phenol from naphthalen. Now perfectly pure phenol does not discolour, but it does so when containing traces of higher homologues, and when exposed to the air. The presence of traces of mineral acids seems to be another condition for the development of the pink colour. It may be that the latter influence causes the formation of aurin, thus:—

$$2C_6H_6O + C_7H_8O + 3O = 3H_2O + C_{19}H_{14}O_3;$$

but it is immaterial whether this or any other pink compound is formed. In any case it seemed possible to form at once, by previous oxidation, the substance which causes the gradual discolouration of phenol, or of naphthalen, and to separate it, if not volatile, by distillation so as to obtain permanently white products.

Starting from this idea, I tried the addition of an oxidising agent in the ordinary chemical washing of naphthalen, and I succeeded at once. Crude naphthalen is usually obtained from tar oils previously treated with alkali for the purpose of extracting the phenols, and in this case evidently the action of acids should commence the purifying operations; but if naphthalen, obtained direct from tar, were to be treated, the first operation should be washing with alkali. The crude naphthalen is fused with a certain quantity of sulphuric acid. Acid of 170° Tw. is best, and of this from 5 to 10 per cent will be required on the large scale, but even acid of 140° Tw., employed in a little larger quantity, will do very well. When the liquid naphthalen and the vitriol have been well mixed up together, 5 per cent of the weight of naphthalen of manganese dioxide is gradually added. Native manganese, well ground up, may be used, but recovered manganese (dried Weldon mud) is preferable. The mixture is heated on the water-bath till no further reaction takes place, say for 15 or 20 minutes. The acid is now drawn off, the naphthalen washed several times with hot water, then with weak caustic soda solution, and again with water. It proved unnecessary to repeat the acid treatment, or to employ strong alkali.

Evidently manganese dioxide may be replaced by any other oxidising agent, but I did not make any experiments thereon, as there was no hope of finding a cheaper agent. Even a current of air would not be much cheaper, but it would be hardly as efficient, and would carry away a good deal of naphthalen.

The naphthalen cake is now distilled, and nearly all can be collected within one or two degrees of the boiling-point of pure naphthalen. The distillation should be carried on on the small scale in a long-necked flask; on the large scale in a still provided with a dephlegmating column.

A sample of naphthalen prepared by me according to the above simple and cheap plan has already kept its pure white colour for eight or nine months, whilst all the samples of "chemically pure" naphthalen which I had obtained from the most celebrated manufacturers, and which were kept in the same glass case, have long since turned pink.

ASBESTOS STOPPER FOR COMBUSTION TUBES.

By J. FLEMING WHITE, Laboratory of U.S. Geological Survey.

Some years ago, when working in the laboratory of organic chemist of Harvard University, I conceived the idea of an asbestos stopper for combustion tubes, which I make as follows:—The asbestos is separated into fine threads, moistened with water, twisted into a plug, crowded into the cylinder of an ordinary steel crusher, such as is used to pulverise minerals for analysis, and compressed by driving the piston of the crusher down upon it with a hammer, or better, by the screw of a vice. The plug is kept under pressure for several hours, then dried within the cylinder upon a sand-bath, pushed out of the cylinder, and after ignition over a blast-lamp is ready for use.

In this condition the plug loses no weight under prolonged ignition, is elastic enough to make a tight joint when fitted to a combustion tube of suitable size, and may be smoothly perforated with an ordinary cork borer.

Besides simplifying the method of organic analysis by permitting the substitution of short metallic tubes for the long glass combustion tubes in ordinary use, asbestos stoppers are very useful for closing bottles which contain substances corrosive to stoppers of rubber or cork.—*American Chemical Journal.*

THE TITRATION OF TARTARIC, MALIC, AND CITRIC ACIDS WITH POTASSIUM PERMANGANATE.

PRELIMINARY NOTE.

Communicated by F. W. CLARKE.

Some time ago, in the course of certain investigations upon the tartrates of antimony, it occurred to me that tartaric acid, like oxalic acid, might, perhaps, be conveniently titrated with potassium permanganate. A single qualitative experiment showed that a fair end reaction was attainable, and the same thing proved to be true of malic and citric acids also. Accordingly I put the question into the hands of Mr. Miles Beamer, who made the following determinations:—

The titrations were performed in all essential particulars exactly as for oxalic acid. A solution was prepared containing a definite quantity of tartaric acid, and upon this the permanganate solution, which was approximately twentieth normal, was standardised. Sulphuric acid was of course added before titrating. The colour changes were rather slower than with oxalic acid, and required a somewhat higher temperature. They were also possibly a trifle less delicate, but still fairly concordant results were easily obtained.

Having standardised the permanganate solution, it was used for estimating the percentage of tartaric acid in sodium potassium tartrate, $C_4H_4KNaO_64H_2O$. The following was the result, reckoning the acid as $C_4H_4O_6$:—

Percentage found..	51·63
„ theoretical	52·48
Error	0·85

As this percentage was rather roughly determined, a fresh experiment was made, with a new and more carefully standardised permanganate solution.

$C_4H_4O_6$ found	52·75
Error	0·27

Two sets of titrations were also made upon hydrogen potassium tartrate, $C_4H_5KO_6$. The percentages of acid, reckoned as $C_4H_5O_6$, came out as follows:—

First set	79·20
Second set	78·88
Theory	79·25

Tartar emetic was treated as follows:—Its solution was mixed with a slight excess of ammonium sulphide, and then acidulated with dilute sulphuric acid. By warming and filtration, all the antimony was thus removed, and the tartaric acid was left in a suitable condition to be determined. The salt used, however, was found to have lost some of its crystalline water, so that the results were not comparable with theory. Other determinations are now in progress upon certain tartrates of antimony, and will be published in due time.

The experiments upon malic acid precisely resembled those upon tartaric acid, and were conducted by Mr. C. S. Evans. As we had no definite malates at hand, a standardised solution of malic acid was neutralised partly with caustic soda and partly with ammonia. Thus solutions of alkaline malates were obtained containing known quantities of acid. Upon titrating these solutions, it was found that they behaved exactly like the acid itself. The ammonium malate gave 99·89 per cent of the acid known to be present, while the sodium salt gave 100·007 per cent.

With citric acid the results are still very incomplete. Mr. L. R. Freeman standardised a solution of permanganate upon this acid, and found the final reaction to be fairly sharp, but very slow towards the end. This standard permanganate, applied to an analysis of trisodium citrate, gave in mean 53·36 per cent of acid, reckoned as $C_6H_5O_7$. The theoretical amount should be 52·94. Error, 0·42. Mr. Evans attempted a repetition of these experiments, but, for some unknown reason, was not successful.

These preliminary figures show fairly well that the permanganate solution is suited to the titrations in question. The results may not be as sharp as with oxalic acid, but still they are fairly good. Some comparative titrations by Mr. Freeman show that tartaric and malic acids are oxidised to carbonic acid and water, while with citric acid the result is, of course, more complex. Although, then, it may be possible to standardise the permanganate upon oxalic acid once for all, I suspect it is better to standardise it directly upon whichever acid is actually to be estimated. I hope that either Mr. Beamer or myself will be able soon to present some additional figures.—*American Chemical Journal.*

ON THE SOLUBILITY OF TRIBASIC CALCIUM PHOSPHATE IN AMMONIACAL SALTS AND IN NEUTRAL ALKALINE SALTS, FROM AN ANALYTICAL AND AGRICULTURAL POINT OF VIEW.

By M. A. TERREIL.

In 1862, I published a memoir on the mineral principles which water removes from vegetable substances by maceration, infusion, and decoction, showing that water, even cold, removes from such matters calcium and magnesium phosphates, although the solutions were perfectly neutral. I have been often concerned to know what matters aid in dissolving these insoluble compounds. Being persuaded that, as regards the absorption of phosphates by plants, there is an important point to elucidate, and rejecting the idea put forward that the introduction of these phosphates into plants is effected by means of free carbonic or acetic acids, I have for some time undertaken researches on the alkaline salts, and on neutral organic proximate principles, as serving to hold in solution the insoluble phosphates, and in particular the phosphate of lime, and I have undertaken to determine their solvent power in this respect.

My attention was first drawn to the ammoniacal salts by the following circumstance:—Wishing to determine the solvent power of citric acid as ammonium citrate upon calcium phosphate, I dissolved some of this phosphate in hydrochloric acid; I added a known weight of citric acid, supersaturated with a slight excess of ammonia, and after filtering off the precipitated calcium phosphate, I determined the phosphoric acid in the filtrate. On operating thus with equal weights of citric acid I obtained very different numbers, *e.g.*, 24·7 per cent of the weight of the acid in one case, and 13·4 per cent in another. But as I had not measured the quantities of hydrochloric acid employed for dissolving the phosphate, I thought these differences might depend on the solubility of the phosphates in all the ammoniacal salts in general.

Setting out with this idea I began a series of experiments on the solvent power of the different ammoniacal salts for calcium phosphate, operating as follows:—

I first prepared a very pure phosphate of lime in a gela-

tinous state, and I dissolved a certain quantity of this phosphate in a known weight of acid. I then saturated with ammonia till an alkaline reaction was perceived. I filtered, washed, and in the filtrate I determined the phosphoric acid remaining in solution as ammoniaco-magnesian phosphate. The lime was determined in the ordinary manner, the ammoniacal salts having first been expelled by heat.

On operating thus, and with different weights of acid, there is found apparently the same coefficient of solubility of calcium phosphate for 100 parts of acid employed, showing that the more ammoniacal salt is formed the more calcium phosphate remains in solution. This is a very important fact from an analytical point of view, and explains the differences noticed above as regards citric acid, differences which reappear, doubtless, in the commercial analyses of superphosphates.

The author then gives a table of the coefficients, which he has found for the principal acids, converted into ammoniacal salts. These numbers, for 100 parts of acid by weight, range from 0·225 for acetic acid to 6·95 for crystalline citric acid. These numbers are rather low, in consequence of the solubility of the ammonium-magnesian phosphate in ammoniacal salts, the exact proportion of which the author purposes to determine.

Calcium phosphate is also held in solution by the salts of potassium and sodium, but in a much less degree than by the ammoniacal salts.

The author purposes extending his researches so as to determine the solvent influence of sugars, gums, and other proximate organic principles upon calcium phosphate in neutral solutions.—*Bull. de la Soc. Chimique de Paris.*

ON DECIPIUM AND SAMARIUM.

By M. DELAFONTAINE.

On October 28, 1878, I had the honour of communicating to the Academy the discovery of a new metal from samarskite. At that time I fixed the molecular weight of decipia at about 122, and I described its absorption-spectrum. Since then the defective situation of my windows and other material obstacles have caused me to lay spectroscopic observations almost entirely aside, and I have confined myself to the chemical study of decipium. Without these difficulties the facts about to be laid down in this note would have occurred to me much earlier.

On submitting to methodic washings in cold water those of the earthy-sodic double sulphates of samarskite which are the least soluble in sodium sulphate, I obtained separations showing that my decipia of 1878 was in reality a mixture of two new oxides, one of them with a molecular weight of about 130, the other with a molecular weight notably lower. The former does not appear to give an absorption-spectrum, whilst the second gives that which I described two years ago.

No chemist has made known these facts before me. M. Lecoq has, indeed, subsequently announced the discovery of samarium, but he had in his hands merely a mixture like mine. I consider myself, therefore, entitled to name these two new elements.

As in my memoir published in the *Archives des Sciences Physiques et Naturelles*, March, 1880, I will retain the name decipium for the radicle of the earth which has the molecular weight of about 130. In this memoir it is merely requisite to cancel the paragraph treating of the absorption-spectrum. Now, as a year ago dry decipium sulphate gives 61·4 per cent of earth (the mean of four analyses made upon quantities comprised between 2·5 and 8 grms.), three analyses of acetate give 45·03, and two of formiate 63·56 per cent. The salts are colourless, and their solubility is identical.

In order the better to utilise the good description of the absorption-spectrum of the other metal, published by M. Lecoq, I propose to transfer to it the name samarium. The molecular weight of samaria does not exceed 117, and is probably lower. In equal concentration its solution gives absorption-bands more intense than those of the original specimen of 1878, the equivalent of which was 122.

In May, 1880, M. Marignac described two of the earths of samarskite, distinguishing them as Yα and Yβ. The latter, to which the Genevese *savant* attributes the equivalent 115, seems to me identical with samaria. As to the former (Yα = 120·5) it may be supposed a mixture of decipia and terbia. I have a few grammes of it, but its study is not sufficiently advanced to warrant the assertion that it is not a distinct species.—*Comptes Rendus.*

INDIGO, AND ITS ARTIFICIAL PRODUCTION.*

By H. E. ROSCOE, LL.D., F.R.S., &c.
President of the Chemical Society.

(Continued from p. 54.)

Step No. 3.—The next advance of importance in this somewhat complicated matter is the discovery by Erdmann and Laurent independently, that indigo on oxidation yields a crystalline body, which, however, possesses no colouring power, to which they gave the name of isatin.

$$\underset{\text{Indigo.}}{C_8H_5NO} + O = \underset{\text{Isatin.}}{C_8H_5NO_2}.$$

Step No. 4.—The reverse of this action, viz., the reduction of isatin to indigo, was accomplished by Baeyer and Emmerling in 1870 and 1878, by acting with phosphorus pentachloride on isatin, and by the reducing action of ammonium sulphide on the chloride thus formed.

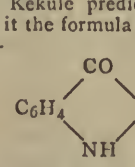
Understanding now something of the structure and of the relationships of the body which we wish to build up, let us see how this edifice has, in fact, been reared. Three processes have been successfully employed for carrying out this object. But of these three only one is of practical importance. A synthetic process may yield the wished-for result, but the labour incurred may be too great and the losses during the campaign may be too severe to render it possible to repeat the operation with advantage on a large scale. Just as it costs, at the usual rate of wages, more than twenty shillings to wash a sovereign's worth of gold out of the Rhine sands, so that this employment is only carried on when all other trades fail.

For the sake of completeness, let us, however, consider all three processes, although Nos. 1 and 2 are at present beyond the pale of practical schemes.

These three processes have certain points in common. (1) They all proceed from some compound containing the benzene nucleus. (2) They all start from compounds containing a nitrogen atom. (3) They all commence with an ortho-compound.

They differ from one another, inasmuch as process No. 1 starts from a compound containing 7 atoms of carbon (instead of 8), and to this, therefore, one more atom must be added; process No. 2, on the other hand, starts from a body which contains exactly the right number (8) of carbon atoms; whilst No. 3 commences with a compound in which 9 atoms of carbon are contained, and from which, therefore, 1 atom has to be abstracted before indigo can be reached.

Process No. 1 (Kekulé—Claissen and Shadwell).—So long ago as 1869 Kekulé predicted the constitution of isatin, and gave to it the formula which we now know that it possesses, viz.,—



* A Paper read before the Royal Institution of Great Britain, Friday, May 27, 1881.

Following up this view, Claissen and Shadwell, two of Kekulé's pupils, succeeded in preparing isatin, and, therefore, now indigo, from ortho-nitro-benzoic acid.

The following are the steps in the ascent :—

1. Ortho-nitro-benzoic acid acted on by phosphorus pentachloride yields the chloride, $C_6H_4(NO_2)COCl$.
2. This latter heated with silver cyanide yields the nitril, $C_6H_4(NO_2)CO.CN$.
3. On heating this with caustic potash it yields ortho-nitro-phenyl-glyoxylic acid, $C_6H_4(NO_2)CO.CO_2H$.
4. This is converted by nascent hydrogen into the amido-compound, $C_6H_4(NH_2)CO.CO_2H$.
5. And this loses water and yields isatin,—

$$C_6H_4NH.CO.CO.$$

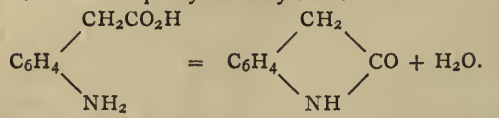
(Q. E. D.)

The reasons why this process will not work on a large scale are patent to all those who have had even bowing acquaintance with such unpleasant and costly bodies as phosphorus pentachloride or cyanogen.

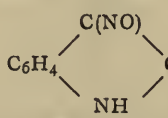
Process No. 2.—Baeyer's (1878) synthesis from ortho-nitro-phenyl-acetic acid.

This acid can be obtained synthetically from toluol, and it is first converted into the amido-acid, and which, like several ortho-compounds, loses water, and is converted into a body called oxindol, from which isatin, and, therefore, indigo, can be obtained. The precise steps to be followed are :—

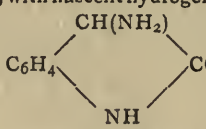
1. Ortho-amido-phenyl-acetic yields oxindol :



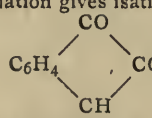
2. This on treatment with nitrous acid yields nitros-oxindol :



3. This, again, with nascent hydrogen gives amidoxindol :



4. Which on oxidation gives isatin :



(Q. E. D.)

This process, the feasibility of which had also been foreseen by Kekulé, is, however, not available as a practical scheme, for various reasons.

Process No. 3.—This may be called the manufacturing process, and was also proposed by Baeyer. It starts from cinnamic acid, a substance contained in gum benzoin, balsam of Peru, and some few other aromatic bodies. These sources are, however, far too expensive to render this acid thus obtained available for manufacturing purposes. But Bertagnini, in 1856, had obtained cinnamic acid artificially from oil of bitter almonds, and other processes for the same purpose have since been carried out. Of these, that most likely to be widely adopted is the following practical modification by Dr. Caro of Mr. Perkin's beautiful synthesis of cinnamic acid :—

1. $C_6H_5CH_3 + 4Cl = C_6H_5CHCl_2 + 2HCl$.
   Toluene. Benzylene Dichloride.
2. $C_6H_5CHCl_2 + 2CH_3.CO.O.Na =$
   Benzylene Dichloride. Sodium Acetate.
   $= C_6H_5CH{=}CH.CO.OH + 2NaCl$.
   Cinnamic Acid.

But why did Baeyer select this 9-carbon acid from which to prepare indigo ? For this he had several reasons. In the first place, it had long been known that all indigo compounds when heated with zinc dust yield indol, C_8H_7N, a body which stands therefore to indigo in the same relation as anthracen to alizarin, and Baeyer and Emmerling had so long ago as 1869 prepared this indol from ortho-nitro-cinnamic acid thus :—

$$C_8H_6(NO_2)CO_2H = C_8H_7N + O_2 + CO_2.$$

Secondly, the ortho-nitro-cinnamic acid required (for we must remember that indigo is an ortho-compound and also contains nitrogen) can be readily prepared from cinnamic acid, and this itself again can be obtained on a large scale. Thirdly, this acid readily parts with 1 atom of carbon, and thus renders possible its conversion into 8-carbon indigo.

The next steps in the process are (3) the formation of ortho-nitro-cinnamic acid, (4) the conversion of this into its dibromide, (5) the separation from this of the two molecules of hydrobromic acid, giving rise to ortho-nitro-phenyl-propiolic acid, and (6) lastly, the conversion of this latter into indigo by heating its alkaline solution with grape sugar, xanthate of soda, or other reducing agent. These reactions are thus represented :—

3. $C_6H_5CH{=}CHCOOH \quad C_6H_4(NO_2)CH{=}CH.COOH$
   Cinnamic Acid yields Ortho-nitro-cinnamic Acid.

In this process the para-acid is also obtained, and as this is useless for the manufacture of indigo, it has to be removed. This is effected by converting the acids into their ethyl-ethers, which, possessing different degrees of solubility, can be readily separated from one another.

4. This is next converted into the dibromide,

$$C_6H_4(NO_2)CHBr.CHBrCOOH.$$

5. And by careful treatment with caustic soda this yields ortho-nitro-phenyl-propiolic acid, thus :—

$$C_6H_4(NO_2)CHBrCHBrCOOH + 2NaOH =$$
$$= C_6H_4(NO_2)C_2.COOH + 2NaBr + 2H_2O.$$

6. $n[C_6H_4(NO_2)C_2.COOH + H_2 = C_8H_5NO + CO_2 + H_2O]$.
   Ortho-nitro-phenyl-propiolic Acid. Indigotin.

(Q. E. D.)

The last of these reactions is in reality not so simple as the equation indicates. For only about 40 per cent of indigo is obtained, whereas according to theory 68 per cent should result. Indeed, although, as we have seen, indigo can be prepared by these three methods, chemists are as yet in doubt as to its molecular weight, the probability being that the molecule of indigo contains twice 16 atoms of carbon, or has the formula $4(C_8H_5NO)$ or $C_{32}H_{20}N_4O_4$. Still it must be remembered that according to Sommaruga the vapour-density of indigo is 9·45, a number corresponding to the simpler formula $C_{16}H_{10}N_2O_2$.

The artificial production of indigo may even now be said to be within reasonable distance of commercial success, for the ortho-nitro-phenyl-propiolic acid, the colourless substance which on treatment with a reducing agent yields indigo-blue, is already in the hands of the Manchester calico printers, and is furnished by the Baden Company for alkali and aniline colours at the price of 6s. per lb. for a paste containing 25 per cent of the dry acid.

With regard to the nature of the competition between the artificial and the natural colouring matters it is necessary to say a few words. In the first place, the present price at which the manufacturers are able to sell their propiolic acid is 50s. per kilo. But 100 parts of this can only yield, according to theory, 68·58 parts of indigo-blue, so that the price of the artificial (being 73s. per kilo.) is more than twice that of the pure natural colour. Hence, competition with the natural dyestuff is not to be thought of until the makers can reduce the price of dry propiolic acid to 20s. per kilo., and also obtain a theoretical yield from their acid. This may, or it may not, be some day accomplished, but at present it will not pay to produce indigo from nitro-phenyl-propiolic acid. Nevertheless, a large field lies open in the immediate future for turning

Baeyer's discovery to practical account. It is well-known that a great loss of colouring matter occurs in all the processes now in use for either dyeing or printing with indigo. It has already been stated that a large percentage of indigo is lost in the "cold vats" in the sediment. Another portion is washed off and wasted after the numerous dippings, whilst in order to produce a pattern much indigo must be destroyed before it has entered into the fibre of the cloth. Moreover, the back of the piece is uselessly loaded with colour. In the processes of printing with indigo the losses are as great, or even greater, and, in addition, such considerable difficulties are met with that only a few firms (Potter, Grafton in Manchester, and Schlieper in Elberfeld) have been successful in this process. But a still more important fact remains, that no printing process exists in which indigo can be in combination with other colours in the ordinary way, or without requiring some special mode of fixing after printing. Hence it is clear that the weak points of natural indigo lie in the absence of any good process for utilising the whole of its colouring matter, and in the impossibility, or at any rate great difficulty, of employing it in the ordinary madder styles of calico printing. Such were the reasons which induced the patentees to believe that although the artificial dye cannot be made at a price to compete with natural indigo for use in the ordinary dye-beck, it can even now be very largely used for styles to which the ordinary dyestuff is inapplicable.

To begin with, Baeyer employed (Patent 1177) grape-sugar as a reducing agent. The reduction in this case does not take place in the cold, and even on long standing only small traces of indigo are formed, but if heated to 70° or upwards the change takes place. Unfortunately this production of indigo-blue is rapidly followed by its reduction to indigo-white, and it is somewhat difficult in practice to stop the reaction at the right moment. But "necessity is the mother of invention," and Dr. Caro, of Mannheim, to whom the speaker is greatly indebted for much of the above information, found that sodium xanthate is free from many of the objections inherent to the glucose reduction process, inasmuch as the reaction then goes on in the cold. Moreover, he finds that the red isomeride of indigo-blue, Indirubin, which possesses a splendid red colour, also occurring in natural indigo, but whose tinctorial power is less than that of the blue, is produced in less quantity in this case than when glucose is employed. On this cloth alumina and iron mordants may be printed, and this afterwards dyed in alizarin, &c., or this colouring matter may also be printed on the cloth and the colour fixed by moderate steaming without damage to the indigo-blue. This process is now in actual use by printers both in England and on the Continent, so that, thanks especially to the talent and energy of Dr. Caro, Baeyer's discovery has been practically applied within the short space of twelve months of its conception. Operations on a manufacturing scale have been successfully carried on in the Baden Soda and Aniline Works at Ludwigshafen for the last two months, and the directors see no reason why they should not be able to supply any demand, however great, which may be made for ortho-nitro-phenyl-propiolic acid.

The proper way of looking at this question at present is, therefore, to consider ortho-nitro-phenyl-propiolic acid and indigo as two distinct products not comparable with each other, inasmuch as the one can be put to uses for which the other is unfitted, and there is surely scope enough for both. Still, looking at the improvements which will every day be made in the manufacturing details, he must be a bold man who would assert the impossibility of competition with indigo in all its applications. For we must remember that we are only at the beginning of these researches in the indigo field. Baeyer and other workers will not stay their hands, and possibly other colouring matters of equal intensity and of equal stability to indigo may be obtained from other as yet unknown or unrecognised sources, and it is not improbable that these may turn out to be more formidable competitors in the race with natural indigo than ortho-nitro-phenyl-propiolic acid.

Looking at this question of the possible competition of artificial with the natural indigo from another point of view, it must, on the other hand, be borne in mind that the present mode of manufacturing indigo from the plant is extremely rude and imperfect, and that by an improved and more careful carrying out of the process great saving in colouring matter may be effected, so that it may prove possible to produce a purer article at a lower price, and thus to counterbalance the production of the artificial material.

(To be continued.)

NOTICES OF BOOKS.

The Chemistry of the Farm. By R. Warington, F.C.S. London: Bradbury, Agnew, and Co.

The author of this work gives as a special reason for its appearance "the scarcity of books on farm chemistry in the English language." He considers that we have no text-books in which "the present aspects of the science are at all adequately represented."

We cannot entirely accept Mr. Warington's contention. We will admit that the agricultural treatises of Davy, and even of Liebig, are now no longer of special use to the student, what in them was of value having been reproduced in later works. But an edition of Prof. Johnston's "Agricultural Chemistry," brought down to the present state of knowledge, has appeared at no very remote date. We find also that our author has forgotten the existence of a book by M. Ville, embodying the results of a long series of important experiments. This omission is the more striking, as the work in question has appeared in an English version.

Still we cheerfully admit that manuals of agricultural chemistry have not yet, like elementary treatises on general chemistry, multiplied to such an extent as to become little short of a nuisance.

The work before us is of such a nature that it might perhaps claim the title "The Physiology of the Farm" quite as legitimately as that which it actually bears. Agriculture, however, is undoubtedly based upon physiology not less than upon chemistry in the true sense of the term.

One of the first points which strike us on a close examination of Mr. Warington's treatise is a tendency to repetition. Thus, on page 4 we read that plants obtain "through the instrumentality of their leaves the whole, or nearly the whole, of their carbon, with probably small quantities of nitrogen and water." On page 6 it is again stated that "plants are apparently capable of absorbing a small quantity of ammonia through their leaves;" and on page 13 we are told "that the ammonia of the air is directly absorbed by plants to a very small extent." In one passage the reader learns (page 8) that "most plants are unable to assimilate the nitrogenous humus contained in soil," whilst on page 17—possibly with a view to the old saying, *Repetitio mater est studiorum*—comes the very similar proposition, "The nitrogen contained in humus is not in a condition to serve as a general plant food."

Silica was till lately considered as an essential portion of the food of cereals, and indeed of grasses generally, forming the beautiful surface-glaze which was supposed needful for the stability of the stems. In four distinct passages the author more or less explicitly shows that it is non-essential, and that the silicated glaze aforesaid is a mere excretion. Further instances of similar repetitions might be given if at all necessary.

On page 10 we find the assertion that certain seeds, such as linseed, "contain no starch, but in its place a large quantity of fat." The presence of fat in linseed is of course very evident, but on referring to published ana-

lyses, both of the crude seed and of the cake after expression, we find that a small quantity of starch is present.

"Phosphoric acid, potash, and ammonia," we read, "are very rarely found in drainage water." Some good authorities on the analysis of waters maintain that phosphoric acid is almost universally detected where carefully sought for. But, leaving this point aside, the absence of ammonia in drainage-water is due not so much to its retention in the soil as to its conversion into nitrates.

As exceedingly valuable we must call attention to certain ideas on the characteristics of crops which the author ascribes to Mr. Lawes. This distinguished experimentalist points out that the active growth of the cereals extending only to the end of June places these crops at a disadvantage as far as the supply of nitrogen from nitrates present in the soil is concerned. The nitrates formed in the soil during the foregoing season are generally washed away by the winter rains before the active growth of the corn commences, and by the time nitrification is well resumed in the summer cereal crops are too mature to appropriate fresh supplies of nitrogen. Hence continuous wheat crops impoverish the soil in nitrogen to a greater extent than by the quantity actually assimilated by the plant. On the other hand, green crops which continue growing into the autumn utilise the nitrates formed during the summer, and do not leave it to be washed away.

This work contains much valuable instruction, and if freed from repetitions such as we have pointed out, and from an occasional ambiguity of expression, would prove very useful.

The Harrogate Waters: Data, Chemical and Therapeutical, with Notes on the Climate of Harrogate. By G. Oliver, M.D. London: H. K. Lewis.

There are many persons who consider the benefits of leaving town during the summer to consist, not so much in a temporary relief from the noise and worry of their ordinary life, as in a "change of air." Accordingly, they select their resorts, not so much on account of varied and picturesque scenery, as in accordance with some trifling difference of climate, such as temperature, atmospheric moisture, &c, or with a trifling difference in the death rate. Among the peculiarities of Harrogate we find here enumerated the absence of forests. If this feature is an advantage at all it is one common to at least nine-tenths of the surface or the British Islands. We cannot help remarking that, in warmer climates at least, the extirpation of the forests has proved by no means conducive to health, and that replanting has been advocated no less on sanitary than on agricultural grounds.

Mineral waters are found in this breezy—or as some persons would call it, bleak and bare—district in considerable variety. There are pure sulphur waters, saline sulphur waters, pure chalybeates, saline chalybeates, and sulphuretted chalybeates. A feature, by no means common, is the presence of barium and strontium chlorides. According to Prof. Thorpe—an unimpeachable authority—no mineral springs, either in this country or on the Continent, contain so large a proportion of this substance as the Harogate waters. He found in the "Old Sulphur Spring," in 1875, no less than 0·820 gr. barium chloride per pint. He considers that the proportion of this salt is increasing, and in view of its well-known therapeutic activity, recommends that the proportion should be from time to time re-determined. The largest amount of strontium chloride, 0·418 gr. per pint, is in the "Strong Montpellier Spring." As a matter of course, soluble sulphates are absent. The calcium salts present are the carbonate, and especially the chloride. But the total average of lime in the Harrogate aperient waters is only 9 per cent as against 21 per cent in the Kissengen springs. In none of the Harrogate waters are sulphates—especially calcium sulphate, which the author pronounces indigestible and constipating—present in more than a mere trace.

The sulphur present exists in combination with hydrogen and with sodium. With the sole exception of Challes, the "Strong Sulphur" contains more sodium sulphide than exists in any known water.

Iodine and bromine have been discovered by Prof. Thorpe in the "Old Sulphur Spring," the former in the proportion of 0·0146 and the latter 0·2805 in 10,000 parts. Chloride of manganese has also been detected in one of the chalybeate wells. Arsenic is not recorded as occurring in any of the waters.

Into the second portion of the work, the therapeutic examination of the Harrogate Springs, it is not our province to enter. It may, however, be fairly asked whether the large importation of foreign mineral waters which the turn of fashion and a course of diligent advertising have brought about is really essential?

CORRESPONDENCE.

ON A NEW METHOD FOR THE ESTIMATION OF NITRATES IN POTABLE WATERS.

To the Editor of the Chemical News.

Sir,—Allow me to inform Mr. West Knights that his process for the estimation of nitrates is not the only one that has been devised for the estimation of nitric acid based on the brucine reaction, and that his statement—viz., such a process has never been given—is very premature. Mr. Knights will also find that his standard red solution is liable to decompose if it does not contain alcohol; it also requires to be kept from the light.—I am, &c.,

William Johnstone.

King's Lynn, July 29, 1881.

CHEMICAL NOTICES FROM FOREIGN SOURCES.

Note.—All degrees of temperature are Centigrade, unless otherwise expressed.

Comptes Rendus Hebdomadaires des Séances, de l'Académie des Sciences. No. 26, June 27, 1881.

Use of Liquid Prisms in Direct Vision Spectroscope.—C. V. Zenger.—The author employs a mixture of anethol and benzol. Its absolute dispersion is 3·7 times that of quartz.

Photography of Colours by Dyeing Layers of Coagulated Albumen.—C. Cros and J. Carpentier.—The authors submitted to the Academy two photographic proofs of a painting in water colours, along with the original, showing the exact reproduction of the details and colours. Three photographs of the object are taken respectively through liquid screens of an orange, a green, and a violet colour. For the image obtained through the green screen there is employed a red colour bath, for that produced through the orange screen a blue, and for the image of the violet screen a yellow bath. In this process there is not a direct photographic reproduction of images with the natural colours of the bodies.

Silicium.—P. Schützenberger and A. Colson.—Crystalline silicium heated almost to whiteness in an atmosphere of carbonic acid absorbs this gas rapidly, and is ultimately converted into a greenish white mass. On being freed from unchanged silicium by treatment at a boil with moderately concentrated potassa lye, the residue is found partially soluble in hydrofluoric acid, which dissolves silica and leaves a residue, which, when washed and dried, is a greenish powder, not attacked by boiling alkaline lyes

or by acids, including the hydrofluoric. If heated to redness in a current of oxygen it is little modified, and yields carbonic acid, corresponding only to 2 or 3 per cent of carbon. But if heated to dull redness with lead chromate and litharge it becomes incandescent, and evolves notable quantities of carbonic acid. On analysis it is found to contain 21·4 per cent of carbon. The silicium nitride of Wœhler contains also carbon. Hence the authors admit the existence of a tetratomic radicle, carbosilicium, which, like carbon, yields a binoxide and a nitride. On heating the product of the action of dry ammonia upon silicium chloride in a current of hydrogen, the authors obtained a white powder, $Si_5N_6Cl_2$. If this powder is heated to redness in a current of ammonia it loses all its chlorine in the form of hydrochloric acid, and leaves a residue, Si_2N_3.

A Cyanic Ether of Borneol.—A. Haller.—If melted with potassa the borneol cyanate is decomposed, yielding camphol, potassium carbonate, and ammonia. Its solution in absolute alcohol, heated with potassa, yields on cooling potassium cyanate. If heated to 200° to 210° it is split up into borneol and cyanuric acid.

Part Played by Phosphoric Acid in Volcanic Soils.—L. Ricciardi.—A reply to a memoir presented to the Academy by M. de Gasparin, June 6th.

Bulletin de la Société Chimique de Paris.
No. 4, February 20, 1881.

Potassium and Ammonium Tetra-chromates.—G. Wyrouboff.—The author shows that the potassium nitrobichromate and nitro-trichromate of Darmstædter are in reality one and the same compound, a potassium tetrachromate.

Russian Chemical Society.—Session May 1/12, 1880.—The Secretary read an obituary notice of M. Wischnegradsky.

M. Louguinine communicated the continuation of his researches on the combustion-heats of organic compounds, and especially of isomeric bodies. He has particularly studied the amylic alcohol of fermentation, dimethyl-ethyl carbinol, and œnanthol.

M. Potilitzine gave an account of his investigations on the displacement of the chlorine in potassium chloride by bromine in an atmosphere of nitrogen. With reference to the memoir of M. Berthelot on the same subject (*Comptes Rendus*, 90, p. 893), he considers that the displacement of chlorine by bromine cannot be ascribed to any fortuitous cause whatever, and that its reason must be sought in the very nature of the reacting bodies.

M. Almedingen communicated an analysis of stibine found in the district of Birsk.

MM. Beilstein and Jawein indicated a method of determining zinc and zinc powder, based upon the determination of the hydrogen evolved when the metal is dissolved in hydrochloric acid.

M. Beilstein presented some observations on the properties of platinum crucibles.

M. Sokoloff described the result of the analysis of the mineral waters of Staraja-Roussa.

M. Orloff sent in a memoir on the determination of mercury in the bodies of animals poisoned with corrosive sublimate.

M. Mokoonsoff gave in researches on the determination of arsenic in animals which had been submitted to sudden or slow poisoning.

M. Bartholomeeff sent in a paper on the comparison of the process of MM. Wœhler and Siebold for the destruction of organic tissues with the process of Fresenius and Babo when it is required to determine antimony in a poisoned animal.

M. Konowaloff on causing nitric acid of sp. gr. 1·3 to react upon iso-tributylene, obtained a body which, on reduction, furnished an amine.

M. Kajander has studied the speed of the dissolution of magnesium in acids.

M. Chrapowicki presented to the Society the crystals of a new saturated hydrocarbon obtained by causing metallic sodium to react upon an ethereal solution of the iodide of tertiary butyl.

M. Lwow treated on the influence of iodine, water, carbonic acid, and some other bodies on the polymerisation of vinyl bromide exposed to light.

The same author gave an account of the action of chlorine and bromine on two isomeric quintanes, tetramethyl-formen, and dimethyl-ethyl-formen. To take date he also announced that he had obtained an amylen bromide, boiling at 110° to 115°.

M. Lagermark explained the principal results of researches on tetrolic acid.

M. Flavitzky announced that commercial oil of citron contains, along with dextro-rotatory terebenthen, more than 10 per cent of a lævo-rotatory terebenthen.

Red Dyeing with Artificial Alizarin.—M. Maurice Prud'Homme.—Inserted at length.

Die Chemische Industrie.
No. 1, January, 1881.

Determination of Potassium Sulphate in Kainite.—Dr. H. Precht.—The author proposes an indirect method, useful in all cases, where time is an object. He finds that for an increase of 1 per cent chlorine there is a decrease of 0·76 per cent potassium sulphate. He dissolves 10 grms. finely ground kainite in 500 c.c. of water, and titrates 20 c.c. of the unfiltered solution with decinormal silver nitrate. If 24 c.c. of the solution are consumed the sodium chloride present is 15·17 per cent, and the potassium sulphate 29·33. If the c.c. of silver solution taken rise to 34, the sodium chloride is 34·32, whilst the potassium sulphate falls to 22·52 per cent.

No. 2, February, 1881.

Certain New Products of the Alkali Manufacture.—Dr. Rammelsberg.—Certain colourless crystals obtained from the so-called red liquor have the same composition as crystals formed by treating disodium phosphate and caustic soda with sodium fluoride, and may be represented as $NaF+2Na_3PO_4$. The red vanadiferous crystals dissolve in water without colour, depositing a little iron sulphide. The solution gives with salts of silver a yellow precipitate containing phosphorus and vanadium, traces of chlorine and sulphur, carbonic acid, fluorine, and silica. The presence of phosphorus, vanadium, and fluorine in black-ash is due to the lime-stone and coal, and to the bricks of which the furnace is constructed. The clay used for fire-bricks often contains vanadium. In a second communication, Dr. Rammelsberg describes artificial Gay-Lussite, $Na_2CO_3+CaCO_3+5$ aq., produced in the carbonating towers. These crystals are produced when a large excess of lime is used in the manufacture of alkali. —*Monathsber, d. König. Acad. Wissen. Berlin.*

No. 3, March, 1881.

Loss of Soda in the Alkali Manufacture.—Dr. C. Reidemeister.—This paper treats mainly on the formation of sodium-calcium carbonate (artificial Gay-Lussite). The author concludes that the temperature at which sodium carbonate is formed in the Leblanc process is rather below the point at which calcium carbonate and sodium carbonate melt together.

The Composition of the Hydrates of Stannic, Manganic, and Silicic Oxides.—J. M. Van Bemmelen.—The author undertakes to show that the composition of

these compounds depends, first, on the degree of moisture and on the temperature of the ambient medium, and consequently on their own vapour-tension at each temperature, and, secondly, on their molecular state, ordinarily termed their allotropic state or condition. He shows that the composition of meta-stannic and stannic acids is not constant, even under ordinary circumstances. Silicic acid retains water with less force than stannic acid. M. Van Bemmelen thinks that of the maximum quantity of water which an oxide can retain at a given temperature different portions are fixed with a different force. In a dry medium the portion combined with a greater force is retained, whilst a portion united by a feebler force escapes. The case may occur that the number of molecules of an oxide is greater than that of the molecules of water retained. The water linked with less force is anew absorbed in the moist medium, and an equilibrium is established, when in a unit of time as many molecules enter as are given off. To each temperature there must correspond for each degree of moisture in the medium a different state of equilibrium, that is, a different composition of the hydrate. The connection is consequently a phenomenon of dissociation. At each temperature and at each degree of humidity the hydrates of stannic and manganic oxides and silicic acid have a given dissociation-tension.

Tome xv., Livraison 5me.

Combinations of Certain Solid Hydrates of Dioxides with Acids, Salts, and Alkalies.—J. M. Van Bemmelen.—The author seeks to demonstrate that certain phenomena are wrongly excluded from the domain of chemistry properly so-called and spoken of as cases of adhesion, absorption, retention, &c. A series of experiments on the behaviour of the amorphous hydrates of oxides with solutions of salts, acids, and alkalies has led him to conclude that the bulk of such phenomena enter into the general class of phenomena presented by feeble chemical combinations, and that these apparently irregular facts are governed by constant laws. The starting point for these researches was furnished by the results of a former investigation on the absorptive power of vegetable mould and silicic acid upon solutions of salts. If in such phenomena feeble chemical affinity is concerned, we shall find that the ultimate result will vary according to the relative proportions of silicic acid and of dissolved matter, and according to the concentration of the liquid. Other amorphous hydrates, *e.g.*, those of the oxides of tin, manganese, aluminium, iron, titanium, &c., will behave in an analogous manner. On comparing together various hydrates of oxides, or various modifications of one and the same hydrate, the phenomena of absorption will be found more pronounced in some than in others; transitions will be discovered between these phenomena and those of ordinary chemical combination, and other acids, bases, or salts may be substituted for the acids, bases, or salts absorbed. All these deductions, the author shows, have been confirmed by experiment.

Bulletin de la Société d'Encouragement pour l'Industrie Nationale. January, 1881.

Process of M. Baeyer for the Artificial Preparation of Indigotin.—M. Rosenstiehl.—After giving an account of the researches of Baeyer, the author stated that by means of ortho-nitro-phenyl-propiolic acid indigotin may be formed directly upon the tissue. He produced a piece of calico upon which had been printed a mixture of gum-water, containing the above-mentioned acid along with carbonate of soda and glucose. The design is scarcely visible at first, all the substances being colourless. But if the cloth is exposed for two minutes to a temperature bordering upon 100°, the design appears, and the formation of indigotin is so plentiful that the colour appears black. Washing with water removes the soluble matter, and indigo-blue becomes visible with all its characters, and is intimately fixed upon the fibre. This formation, so neat and rapid, is of undoubted interest in tissue-printing. Many attempts have lately been made to introduce indigo-blue in the composition of polychromic designs in fast colours, but the effects obtained have not been quite satisfactory. Possibly Baeyer's process may effect the solution of the question. The phenyl group contained in indigotin admits of numerous substitutions without the molecule losing its property of being a colouring-matter.

February, 1881.

Report delivered by M. Aimé Girard on Behalf of the Committee of Chemical Arts on the Machines for Casting Candles, Invented by M. Paul Morase.—This invention, though relating to one of the chemical arts, is of a purely mechanical nature.

Report given in by M. Troost on Behalf of the Committee of Chemical Arts on the Process for the Manufacture of Vinegar, Imported into France by M. Barbe.—The process is a modification of the "quick vinegar process" used in Germany. A number of casks containing beech-wood shavings and a mixture of alcohol, water, and the product of the fermentation of sugar-cane treacle are made to revolve horizontally six times daily.

We cannot undertake to let this column be the means of transmitting merely private information, or such trade notices as should legitimately come in the advertising columns.

Soft Soap.—Can any of your readers inform me whether soda-ash is now used instead of potash in making soft soap, and if so, how the soda-ash lees are prepared?—A Reader.

Soap Making.—If not troubling you too much, I will inquire through your valuable paper the method of separating the *resin* from the fat in commercial soaps, also how to estimate the amount of *resin* which invariably exists in commercial soaps.—J. R.

THE CHEMICAL NEWS.

Vol. XLIV. No. 1133.

ON A CURIOUS ACTINIC PHENOMENON.

(Second Note.)

AND ON THE QUESTION OF THE PRESENCE OF A NEW METALLIC ELEMENT IN COMMERCIAL ZINC.

By Dr. T. L. PHIPSON, F.C.S., &c.

In my first communication on this subject (Chemical News, vol. xliii., p. 283) I endeavoured from the results of a certain number of observations to give an explanation of it. I have now satisfied myself that the darkening of the white zinc pigment under the influence of light is really due to *reduction*, and that it returns to its former white colour, when placed in the dark, by a process of *oxidation*.

A certain quantity of the white substance is spread as thinly as possible over a flat surface and exposed to the morning sun. In about twenty minutes it has changed from pure white to a much darker tint, and in two hours it is as dark as slate. In this state it is scraped off, and placed in a very small hermetically sealed bottle, which is removed to a dark place. Half of the darkened specimen is also placed in the dark, but unprotected from the air. The latter, sooner or later, becomes quite white, whilst that which is enclosed remains a dark slate colour. When air is allowed access to the little bottle its contents gradually assume a white colour also.

This proves conclusively that by exposure to the sunlight a reduction occurs, which is changed into oxidation as soon as the product is placed in the dark. The question now remains: *What is the substance present in the white zinc pigment which causes this phenomenon?* In endeavouring to answer this question I must observe that—

(1.) The substance is originally quite white.

(2.) It is changed under the influence of sunlight, first, to a light fawn colour, which soon darkens, and gradually acquires a dark slate colour.

(3.) This effect is hindered to a *very great* extent by covering the white pigment with a piece of glass, so much so that *photographs can be produced* readily by the presence of this transparent medium. This action of glass is very remarkable: the light of day which filters through the windows of the laboratory is not capable of darkening the pigment after an exposure of eight months—the discolouration is only slight—it is necessary to place the white substance outside the window in order to observe the action of light upon it. A piece of glass placed directly upon a thin layer of the white substance cuts off the action of light almost as effectually as an opaque piece of cardboard. Vapour of water and atmospheric air act in the same manner as glass. Thus the actinic action is much less energetic in the afternoon when the sun is nearing the horizon than in the morning, and it is also less developed when the wet and dry thermometers register near together.

(4.) The phenomenon is due to a *reduction* which, when the substance is removed to the dark, becomes an *oxidation*, and the pigment is then restored to its original whiteness.

(5.) Pyrogallic acid facilitates the reduction (and causes it to proceed *to a certain extent* under glass), and when employed in rather large quantity makes the dark colour produced permanent for a length of time in the dark.

(6.) The dark product is soluble in acetic acid, which allows it to be separated from the sulphide of zinc. Precipitated from this solution by sulphide of ammonium (after neutralisation) it forms a dark green precipitate, which on gradual oxidation becomes white, and gives the reactions of zinc and iron.

(7.) The original white pigment allowed to remain for two days and nights in a large excess of acetic acid (which dissolves out the oxide of zinc, &c.), and the residue being well washed on a filter, this residue, when exposed to sunlight, also darkens; so that acetic acid does not, previous to the action of light, dissolve the substance which is affected by this action (and this points to *sulphide of zinc* itself as being the substance affected).

The constant presence of minute quantities of iron in the numerous samples of these white pigments which I have examined led me to believe that the dark slate-coloured product obtained by exposure to sunlight was owing to the production of a sulphide of iron, or to some compound sulphide of iron, zinc, and barium, as mentioned in my first note. In order to decide this point if possible, I took a specimen of the pigment which contained very little iron, and by exposing it over and over again to the alternate action of sunlight (reduction) and darkness (oxidation)—renewing the surface after each experiment—I hoped to oxidise the iron completely, so that a moment would arrive when the pigment would no longer darken on exposure to the light. But although this experiment was continued on a very thin layer of substance for more than a week, the newly exposed surfaces continued to darken as at first. It appears probable, then, that the minute quantities of iron present are *not* the cause of the phenomenon.

Now, as to the question of the presence of a new metallic element (Actinium) in this white pigment, let us see how far the observations already made authorise the assumption of its existence. The pigment consists of *sulphide of zinc* containing more or less oxide of zinc, together with traces or minute quantities of several impurities (iron, manganese, lead, barium—soluble in acids—calcium, sodium, arsenic, and indium), and mechanically mixed with a large amount of sulphate of baryta. We know that the mineral sulphide, *Blende*, is sometimes more or less fawn-coloured, and sometimes quite black ("Black Jack" of the Cornish miners), although it gives a whitish powder; in fact, that it is found with all the gradients of colour through which my specimens of pigment pass under the influence of sunlight. Hence, whatever causes the production of colour in this actinic phenomenon is very probably present in the natural mineral. We are also aware that Berzelius and some other chemists admit the existence of a *suboxide of zinc* of a dark grey colour, and it is possible that the suboxide, or a corresponding subsulphide, may be produced by the action of light on this mixture of substances. Again, there have been discovered of late years in zinc ores, besides cadmium and manganese, two new metallic elements, *indium* and *gallium*, the actinic properties of whose compounds have not hitherto been examined. Finally, it is by no means impossible that a new metallic element, Actinium, may be present in the specimens of white zinc examined by me, and account for the singular actinic phenomenon.

These few considerations will give some idea of the difficulties which surround the subject. The problem cannot be solved without the aid of a much larger number of observations than I have hitherto been able to make.

PS.—I have perused two short notes recently communicated to this journal by Mr. Orr and Mr. Crawley upon the subject of my first communication, but these gentlemen do not appear to have the slightest idea of the cause of the phenomenon under consideration.

Influence of Alcohol upon the Transformation of the Albumenoids.—J. Munk.—Small doses of alcohol decrease the decomposition of the albumenoids in the organism, but large stupefying quantities have the opposite effect.—*Chem. Zeitung*, iv., 20.

INDIGO, AND ITS ARTIFICIAL PRODUCTION.*

By H. E. ROSCOE, LL.D., F.R.S., &c.
President of the Chemical Society.

(Concluded from p. 69.)

THE following are the directions issued by the patentees to calico printers for using the new colour :—

PRINTING WITH ARTIFICIAL INDIGO.

No. I.—*On Unprepared Cloth.*

Standard.—Take 4 lbs. propiolic acid paste (equal to 1 lb. dry acid), and 1 lb. borax finely powdered; mix well. The mixture first becomes fluid and at last turns stiff. Then add 3 quarts white starch thickening (wheat starch), mix well, and strain.

Printing Colour.—Take the above standard and dissolve in it immediately before printing 1½ lbs. xanthate of soda, stir well, and ready for use.

For lighter shades reduce the above printing colour with the following :—In 1 gallon white starch paste dissolve 1 lb. xanthate of soda.

Directions for Use.—Print and dry as usual. The pieces ought not to be placed in immediate contact with drying cylinders, or otherwise be subjected to heat above 100° C. The indigo-blue is best developed by allowing the printed goods to remain in a dry atmosphere and at an ordinary temperature for about forty-eight hours. Damp air ought to be excluded as much as possible until the colour is fully developed. Then the pieces may be passed through the ageing machine, or steamed at low pressure if such treatment should be required for fixing any other colour or mordant printed along with the indigo-blue.

After the blue is ready formed, the pieces are first thoroughly washed in the washing machine and *then boiled* in the clean water, or better, in a weak solution of hyposulphite of soda (1 lb. to 10 gallons), *and at a full boil* for half an hour in order to volatilise the smell which would otherwise adhere to the goods.

Clean in a soap-bath, at a temperature not above 40° C.; wash, dry, and finish.

Observations.—Wheat starch gives the best results in the colour, then follows gum tragacanth. The colour is considerably reduced by using gum senegal, dark British gum, or calcined farina as thickening materials.

So far borax has answed best as an alkaline solvent of propiolic acid; it may, however, be replaced in the above standard by acetate of soda (from 1 to 1½ lbs.) or by 6 ozs. pearlash or soda. Any excess of caustic potash, or soda, destroys propiolic acid.

The above standard keeps unchanged for any length of time; it is likewise not sensibly altered by a small amount of xanthate of soda; but when mixed with its full proportion of xanthate, as in the above printing colour, it gradually loses strength after several hours.

The xanthate ought, therefore, to be mixed with the standard immediately before printing, and any colour remaining unused may then be saved by mixing with the same a large proportion of starch paste.

Propiolic acid may be printed along with aniline-black, catechu brown and drabs, and with alumina and iron mordants for madder colours.

After the indigo-blue is fully developed, the mordants are fixed in the ordinary manner, dyed with alizarin, padded with Turkey-red oil, steamed, and otherwise treated as usual.

Indigo-blue, whether natural or artificial, suffers by prolonged steaming at high pressure. For this reason, only such steam colours can be associated with propiolic acid as may be fixed by short steaming at low pressure.

No. II.—*On Prepared Cloth (for Full Shades).*

Dissolve 2 lbs. of xanthate of soda in 1 gallon of cold water. Pad the goods with the above; dry, print with standard, and after printing follow the above treatment. The pieces may also be first printed with xanthate and then covered with standard. Alumina and iron mordants for madder colours may be likewise printed on cloth thus prepared, or printed with xanthate of soda.

The potential importance, from a purely commercial point of view, of the manufacture, may be judged of by reference to the following statistics, showing that the annual value of the world's growth of indigo is no less than four millions sterling.

Estimated Yearly Average of the Production of Indigo in the World, taken from a Total Crop for a Period of Ten Years

	Pounds Weight.	Pounds Sterling.
Bengal, Tirhoot, Benares, and N.-W. India—	8,000,000	2,000,000
Madras and Kurpah	2,200,000	400,000
Manilla, Java, Bombay, &c..	—	500,000
Central America	2,250,000	600,000
China and elsewhere, consumed in the country—	—	Say 500,000
		4,000,000

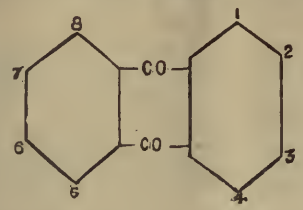
How far the artificial will drive out the natural colouring-matter from the market cannot, as has been said, be foreseen. It is interesting, as the only instance of the kind on record, to cast a glance at the history of the production of the first of the artificial vegetable colouring-matters, alizarin. In this case the increase in the quantity produced since its discovery in 1869 has been enormous; such indeed that the artificial colour has now entirely superseded the natural one, to the almost complete annihilation of the growth of madder root. It appears that whilst for the ten years immediately preceding 1869 the average value of the annual imports of madder-root was over one million sterling, the imports of the same material during last year (1880) amounted only to £24,000. The whole difference being made up by the introduction artificial alizarin. In 1868, no less a quantity than 60,000 tons of madder-root were sent into the market, this containing 600,000 kilos. of pure natural alizarin. But in ten years later a quantity of artificial alizarin, more than equal to the above amount, was sent out from the various chemical factories. So that in ten years the artificial production had overtaken the natural growth, and the 300,000 or 400,000 acres of land which had hitherto been used for the growth of madder, can henceforward be better employed in growing corn or other articles of food. According to returns, for which the speaker had to thank Mr. Perkin, the estimated growth of madder in the world previous to 1869 was 90,000 tons, of the average value of £45 per ton, representing a total of £4,050,000.

Last year (1880) the estimated production of the artificial colouring-matter was 14,000 tons, but this contains only 10 per cent of pure alizarin. Reckoning 1 ton of the artificial colouring-matter as equal to 9 tons of madder, the whole artificial product is equivalent to 126,000 tons of madder. The present value of these 14,000 tons of alizarin paste, at £122 per ton, is £1,568,000. That of 126,000 tons of madder at £45 is £5,670,000, or a saving is effected by the use of alizarin of considerably over four millions sterling. In other words, we get our alizarin dyeing done now for less than one-third of the price which we had to pay to have it done with madder.

Our knowledge concerning the chemistry of alizarin has also proportionately increased since the above date. For whilst at that time only one distinct body having the above composition was known, we are now acquainted with no less than nine out of the ten dioxy-anthraquinones whose existence is theoretically possible, according as the

* A Lecture delivered before the Royal Institution of Great Britain, Friday, May 27, 1881.

positions of the two semi-molecules of hydroxyl are changed.



Of the nine known dioxy-anthraquincnes, only one, viz., alizarin, or that in which the hydroxyls are contained in the position 1, 2, is actually used as a colouring agent. Then, again, three trioxy-anthraquinones, $C_4H_5O_2(OH)_3$, are known. One of these is contained in madder-root, and has long been known as purpurin. The other trioxy-anthraquinones can be artificially prepared. One, termed anthra-purpurin, is an important colouring-matter, especially valuable to Turkey-red dyers, as giving a full or fiery red. The other, called flavo-purpurin, gives an orange dye with alumina mordants. All these various colouring-matters can now be artificially produced, and by mixing these in varying proportions a far greater variety of tints can be obtained than was possible with madder alone, and thus the power of diversifying the colour at will is placed in the hands of the dyer and calico printer.

It is quite possible that in an analogous way a variety of shades of blue may be ultimately obtained from substituted indigos, and thus our catalogue of coal-tar colours may be still further increased.

To Englishmen it is a somewhat mortifying reflection, that whilst the raw materials from which all these coal-tar colours are made are produced in our country, the finished and valuable colours are nearly all manufactured in Germany. The crude and inexpensive materials are, therefore, exported by us abroad, to be converted into colours having many hundred times the value, and these expensive colours have again to be bought by English dyers and calico printers for use in our staple industries. The total annual value of manufactured coal-tar colours amounts to about three and a half millions; and as England herself, though furnishing all the raw material, makes only a small fraction of this quantity, but uses a large fraction, it is clear that she loses the profit on the manufacture. The causes of this fact, which we must acknowledge, viz., that Germany has driven England out of the field in this important branch of chemical manufacture, are probably various. In the first place, there is no doubt that much of the German success is due to the long-continued attention which their numerous Universities have paid to the cultivation of organic chemistry as a pure science. For this is carried out with a degree of completeness, and to an extent to which we in England are as yet strangers. Secondly, much again is to be attributed to the far more general recognition amongst German than amongst English men of business of the value, from a merely mercantile point of view, of high scientific training. In proof of this it may be mentioned, that each of two of the largest German colour works employs no less a number than from twenty-five to thirty highly educated scientific chemists, at salaries varying from £250 to £500 or £600 per annum. A third cause which doubtless exerts a great influence in this matter is the English law of patents. This, in the special case of colouring-matters at least, offers no protection to English patentees against foreign infringement, for when these colours are once on the goods they cannot be identified. Foreign infringers can thus lower the price so that only the patentee, if skilful, can compete against them, and no English licencees of the patent can exist. This may to some extent account for the reluctance which English capitalists feel in embarking in the manufacture of artificial colouring-matters. That England possesses both in the scientific and in the practical direction ability equal to the occasion none can doubt. But be that as it may, the whole honour of the discovery of artificial indigo belongs to Germany and to the distinguished chemist, Professor Adolf Baeyer, whilst towards the solution of the difficult problem of its economic manufacture the first successful steps have been taken by Dr. Caro and the Baden Aniline and Soda Works, of Mannheim.

NOTE ON PHOTOGRAPHS OF THE SPECTRUM OF THE COMET OF JUNE, 1881.*

By Professor HENRY DRAPER, M.D.

The appearance of a large comet has afforded an opportunity of adding to our knowledge of these bodies by applying to it a new means of research. Owing to the recent progress in photography it was to be hoped that photographs of the comet, and even of its spectrum, might be obtained and peculiarities invisible to the eye detected. For such experiments my observatory was prepared, because for many years its resources have been directed to the more delicate branches of celestial photography and spectroscopy, such as photography of stellar spectra and of the nebulæ. More than a hundred photographs of spectra of stars have been taken, and in the nebula of Orion details equal in faintness to stars of the 14·7 magnitude have been photographed.

It was obvious that, if the comet could be photographed by less than an hour's exposure, there would be a chance of obtaining a photograph of the spectrum of the coma, especially as it was probable that its ultra-violet region consisted of but few lines. In examining my photographs of the spectrum of the voltaic arc, a strong band or group of lines was found above H, and on the hypothesis that the incandescent vapour of a carbon compound exists in comets, this band might be photographed in their spectrum.

Accordingly, at the first attempt, a photograph of the nucleus and part of the envelopes was obtained in seventeen minutes, on the the night of June 24, through breaks in the clouds. On succeeding occasions, when an exposure of 162 minutes was given, the tail impressed itself to an extent of nearly ten degrees in length.

I next tried, by interposing a direct-vision prism between the sensitive plate and the object glass, to secure a photograph which would show the continuous spectrum of the nucleus and the banded spectrum of the coma. After an exposure of 83 minutes a strong picture of the spectrum of the nucleus, coma, and part of the tail was obtained; but the banded spectrum was overpowered by the continuous spectrum.

I then applied the two-prism spectroscope used for stellar spectrum photography, anticipating that, although the diminution of light would be serious after passing through the slit, two prisms, and two object glasses, yet the advantage of being able to have a juxtaposed comparison spectrum would make the attempt desirable; and, moreover, the continuous spectrum being more weakened than the banded by the increased dispersion, the latter would become more distinct.

Three photographs of the comet's spectrum have been taken with this arrangement, with exposures of 180 minutes, 196 minutes, and 228 minutes, and with a comparison spectrum on each. The continuous spectrum of the nucleus was plainly seen while the photography was in progress. It will take some time to reduce and discuss these photographs, and prepare the auxiliary photographs which will be necessary for their interpretation. For the present it suffices to say that the most striking feature is a heavy band above H, which is divisible into lines, and, in addition, two faint bands—one between G and *h*, and another

* From the *British Journal of Photography* of August 5, 1881.

between *h* and H. I was very careful to stop the exposures before dawn, fearing that the spectrum of daylight might become superposed on the cometary spectrum.

It would seem that these photographs strengthen the hypothesis of the presence of carbon in comets; but a series of comparisons will be necessary, and it is not improbable that a part of the spectrum may be due to other elements.

RESISTS FOR ANILINE-BLACK.

The *Compagnie Generale des Cyanures et Produits* give the following instructions concerning the use of ammonium and potassium sulpho-cyanides in calico-printing. Gum-water to which 50 grms. per litre of either of the above salts has been added completely resists aniline-black. Reds, greens, blues, violets, and catechu colours can be obtained in the same manner on aniline-black. The aniline colours, whether applied with albumen, tannin, or arsenic, are mixed with 50 to 60 grms. per litre of either of the sulpho-cyanides. These colours resist aniline-black perfectly: the colour is left pure and well-defined on a black ground. For acid colours sulphocyanide of lead should be used. Sulphocyanide of ammonium may be used successfully for alizarin-reds instead of red liquor. They are also employed in the production of persulpho-cyanogen, sometimes used as an orange colour in printing. In photography the sulphocyanides serve for toning and fixing. They are used for fixing negatives on collodion in the proportion of 800 grms. per litre of water. They may be advantageously substituted for sodium hyposulphite, which requires prolonged washing for its removal, whilst the sulphocyanides act more rapidly, are less disposed to occasion spots, do not interfere with the inalterability of the proof, and are removed with less washing.

IMPROVEMENT IN THE PRODUCTION OF MAGNESIA.

Magnesia is becoming of great importance in the manufacture of cements, artificial stones, fireproof bricks, furnace linings, retorts, &c. Many of its industrial applications have been limited by the high price of the native magnesite as imported from Greece. Magnesium chloride has been produced in abundance at Stassfurt and elsewhere, but all attempts at its conversion into magnesia have hitherto proved unsuccessful. Finely-ground lime has been added to the liquid magnesium chloride, but even with the greatest care the result has been an almost worthless article, containing only from 60 to 70 per cent of actual magnesia, and costing £4 per ton. Another process has been to concentrate the magnesium chloride liquors, and heat till hydrochloric acid was evolved and magnesia remained behind. Here also practical difficulties were encountered. The decomposition is very tedious, the acid too weak to be saleable, and the magnesia is apt to retain compounds of chlorine which interfere with its applications. If a stronger heat is used the material loses all coherence and becomes worthless. A patent recently taken out by M. Closson, of Paris, solves the problem in the simplest manner. The crude lye of magnesium chloride is treated not with burnt lime, but with burnt dolomite. In this natural combination the chlorine of the lye combines completely with the lime of the dolomite, so that if the latter is used in a state of purity—as it is readily procurable in bulk—a magnesia of from 98 to 99½ per cent can be made on the large scale without any difficulty. The process is already in operation at Leopoldshall. The magnesia bricks there prepared resist even the flame of the oxy-hydrogen blast. If lime is present, even to the extent of 5 per cent, the bricks, &c., if moistened when hot, fly into fragments. Magnesian bricks prepared about ten years ago by Tessié du Motay from Greek magnesite, and containing about 13 per cent of lime and silica, were melted in some experiments recently made in Sheffield. The cost of magnesia as prepared by the Closson process is about 15s. per ton. There is another important feature in the patent. The crude magnesium chloride contains a certain quantity of magnesium sulphate. To remove this calcium chloride is added. The sulphate of lime as thus precipitated is used by paper makers under the name of pearl-hardening, and has been specially prepared in England for their purposes.

Closson's patents for Germany, Austria, and England have been brought up by a M. Schmidtmann, a potash manufacturer of Aschersleben. It is to be expected that as absolutely fireproof furnace linings, crucibles, &c., can now be procured the use of the oxygen blast will assume a practical form, and that the way will be opened for great improvements in metallurgy.

SEPARATION OF NICKEL AND COBALT FROM IRON.

By THOMAS MOORE.

The undernoted process, which to the best of my knowledge is quite new, will, I think, prove very serviceable to metallurgical chemists in general, but more especially so to those who, like myself, are often placed in the position to estimate, with as much accuracy as is compatible with the time at disposal, the amount of nickel or cobalt in a regulus or "stem."

This process has, with other advantages, that of giving a solution very suitable for electrolysis, and this of itself is a point practical assayers will not be slow to appreciate.

If the solution contains much free acid, this should be got rid of by evaporation, and dissolving the residue in water. To the solution so obtained a quantity of ammonic sulphate should be added, sufficient to form a double sulphate with the nickel and cobalt present. Dilute to about 150 c.c., and then add rather a large excess of oxalic acid and stir well. If a precipitate forms more ammonic sulphate must be added until a clear solution is obtained. Ammonic hydroxide is now added in considerable excess; stir, heat gently for a few minutes, and filter; wash well with water containing ammonia; or dilute to say 500 c.c., and after allowing the precipitate to settle, withdraw a given portion of the clear upper stratum of liquid, which, after a further addition of ammonic sulphate (to lessen the resistance of the solution to the electric current), is ready for electrolysis or any other method of estimating the nickel or cobalt the chemist may desire.

Taking at random the results of two experiments we have,—

	Taken.		Found.
	Fe.	Ni.	Ni.
I.	0·750 grm.	0·0753 grm.	0·0755
II.	0·250 ,,	0·1507 ,,	0·1505

plainly pointing to the fact that the separation is tolerably complete.

The Determination of Reverted Phosphoric Acid by means of Ammonium Citrate.—A. König.—The author concludes from his experiments that the proportion between the phosphate and the solution of ammonium citrate has a great influence upon the result, and that in order to obtain accordant figures an equal quantity of soluble phosphate must be allowed to act upon the usual quantity of citrate—a condition practically impossible. The value of ammonium citrate for the determination of reverted phosphoric acid is thus greatly reduced.—*Zeitschrift für Analytische Chemie*, xx., 1.

IMPROVEMENTS IN BATTERIES.

By DAVID LINDO.

M. Azapis recommends (Chemical News, vol. xlii., p. 184) the substitution of solution of chloride of sodium or sal-ammoniac for the acidulated water in contact with the zinc in Bunsen's battery, the great advantage being that the zinc does not require to be amalgamated. My experience of this modification is so much in its favour that I should never resort again to the use of dilute sulphuric acid with Bunsen's cells.

As the introduction of chlorine compounds into a Grove's battery might prove injurious, I was led to try the effect of a solution of sulphate of sodium in this battery in place of the dilute sulphuric acid. The results obtained were excellent. I employ a solution containing one part sulphate of sodium in crystals dissolved in 5 parts of water. No amalgamation of the zinc is required, and the intensity of current appears to be quite as great as when dilute sulphuric acid is employed. I have used two Grove's quarts charged in this way on several occasions for the purpose of precipitating copper when estimating it in the metallic state. Solution of sulphate of sodium answers equally well in Bunsen's cells.

Falmouth, Jamaica, July 5, 1881.

ESTIMATION OF POTASSIUM AS PLATINUM SALT.

By DAVID LINDO.

Several modifications of this method of determining potassium have been suggested by different chemists: opinion seems still divided as to which modification is the best.

The Committee appointed by the British Association to enquire into this subject gives, in an able and lengthy report* (to which I am indebted for many valuable suggestions), the results of a large number of analyses made by the processes of Fresenius, Frank, and Tatlock. The conclusions arrived at are briefly as follows:—

(1.) Potassium in the form of pure chloride can be determined with great accuracy by precipitation as chloro-platinate. If a large excess of platinum be employed and alcohol only used for washing the precipitate, the results have a tendency to exceed the truth. If a small volume of platinum solution be employed in the first instance for washing the precipitate, and the washing then completed with alcohol, the results are very accurate.

(2.) In presence of a considerable proportion of chloride of sodium, washing the precipitate with alcohol alone tends to give results in excess of the truth. If the precipitate be first treated with platinum solution the results are somewhat low, apparently owing to the solubility of the precipitate in solution of sodium chloro-platinate: the error increases with the amount of sodium, but is never very large.

(3.) If Tatlock's method be employed there is no occasion to separate any sulphates, nitrates, or magnesia; but if the amount of chloride present is insufficient for the existence of all the potassium as chloride of potassium, the deficiency must be supplied by the addition of chloride of sodium or hydrochloric acid.

The final conclusion arrived at is, that of the various methods tried Tatlock's gives in general the best results. The essential features of his process consist—

(1.) In the use of a large excess of platinum.

(2.) Diluting the solutions largely.

(3.) Digesting the precipitate for at least an hour in solution of platinic chloride, washing again slightly with more of the solution, finally washing with the smallest possible quantity of 95 per cent alcohol, and drying at 100° C.

Previous to this my experience in the determination of potassium had been very limited. I had employed the method recommended by Messrs. E. F. Teschemacher and J. Denham Smith (Chemical News, vol. xvii., p. 244), and the results obtained were concordant, but I had made no experiment with potash salts of known purity.

The present investigation was originally undertaken for the purpose of testing their method more thoroughly. During the progress of the enquiry certain modifications that occurred to me were adopted, and led to excellent results. These will be described in the proper place. The essential features of Teschemacher and Denham Smith's process consist—

(1) Dilution of solutions.

(2) Use of large excess of platinum.

(3) Obtaining the potassic salt in a crystalline scale-like condition.

(4) Evaporation on water-bath to a pasty condition—no further.

(5) Washing by decantation and avoiding breaking down of the crystalline precipitate.

They wash with methylated spirit containing about 85 per cent of the alcohols.

Gooch's ingenious method for the separation of precipitates (Chemical News, vol. xxxvii., p. 181) was adopted by me throughout this investigation for the purpose of separating and finally washing the platino-potassic chloride. This process consists in filtering under pressure through a felting of purified asbestos deposited at the bottom of a platinum crucible, the bottom being perforated with numerous small holes.

The crucibles used in my experiments are of the following dimensions:—Height, $\frac{3}{4}$ inch; diameter at top, $\frac{7}{8}$ inch; diameter at bottom, $\frac{1}{2}$ inch. They are provided with light dish-shaped covers, flanged. As these merely rest on the edges of the crucibles, there is no risk of spilling the contents of the latter in putting on or taking off the covers.

I fixed the crucible in a hole made through an india-rubber stopper, which fitted into a clear white glass bottle. One end of a glass tube, open at both ends and bent at a right angle, was fixed air-tight into another hole made through the stopper, and just entered the bottle; the other end of the tube led to the filter-pump. I made the feltings thick so as to secure perfectly brilliant filtrates. Two sizes of porcelain dishes were employed; the diameter for small estimates being $3\frac{1}{4}$ inches, and for larger $4\frac{1}{2}$ inches, the lips well formed.

The following atomic weights were employed:—

Chlorine	35·46
Potassium	39·13
Platinum	197·18
Silver	107·93

The three first give the factor 0·3050 for converting the chloro-platinate into chloride of potassium. I will describe—

(1) Preparation of platinic chloride.

(2) Preparation of pure chloride of potassium.

(3) The methods employed and results obtained.

(4) Results of a few experiments on the solubility of the chloro-platinate.

*Preparation of Platinic Chloride.**

Commercial platinum was converted into crude platinic chloride. Reduced, by boiling in solution of soda, and adding alcohol. Washed the metal thoroughly. Boiled for about an hour in HCl. Washed, dried, and ignited. Boiled a short time in nitric acid. Violent bumping. (This always occurs when the spongy metal is boiled in the acid after ignition.) Washed. Tested sample of the metal by

* Chemical News, vols. xxxv. and xxxvi.

* The process is the same as that employed by Tatlock and others. The residues were recovered in the same way.

boiling in pure nitric acid. Iron and copper present in more than slight traces. Placed all the metal in a beaker. Added pure nitric acid, S.G. 1·24. Covered with a dish, and digested twenty-six hours with frequent stirring—eighteen hours of the time on the sand-bath at a temperature near boiling-point. Tested a sample of the metal after washing. Traces of iron and copper still present. Repeated the digestion in the same way for twenty-six hours longer in fresh acid. Washed, dried, and ignited. Weighed. Dissolved in *aqua regia* (very pure acids employed). Evaporated three times with HCl, then repeatedly with water as near to dryness as possible. The final product still contained HCl, which it appears impossible to remove entirely at the temperature of the water-bath. Added water. Filtered. Weighed the small residue and deducted from weight of metal. Diluted further, so that 20 c.c. of the solution contained 1 grm. of platinum.

So far as my experience goes, this method of purification, when conducted with ordinary care, yields a product (even from a pretty impure sample of commercial platinum), which gives accurate results when tested by assays made with pure KCl. As this is sufficient proof of its fitness for the intended purpose, little more need be said on the subject. I may, however, add that according to my observation the *complete* separation of iron and copper from platinum can only be effected by this process with great labour, if indeed it can be accomplished at all, and that it must not be supposed the platinic chloride used in these experiments was *absolutely* pure, it certainly was not for all the time and trouble expended in trying to obtain it so.

*Preparation of Pure Chloride of Potassium.**

Chlorate of potash was purified by re-crystallisation, ignited until all the oxygen was expelled, dissolved in water, the solution filtered, then slightly acidulated with pure HCl. Evaporated to dryness, ignited, reduced to powder, and bottled. The salt gave a very pure potash reaction in flame. Other tests applied failed to detect any impurity whatever. 10 grms. dissolved in 90 grms. water, forming a 10 per cent solution. Four more solutions of the same strength had to be prepared in the course of this investigation; call these solutions A, B, C, D, E.

Analyses with nitrate of silver gave the following results. The solutions were weighed.

		KCl taken.	Wght of AgCl.	= KCl p.c.
A.	1	0·45815	0·8803	99·94
A.	2	0·59295	1·1395	99·96
B.	1	0·53046	1·0200	100·03
B.	2	0·56068	1·0787	100·07
B.	3	0·59016	1·1349	100·04
B.	4	0·50128	0·9638	100·02
C.	1	0·54440	1·0464	99·97
C.	2	0·51112	0·9834	100·08
C.	3	0·45332	0·8706	99·90
D.	1	0·57948	1·1135	99·96
D.	2	0·56211	1·0809	100·03
E.	1	0·49570	0·9532	100·03
E.	2	0·51534	0·9904	99·97

The five solutions employed have therefore given the following average results by analyses with nitrate of silver:—

A.	Mean of two experiments	99·95 p.c. KCl
B.	Average of four experiments	100·04 ,,
C.	Average of three experiments ..	99·98 ,,
D.	Mean of two experiments	99·99 ,,
E.	Mean of two experiments	100·00 ,,

* The method was suggested, and afterwards employed, by the Committee.

I have placed the letter indicating the solution used against each of the experiments given in the tables that follow.

(To be continued.)

ON SALT-BUSH AND NATIVE FODDER PLANTS OF NEW SOUTH WALES.*

By W. A. DIXON, F.I.C., F.C.S., Technical College, Sydney.

In all civilised countries much attention has been directed to the composition and value of the various fodder plants grown in them, ever since Leibig first directed attention to the valuable aid which agriculture might obtain from the study of such subjects by chemical methods. That this should be so is not susprising, seeing the important *rôle* which the cultivation of these plants plays in European agriculture, forming, indeed, the foundation on which modern farming is based, feeding the animals which not only supply meat and much of our clothing, but also furnish the greater part of the manure required to bring the vegetable food of man to perfection. It is, however, somewhat surprising that in this country no attention whatever has, as far as I can learn, been directed to the native plants, and the more so when perhaps three-fourths of the wealth of the community is, or has been, derived from its flocks and herds. For many reasons foreign to the purpose of this paper, it has been too much the interest of every one to let the sheep and cattle of to-day eat the best there is, even if they destroy it off the face of the earth, without regard to what those of to-morrow will do. It seems reasonable to suppose that in our peculiar climate, subject to periods of continued drought, and having in many cases soils peculiarly saline, that the plants which have withstood these influences for ages past would be more reliable than others developed under indifferent conditions of soil and climate. That many introduced plants do flourish here and grow with a vigour never seen in their native habitats is undoubted, but, as Dr. Schomberg remarks in his pamphlet on introduced weeds in South Australia, it remains to be seen whether that increased growth may not be the means of their own destruction.

It has therefore been thought of sufficient interest to induce me to make a beginning, by examining a few of those plants which form the staple pasture of the famed Riverina district, and I now lay the results before you, accompanying them with a table showing the average composition of other fodders of good quality for comparison. All the European plants which are used for feeding vary greatly in composition at different periods of their growth, and I have selected analyses of hay or straw made of the plant at the period of flowering, when they are at their best. The analyses have all been re-calculated from the authorities given, so as to reduce them to the same method of statement adopted for my own work. The analyses of the meadow hay, red clover, and lucerne were all stated as containing 15 per cent of water, which is the average in well made hay; and the ashes were all, with the exception of the oats, given in 100 parts of ash only, and that containing carbonic acid, and the chlorine was given in the free state. As the plants which are to be brought under your notice are not used in the form of hay, and as the specimens examined had in their long journey become in some cases partially dried, and in others (the more succulent ones) were in a state of incipient fermentation, which rendered it necessary to dry them as rapidly as possible, no water determinations were made, and the analyses are given on the dried plants.

Immediately on their arrival they were divided into woody portions, and tender parts, including small twigs and every part it was considered probable that the sheep

* A Paper read before the Royal Society of New South Wales.

would eat; the separate parts were weighed, and a sufficient quantity of the edible matter was dried on a water-bath, and afterwards ground in a coffee mill for the proximate organic analyses. The remainder of the plant was partially air-dried and then charred in a clay crucible at a dull red heat; from the excessive quantity of alkaline salts present it was found impossible to remove much more of the carbon without running serious risk of losing part of the salts by volatilisation, and the analyses were therefore made on the charred material, which generally contained about 50 per cent of carbon. In determining the quantity of ash the carbon was removed as far as possible by incineration, the remainder being afterwards determined and deducted. As the char evolved sulphuretted hydrogen on treatment with acid, it was moistened with concentrated nitric acid for the estimation of sulphuric and phosphoric oxides. In calculating the analyses the carbon dioxide, sand, and alumina found have been deducted, following in respect to the first the Continental method. It is not, properly speaking, an inorganic constituent, the salts not being in combination with it in the plant; and although its rejection is regarded by some English chemists as removing a distinctive feature of the ash, that is simply a question of what one regards as such feature. In some of the ashes—that from plants which could be well dusted—there was no sand nor alumina, and in the others the amount of these constituents rose and fell together, showing that both were derived from adherent impurity; but as no such connection could be observed with regard to the soluble silica, this has been retained. A large portion of each ash was examined for manganese and the rarer constituents of plant ashes, which could in no case be detected. The greatest variation in the original ash analyses amounted to 0·24 over and 0·31 under 100, and I have therefore, for simplicity of calculation, ventured to calculate the analyses into 100 parts exactly. The ash analyses are stated in two columns, the first showing the composition in 100 parts, the second on the dried plant.

(To be continued.)

Determination of the Melting-Point of Fats.—O. Kellner.—The author uses a straight capillary tube with a club-shaped expansion at one end. The latter is closed and before it is quite cold the capillary end is plunged into the liquid fat. A stratum 3 to 5 c.m. in length is allowed to enter, and this end of the tube is quickly plunged into cold water, the club-shaped end remaining above the surface. If the tube is then plunged into warm water, and heat applied at the moment of melting, the fat rises into the vacuum, the exact point of temperature being easily noticed.—*Zeitschrift für Anal. Chemie*, xx., 1.

CORRESPONDENCE.

ANALYSIS OF GERMAN MURIATE OF POTASH.

To the Editor of the Chemical News.

Sir,—I am sorry to see so much personal feeling introduced into the discussion of a purely chemical controversy as appears in Messrs. E. F. Teschemacher and J. Denham Smith's correspondence in the Chemical News, vol. xliv., p. 35.

My firm (John and James White) are large buyers and consumers of German muriate of potash, and having made many hundred analyses of them by all the known methods, I think I can speak with some little experience.

I value Tatlock's method highly, and have proved the advantage of using the "aqueous solution of platinic chloride," not only in commercial muriates with their 1·5 per cent "soda salts," but also in other mixtures which I have frequently to analyse, and which contain, along with metallic salts, potassium sulphate, potassium chloride, with upwards of 40 per cent sodium sulphate.

I am surprised to see Messrs. Zuckschwerdt and West, as representing the German muriate manufacturers, criticising Mr. Tatlock's method in the way they do; pointing out items, which are quite secondary, as reasons for condemning his process, while their own process condemns itself at the outset by making use of alcohol before having got rid of the sulphates of the alkalies and alkaline earths.

Though Prof. Fresenius gives credit to their paper, it is quite contrary to his own use and wont, and to all laws of chemical analyses.

There is no practical value in making 40 or even 400 analyses of a made up muriate containing only potassium chloride and sodium chloride in order to test Fresenius's, Tatlock's, Zuchschwerdt and West's, Teschemacher and Smith's, or anybody else's method. Anyone, with ordinary care, could determine the potash in such a salt by any of these methods to within 0·35 per cent; but German muriate does not consist of pure KCl and pure NaCl, but of potassium chloride, potassium sulphate, calcium sulphate, sodium chloride, magnesium chloride, insoluble matter, and water. Most of these salt which are not in the made up salt are the very items which in most methods are the source of error.

Tatlock's method is a rapid and accurate one for estimating potash *direct* from this mixture of salts, washing out the soda, lime, and magnesia salts, and leaving the double platinum salt pure; the average of many analyses coming out 99·99 per cent. The German method, which adds alcohol to the basin after evaporation (see Zuckschwerdt and West's paper, Chemical News, vol. xliii., p. 252), precipitates the sulphate of lime, &c., along with the potash, with which it is then weighed; and if the analysis is checked by separation of the salts and repetition, there will be found a difference of from 1 to 2 per cent.

Messrs. Zuchschwerdt and West in their paper say "that the first drops of Tatlock's filtrate are rendered turbid by the addition of absolute alcohol." This is quite true, and is just what is wanted, but the precipitate is not potassium platino-chloride, as they state, but crystallised calcium sulphate. They, of course, do not get this turbidity, as it is caught on their filter along with their platinum precipitate.

Messrs. Teschemacher and Smith at the close of their letter say, "As respects German makers and English buyers of muriate of potash, we take leave to say that if these gentlemen can transact their business, selling and buying within a quater per cent of the actual value, they will be contented."

My firm would certainly be contented even with one-half per cent. The facts, however, are very different, for the difference in all cases amounts to 1 or 2 per cent.

German analyses come over to this country showing potassium chloride and water, together making up the 100 per cent, and leaving no room for the sulphates of potassium and lime, the chlorides of sodium and magnesium, or insoluble matter, which everyone knows must exist. Why is this? Is it not because they precipitate the impurities along with the potash?

We buy the best muriates that are made, and find that on the average they contain besides potassium chloride and water—

	Per Cent.
Sulphate of potash	0·22
Chloride of sodium..	1·00 to 1·50 per cent.
Sulphate of lime	0·40
Chloride of magnesium.. ..	0·12
Insoluble matter	0·20
	1·94 to 2·44 per cent.

The German manufacturers might be willing to pay for common salt, gypsum, and magnesium, as if they were muriate of potash, the British consumer, however, prefers to pay only for what he gets.—I am, &c.,

W. J. Chrystal.

Shawfield Works, Rutherglen,
Near Glasgow, August 2, 1881.

ON A NEW METHOD FOR ESTIMATING NITRATES IN POTABLE WATER.

To the Editor of the Chemical News.

Sir,—Mr. Johnstone still asserts that my process is not new, but he has omitted to give a reference to any paper written on the subject previous to mine; if he can and will kindly do so, I shall be much obliged, for until he does I am unable to answer the charge.

Mr. Johnstone is quite right in saying that the standard red solution is liable to decompose, for I find it will not keep more than a week or so: the remedy is obvious. I may, perhaps, also be allowed to state in connection with my method, that the addition of a little caustic baryta is required to waters containing much sulphate before the evaporation, to prevent the occurrence of free sulphuric acid and consequent partial destruction of the red colouration.—I am, &c.,

J. West Knights.

County and Boro' Laboratory,
Cambridge, August 8, 1881.

CHEMICAL NOTICES FROM FOREIGN SOURCES.

Note.—All degrees of temperature are Centigrade, unless otherwise expressed.

Comptes Rendus Hebdomadaires des Séances, de l'Académie des Sciences. No. 1, July 4, 1881.

This number merely contains the notice of the death of M. E. H. Sainte-Claire Deville, and the discourse pronounced by M. Pasteur at his funeral.

Journal de Pharmacie et de Chimie.
February, 1881.

Observations on Albuminous Urine.—M. Bretet.—The author finds that it is not necessary to eliminate albumen from urines which contain it before determining the urea.

March, 1881.

Remarks on the Characters of Organic Chlorinated Gases and Vapours.—M. Berthelot.—Already noticed.

Researches on the Physiological Action of Thio-tetra-pyridine and Iso-dipyridine.—M. Vulpian.—These bases, though derived from nicotine, do not appear to have the slightest poisonous action upon mammiferous animals.

Determination of Tannin.—A. Remont.—The author after reviewing various processes gives the following:—He places 20 grms. of the sample well ground in a tall tube-shaped vessel, to the bottom of which is adapted a caoutchouc pipe closed by a pinch-cock. The material is moistened with 60 to 80 c.c. of water at 60°, which is allowed to act till the next day. The pinch-cock is then opened, and the liquid is received in a phial having a mark at 200 c c. The bark is then taken out of the vessel, drenched afresh with 50 to 60 c.c. of luke-warm water, which is received in a glass, and which is poured back upon the sample two or three times. The exhaustion is thus continued until a portion of the liquid gives merely an insignificant colouration with a few drops of dilute ferric chloride. In general, the volume of the liquid does not exceed 200 c.c. This exhaustion must be conducted rapidly, otherwise the tannin may be decomposed. For determining the tannin the author uses a solution of gelatin, containing 1 part per cent of gelatin, which is standardised by means of a solution of pure dry tannin, also containing 1 part per cent. 10 c.c. of this latter solution are mixed with 3 drops of sulphuric acid, which greatly aids the precipitation. The solution of gelatin is then run in, stirring continually. As long as the tannin is still present in a certain quantity the precipitation goes on easily, but towards the end it is well to accelerate it by warming gently. The determination of tannin in the solution of the sample is performed on 20 c.c. acidulated with 6 drops sulphuric acid. In certain cases, in spite of the temperature and the acidity of the liquid, the tannate of gelatin is not completely deposited, and the persistent cloudiness prevents the effect of any further addition of the solution of gelatin from being observed. In this case a part of the liquid is thrown upon a small filter placed in a funnel for rapid filtration, and a drop of gelatin is added to the filtrate. If a turbidity is produced this portion is poured back to the bulk of the liquid, and the titration is continued, examining from time to time filtered portions of the liquid with gelatin.

Detection and Determination of Arsenic.—M. E. Reichardt. — This paper requires the accompanying illustrations.

April, 1881.

Action of the Hydracids upon Halogen Salts Containing the same Element.—M. Berthelot.—Already noticed.

Vanilla and Vanilline.—A. Yver.—The author gives a summary of the formations of vanilline. In a state of purity it melts at 80° to 81°, and is very soluble in boiling water, alcohol, ether, chloroform, carbon bisulphide, and the fatty and volatile oils. In cold water it is slightly soluble. It decomposes carbonates and neutralises alkaline bases in the cold, and earthy bases with the aid of heat. It is turned blue by ferric chloride, and yellow by sulphuric acid in the cold. If it contains traces of nitric acid there is a scarlet colouration.

Determination of Indigotin in the Indigos of Commerce.—A. Damoiseau.—The author prepares a liquid containing 100 grms. syrup of glucose, 500 c.c. of water, and alcohol enough to make up a litre. 1 grm. of the indigo in question, finely ground, is placed in a flask fitted with a cork, through which passes a tube drawn out to a point. There is then added a mixture prepared separately, and quite clear, of 10 c.c. soda-lye at 45° (Beaumé ?), 10 c.c. water, and 10 c.c. alcohol. The soda-lye should under these conditions occasion neither precipitate nor turbidity. After agitation, 30 c.c. of the saccharine liquid are introduced, the flask is corked and heated on the water-bath, stirring from time to time. In less than twenty minutes the reduction is complete, and the liquid has become of a fine light yellow colour. It is then requisite to filter through a plug of cotton, placed at the lower end of a tapering tube, wide enough to receive the whole of the liquid at once. The filtration is conducted with the aid of an aspirator. A current of some inert gas, *e.g.*, coal-gas, is allowed to enter at the upper end to prevent oxidation. A rather rapid current of air is then passed through the filtrate, and in two hours the whole of the indigotin is precipitated in a state easy to wash. It is placed on a filter, washed with alcohol at 40 per cent, dried at 100°, and weighed.

May, 1881.

Cause of Error in Proximate Analysis.—M. Schlagdenhauffen.—The author has found a considerable impurity of sulphate of lime in the litharge and lead acetate used in the proximate analysis of vegetable matters.

Butter and Margarine.—M. Riche.—The author finds that the difference of specific gravity between butters, on the one hand, and margarine, oleo-margarine, and a mixture of margarine and oil of earth-nuts on the other, is very limited, and that consequently no apparatus based upon specific gravity is capable of showing the relative proportion of fats and butter found in commercial mixtures.

Asphyxiating Action of Cess-pool Drainage.—MM. Boutmy and Descoust.—A cubic metre of cess-pool liquid, even after official disinfection, rendered 8 cubic metres of air fatal to animals immersed therein.

Zeitschrift für Analytische Chemie.
Vol. xx., Part 1.

Danger-Test for Petroleum.—C. Engler and R. Haass.—The authors sum up the results of their observations and experiments as follows:—Every form of apparatus by which a conclusion is drawn from the vapour-tension of the petroleum to its inflammability, like those of Salleron-Urbain, Van der Weyde, Meusel, &c., are to be rejected, as vapour-tension bears no simple relation to inflammability. Every apparatus with an open petroleum holder gives flashing-points, either too high or not mutually concordant; hence they are useless for determinations which lay even a remote claim to accuracy. Such are the open apparatus of Tugliabue, the Danish petroleum-tester, the Saybolt-tester, the apparatus of Erneeke-Hannemann, Kyll, &c, Among the closed instruments all are to be rejected by which imperfectly accordant results are obtained, in consequence of the employment of a false principle or of small variations in manipulation unavoidable in practice. Under this head must be included both Tagliabue's closed instruments, the pyrometer of Sintenis, and the naphthometer of Parrish. Of the remaining instruments, that of Bernstein and that of Abel give comparable results, and work with certainty. The determinations of the former apparatus are always too low, and those of the latter too high, especially with oils of a low ignition-point. The apparatus of Bernstein has the advantage that the final reaction can be easily and distinctly observed, whilst in Abel's instrument the difficulty of observing faint ignitions must rank as a disadvantage. In currents of air, however, the latter apparatus will work more safely than that of Bernstein, which is more difficult to use on account of its complicated mechanism. The two closed electric instruments of Haass and Engler give the most exact results. Next follows in point of trustworthiness and accuracy the improved naphthometer.

The Applicability of the Azometer in Investigations in Agricultural Chemistry.—Dr. A. Morgen.— This method gives very satisfactory results in pure solutions of ammoniacal salts. It is entirely useless for determining the ammoniacal nitrogen in solutions which, along with ammonium compounds, contain organic nitrogenous bodies, albumenoids, amides, peptons, ferments, alkaloids, glycerides, since these substances are decomposed by a brominised soda-lye with the development of gas. If the ammoniacal salts are accompanied by non-nitrogenous

organic bodies the method is applicable, but if the proportions of such bodies are high the results are not very accurate. For the determination of the ammonia split off from amidoid compounds by the action of acids the azometer is entirely useless.

Determination of Soluble Phosphoric Acid in Superphosphates.—S. Drewsen.—The author finds it necessary to boil the solution with nitric acid before the molybdenum mixture is added.

Determination of Glycerin in Beer,—Dr. F. Klausner.—The author criticises existing processes and gives a method of his own, which cannot be described without the accompanying diagram.

Determination of Nitroglycerin in Dynamite.—W. Hempel.—This paper cannot be usefully reproduced without the accompanying illustration.

Detection of Salicylic Acid in Urine.—Dr. A. Bornträger.—The author gives the preference to the process of Robinet, who precipitates the urine with an excess of lead acetate, removes lead from the filtrate by means of dilute sulphuric acid, and tests with ferric chloride.

Determination of Arsenic as Magnesium Pyro-Arseniate.—Dr. F. Reichel.—The author places the well-dried precipitate as completely as possible in a watch-glass, moistens the filter with a solution of ammonium nitrate, dries, and burns it, previously cut up into pieces in a porcelain crucible. When the crucible is cold the contents of the watch-glass are introduced into it, a few drops of nitric acid are introduced so as to saturate the whole precipitate, and the crucible is dried at 100°, or heated carefully over a small gas-flame, to prevent spirting. As soon as watery vapours no longer escape the crucible is closed and ignited strongly for ten minutes.

Aluminium Phosphate.—Dr. L. L. de Koninck and Thiriart.—In presence of an excess of phosphoric acid or of alkaline phosphates, aluminium phosphate is easily and completely soluble in ammonia.

Determination of Tannin.—J. Löwenthal.—Dr. Seippel, of Barmen, states that in executing Löwenthal's method of determining tannin, it is advantageous, after adding the acid water to the mixed solutions of tannin and glue, to stir well for about five minutes. The liquid filters readily.

Universal Spectroscope.—C. H. Wolff.—The author has arranged an instrument equally applicable for observing the spectra of flames and absorption-spectra, and for quantitative operations.

Parke's Method for the Volumetric Determination of Copper.—R. Ulbricht.—The method yields good results if the operator proceeds in determining the value of the cyanide solution exactly as in the determination of the copper itself. There must be in each case an equal quantity of free and of combined nitric acid, an equal proportion of free ammonia, an equal quantity of one and the same ammoniacal salt, and after titration the same volume of liquid results in each case. The addition of the cyanide solution must take place always in the same manner, and within the same space of time. The proportion of copper in the liquid on determining the standard of the cyanide solution should not deviate essentially from the proportion in the liquid to be analysed. The cyanide should be standardised on the same day when the analyses are to be performed.

Spectroscopic Detection of Indium.—S. Wleügel.—On using a Bunsen burner to produce the flame-reaction quantities small as 1-3000 m.g. can be detected in a solution of the chloride in water. On examining a mixture representing a blende with 20 per cent of iron the limit of perceptibility lies between 0·001 and 0·0001 per cent.

Determination of the Halogens in Chlorates, Bromates, and Iodates.—F. Fleissner.—The substance is boiled for an hour with an excess of zinc powder, washed with boiling water,—at first by decantation. The filtrate is acidified with nitric acid, and in it the halogens are determined in the ordinary manner by precipitation with silver nitrate.

Spectroscopic Determination of Nitric and Phosphoric Acids.—H. Settegast.—This paper does not admit of useful abstraction.

Ergotinine.—C. Tanret.—An extensive paper, not suitable for abridgment.

Solubility of Cane-Sugar in Water.—H. Courtonne.—A solution of sugar saturated at 12·5° contains 66·5 per cent of sugar, and one saturated at 45° contains 71 per cent.

Determination of the Organic Impurities of Drinking-Water.—G. Lechartier.—A modification of the well-known Frankland-Armstrong process. The author determines carbon and nitrogen separately. In case of the latter he destroys the carbonates and nitrates of the water, not by means of sulphurous acid but by evaporating 1 litre water with about 0·2 grm. calcined magnesia.

Milk-Analysis.—A. Müller.—A full account of the author's process which cannot be reproduced without the accompanying illustration.

Presence of the Seed of Agrostemma Githago in Flour.—A. Petermann.—This impurity is best discovered microscopically.

Tests for Lubricating Oils and Determination of their Proportion of Acid.—E. Laugier.—Inserted in full.

Determination of Yeast.—M. Hayduck.—The author counts the number of cells observed in a given space with the microscope.

Determination of Albumenoids and Non-Albuminous Nitrogen Compounds in Cattle Food.—A collection of methods proposed by various authors.

Determination of the Cinchona Alkaloids.—A review of processes, not capable of useful abstraction.

Examination of the Salts of Quinine.—This paper does not admit of abstraction.

Examination of the Ethereal Oil of Bitter Almonds.—M. Boyveau.—The spurious oil has the sp. gr. 1·029 to 1·030, whilst that of the genuine is 1·043, or according to other statements 1·045 to 1·060. The genuine oil if mixed with an equal volume of sulphuric acid turns red, but remains limpid and clear. The spurious oil turns dark-red, and then becomes brown, dull, and thick, and congeals to a brownish mass.

Band 207, Heft 1.

Atomic Weight of Platinum.—Dr. K. Seubert.—In the eighth family of elements (according to the classification of Lothar Meyer and Mendelejeff) and in the third group including osmium, iridium, and platinum, which form a transition to gold in the B group of the first family,

there were till lately a series of irregularities. Instead of the successive order, Os<Ir<Pt<Au, which theory demands, the accepted atomic weights of the elements led to the arrangement Au<Pt=Ir<Os. Two years ago the author, at the request of Prof. L. Meyer, undertook a revision of the atomic weight of iridium, which he found = 192·644; consequently Ir<Pt. He now communicates the results of his investigation on the atomic weight of platinum, which he finds = 194·177. Its position, Ir<Pt<Au, is consequently in accordance with its properties in so far as they can be regarded as a function of the atomic weight. There is still an anomaly in the position of osmium with its atomic weight, 198·5, beyond gold, though it should probably be about 192, and stand before iridium.

Communications from the Laboratory of the Victoria University at Manchester.

1. The Vanadium Sulphides.—W. E. Kay, Dalton Chemical Scholar, Owen's College.—The precipitates obtained by Berzelius were oxygenous compounds. The preparation which he produced in the dry way was a true vanadium sulphide, V_2S_4. Besides this tri-sulphide there exist a di- and a penta-sulphide. The vanadium sulphides are less permanent than the corresponding oxides.

2. Pentathionic Acid.—Toyokichi Takamatsu and Watson Smith.—The authors demonstrate the existence of pentathionic acid, and expect to be able to produce well-crystallised pentathionates.

Isomeric Xylidines.—E. Wroblewsky.—Coal-tar contains three xylols, from each of which a xylidine can be obtained. The author has produced the xylidine corresponding to ortho-xylol.

Azo-Derivatives of Toluol.—J. Barsilowsky.—Not suitable for abstraction.

Note to the Memoir "On Gay-Lussac's Hypochloro-nitric Acid."—Dr. H. Goldschmidt.—The author mentions that Prof. Tilden had previously rendered the non-existence of the compound $NOCl_2$ very probable, though not absolutely certain.

Band 207, Heft 2.

Constitution of the Sulph-hydantoins and Sulphurethans.—C. Liebermann.—An extensive memoir, incapable of useful abstraction.

Causes of the Flame of the Bunsen Burner becoming Luminous, in Consequence of the Heating of the Burner-tube.—R. Blochmann.—A discussion of the views on this subject previously put forward by Wibel and Heumann.

Compounds of the Elements of the Nitrogen Group with the Radicles of the Aromatic Series.—A. Michaelis. —Fourth Memoir: Constitution of Phosphonium and Arsenium Compounds.—The compounds here examined are the derivatives of diphenyl-arsen-chloride and of diphenyl-phosphor-chloride. The author's researches show that both in the phosphorus and the arsenic series, so long as the same number of the same organic radicles are present, the properties of the phosphonium or arsenium compounds are independent of the relative position of these radicles. Hence it is highly probable that in these compounds the elements of the nitrogen group are penta-valent.

Behaviour of Cinchomeronic Acid when Melted.—S. Hoogewerff and W. A. van Dorp.—On melting cinchomeronic acid and also tri-carbo-pyridic acid there is formed a mixture of two mono-carbo-pyridic acids, namely, γ-carbo-pyridic acid and nicotic acid.

Para-cholesterin from Æthalium Septicum.—J. Reinke and H. Rodewald.—The authors have succeeded in isolating the compound in question from the protoplasm of *Æthalium septicum*. In its general properties the substance agrees with the cholesterin and iso-cholesterin of the animal body, and with the cholesterin discovered by Beneke in the pea.

Ortho-anisidin and Amido-dimethyl-hydroquinon.—Otto Muehlhaeuser.—The author examines ortho-nitro-anisol, ortho-anisidin with its hydrochlorate, hydrobromate, hydriodate, nitrate, sulphates, oxalate, and picrate; aceto-aniside with its nitro- and dinitro- derivatives, benzoyl-aniside, the anisyl-ureas and sulphureas, mono- and di-methyl-anisidin, metoxyquinon, nitro-dimethyl-hydroquinon, and amido-dimethyl-hydroquinon.

Band 207, Heft 3.

Optical Rotatory Power of Malic Acid and of its Salts.—Dr. G. H. Schneider.—If we gradually proceed from dilute aqueous solutions of free malic acid, which are lævo-rotatory to more concentrated solutions, the specific rotation first gradually decreases, and when the percentage of the acid reaches 34 it disappears entirely, and on further concentration it passes over into a deviation to the right. The behaviour of the majority of the malates is analogous. The effects of the presence of optically inactive acids were also examined. In presence of sulphuric acid the reversal of the direction of rotation takes place even in very dilute solutions. Sulphuric acid, therefore, has an action opposite to that of water. The action of acetic acid is similar to that of sulphuric acid, but much feebler. The so-called law of multiple rotatory proportions, proposed by Krecke and maintained by Thomsen, does not hold good in the case of malic acid and its salts.

Studies on Quinamine.—O. Hesse.—The author's experiments show that quinamine bears no relation to the ordinary cinchona alkaloids, such as quinine, cinchonine, and their isomers, and has nothing in common with them beyond its occurrence in certain cinchona barks.

New Platinum Salts.—O. Hesse.—The author has obtained neutral platinum salts of the cinchona alkaloids by the following process:—Aqueous solutions of the neutral hydrochlorates of quinine, cinchonine, conchinine, cinchonidine, and homo-cinchonidine, slightly heated, are mixed with sodium platino-chloride, when the desired salts are precipitated, and are almost insoluble in cold water.

Researches from the Chemical Institute of the University of Strassburg.—These investigations consist of a memoir on the diphenyl bases, by G. Schultz; a paper by H. Schmidt and G. Schultz, on benzidine (*a*-diamido-phenyl); an account of diphenyline (*β*-diamido-phenyl), by G. Schultz, H. Schmidt, and H. Strasser; and a memoir on the constitution of the diphenyl derivatives, by G. Schultz.

Le Génie Civil. No. 11, April 1, 1881.

Taxation of Alcohols with Reference to the Manufacture of the Alkaloids in France.—The writer points out the difficulty in which French manufacturers of alkaloids are placed in consequence of the taxation of alcohol.

KING'S COLLEGE, LONDON.—MEDICAL DEPARTMENT.

The WINTER SESSION will be opened on Monday, October 3rd, at Four p.m., when the Distribution of Prizes will take place, and an address be given by Sir JOHN LUBBOCK, Bart., M.P., F.R.S., D.C.L.

A Special Course of Instruction has been established for the Preliminary Scientific Examination at the University of London, including Inorganic Chemistry, Practical Chemistry, Practical Biology, Experimental Physics, Zoology, and Botany.

The following Entrance Scholarships will be given in October next—viz.:—

Two on the Warneford Foundation of £75 each, for previous education in General Literature and Science.

Two by the Clothworkers' Company—one of £100 and one of £50 for proficiency in Science only.

Two on the Sambrooke Foundation—viz.: one of £60 and one of £40, for proficiency in Literature and Science.

During the ensuing Session there will be awarded five Medica Scholarships—viz.: one of £80, one of £30, and three of £20, for professional efficiency; one for Chemistry of £40, one of £50, for resident students only; and two Sambrooke Registrarships of £50 each.

Endowed Prizes of the value of 65 guineas and College Prizes of the value of £60 are also awarded annually.

For Prospectuses and other information, apply personally or by post card, to J. W. CUNNINGHAM, Esq., King's College, London; or to Professor BENTLEY, Dean of the Department.

IRISH HILL BAUXITE (Alum Clay).

The IRISH HILL MINING CO. are now, and always have been, the LARGEST PRODUCERS OF THIS CLAY, of Superior Quality, and supply the Manufacturers of Alum, Sulphate of Alumina, and Alum-Cake, of the United Kingdom, America, and the Continent, almost exclusively.

Analysis by John Pattinson, Esq.

Supplies over 90 % of the Bauxite (Alum Clay) used.

	Dried at 212° F.			
	Gertrude (extra qual.)	1st Quality.	2nd Quality.	
Alumina	59·00	53·83	52·00	
Peroxide of Iron	0·47	1·57	4·57	
Silica	18·00	8·67	12·00	
Titanic Acid		5·80	6·20	
Lime, Magnesia, Potash, Soda, and Sulphuric Acid	0·23	0·83	1·14	
Combined Water	22·30	29·27	24·00	
	100·00	99·97	99·91	

Supplies over 90 % of the Bauxite (Alum Clay) used.

Our MINES, DRYING KILNS, and GRINDING MILLS are situated very close to the Shipping Ports of BELFAST and LARNE, and adjacent to Railways running alongside both Steamers and Sailing Vessels at both Ports, from either of which shipping is abundant and cheap, therefore we can guarantee Regular Delivery as Buyers require it, and are prepared to quote prices f.o.b. c.i.f., or delivered at any Port, in Bulk or Bags, Lump or Ground.

GEO. G. BLACKWELL, *Managing Director.*

Richmond Buildings, 26, Chapel St., Liverpool.

ST HELEN'S ENGINE, BOILER, AND BRIDGE WORKS AND FOUNDRY,
LANCASHIRE.

Carr's Patent Paint and Drug Mill.

Approved by some of the most eminent Chemists, and awarded the Silver Prize Medals of the Manchester and Liverpool, and the Middleton Agricultural Shows.

From Messrs. E. H. Smyth & Co., 21 Duke Street, Edinburgh, and 69, Coleman Street, City, London.—The small Levigator Mill we recently got from you works most efficiently, and is a great economiser of time.

The chief feature in this machine is, that although it can be turned with ease by a boy, it has immense frictional power for levigating purposes. This is caused by the runner being driven at a much greater speed, but in the same direction, than the bowl. The surfaces being Minton ware, they are clean, smooth, and durable.

Testimonials on application.

£11 nett cash, delivered in Manchester.

The diameter of the bowl is 18 ins., and it and the runners are made of Minton ware. It is useful for Painters, Chemists, Grocers, and Cooks, for triturating and mixing Medicines, Vegetable Powders, Ointments, Paints, Sugar, Salt, Spices, Herbs, Meat for Potting, and will grind the coarsest Emery into a nearly Impalpable Powder in a few seconds. The pan can be tilted for emptying, as shown in the dotted lines; it can be worked by hand or power.

THE CHEMICAL NEWS.

VOL. XLIV. No. 1134.

PREPARATION OF PURE NAPHTHALEN.

By WILLIAM W. STAVELEY.

PROF. LUNGE, in his recent communication on the above (CHEMICAL NEWS, vol. xliv, p. 65), in assuming that "the manufacture of pure naphthalen on a large scale and at a cheap rate is still considered a secret process, and is not known to many tar distillers," is, unwittingly, unjust to tar distillers generally. And I would here remark that many writers on coal-tar products, unconnected with the trade, take it for granted that the processes in the tar works are now carried on in the same happy-go-lucky style as they were thirty years ago, when tar was to be got for the asking. In no branch of chemical industry is the competition more keen or the necessity greater for economical improvements, and tar distillers are on the alert to investigate every improvement which chemical science has to offer them. I think I may safely assert that in all large tar works there is sufficient ability for the production of any tar product, in any degree of purity, so soon as the demand and price shall be remunerative. At present, neither the demand nor the price of pure naphthalen is sufficiently encouraging to induce many tar distillers to undertake the production of it. Even were this so, the markets would be overstocked in a few weeks and price would consequently fall.

In tar works, where the refining of benzols, &c., is carried on, pure naphthalen may be easily obtained, without further chemical treatment, by distilling the residues, or foots, from the rectifying stills, and allowing the distillate, say from 0·950 to 1·000 sp. gr., to cool for a day or so; the deposited naphthalen is drained and pressed, re-distilled or sublimed. Naphthalen thus prepared has kept its colour, or rather, it has not become decolourised on exposure to light for some months. The use of MnO_2, $K_2Cr_2O_7$, and other oxidising agents, in conjunction with H_2SO_4, for the purpose of purifying or decolourising tar products, is known to most tar works chemists, and has been used in the laboratory, if not in the works, for many years.

Is it not rather unfair to compare a small sample prepared in the laboratory, probably in glass vessels, with samples prepared in the works on a large scale? Prof. Lunge, from his previous experience in tar works in England, will know how difficult it is to exclude extraneous matter in the form of coal and pitch dust, oily particles, &c., floating in the air of the works, and a very slight trace of these will frequently cause discolouration.

In the description of his process, Prof. Lunge omits to mention that the naphthalin before treatment should be submitted to hydraulic pressure. This is important, inasmuch as samples of naphthalen prepared from light oil residues, &c., by his process, though they would probably remain white for months, would yet retain sufficient cumol, xylol, &c., to render the naphthalen unfit for the preparation of naphthol colours.

In conclusion, would Prof. Lunge kindly state what reasons he has for supposing that aurin may be formed by the oxidation of a mixture of phenol and cresol, as he gives it; thus, $2C_6H_6O + C_7H_8O + 3O = 3H_2O + C_{19}H_{14}O_3$.

Dale and Schorlemmer, in their exhaustive researches on aurin, have come to the conclusion that aurin is formed by the action of nascent CO_2, carbonic dioxide, on phenol, thus— $3C_6H_6O + CO_2 = C_{19}H_{14}O_3 + 2H_2O$.

I cannot reconcile this with the above equation of Prof. Lunge.

The pink discolouration of naphthalen, if "the presence of traces of mineral acids" is another condition for the development of it, may be due to the formation of the red sulpho-salt. It may be interesting to note here that the pink colouration is most frequently observed in tar works on the ends of barrels containing heavy rectified naphthas, the ends of the barrels having previously been "white-washed" with slaked lime. This has led me to attribute the pink colouration on the ends of the barrels to the action of CO_2, absorbed by the CaHO from the atmosphere, on the hydrocarbons which leak through the end of the barrels. I have also noticed that if a sample of impure sublimed naphthalen be mixed with traces of lime dust, the pink colouration is more speedily developed and is more intense than it would be if the lime dust was not present.

SEPARATION AND DETERMINATION OF ALUMINA AND OF THE FERRIC AND CHROMIC OXIDES.

By M. AD. CARNOT.

THE problem of the separation and determination of alumina and ferric oxide is among those which occur most frequently in the analysis of minerals and metallurgical products. Rivot and Sainte-Claire Deville have given methods which are satisfactory when the two oxides can be previously separated from every other substance. But the processes taught by these regretted masters are inapplicable in presence of phosphoric acid, and give questionable results if one of the two oxides is present in very small proportions. These unfavourable conditions are found combined in various ores or minerals and in many products of art—cast-metal, slags, &c. The difficulty is such, especially in cast-iron, that even when the presence of aluminium is suspected, its determination, and even its detection, are rarely attempted.

The author proposes the following method:—The two oxides being dissolved in nitric or hydrochloric acid, there is added pure tartaric acid (about 1 grm.) or potassium bitartrate, and then ammonia in such a quantity that the liquid may become very clear. Ammonium hydrosulphate is then added, the liquid is stirred, and the iron sulphide when deposited is poured upon a filter and washed. The separation is perfectly distinct, provided that the precipitate is not so bulky as to retain by adherence an appreciable proportion of alumina. The iron may then be determined either gravimetrically or volumetrically. In order to determine the alumina there is added, according to its presumed proportion, a quantity of sodium hydrate more than sufficient. The hydrosulphated liquid is then decomposed by hydrochloric acid in slight excess (1 c.c. above the quantity needed for exact saturation), 4 to 5 grms. sodium acetate are then added, and the liquid is raised to a boil. It is kept near 100° for one to two hours, allowing the liquid to become concentrated. The mixture is then poured upon a filter, and washed for a few moments with boiling water.

To remove the tartaric acid with which the precipitate is impregnated, it is re-dissolved in nitric acid, diluted with water, almost neutralised with ammonia, a few drops of phosphoric acid and 2 to 3 grms. ammonium acetate added, and the mixture is boiled for an hour.

The precipitate formed is gelatinous, but there is so little fixed saline matter in the precipitate that after a short washing with boiling water no sensible traces remain in the precipitate. It may be incinerated without detaching from the filter. The phosphate is white, pulverulent, readily soluble in cold dilute nitric acid, and contains 42·04 per cent of alumina.

The precipitation should be effected in liquids not very dilute, and the washing should be effected with a little boiling water, so as to render the loss as slight as possible, for the phosphate is not perfectly insoluble. But 100 c.c.

of boiling water dissolve in reality less than 0·001 grm. of the compound.

The precipitation may even be effected in a complete manner by means of tartaric acid alone, without the addition of an alkaline acetate; but in this case it is more difficult to wash.

The author proposes to return to this method of detecting aluminium in cast-iron.

In order to separate alumina as phosphate from chromic oxide, the latter must first be transformed into chromic acid by fusion with pure potassa and nitre. It is then dissolved, and the liquid is acidified slightly with nitric acid. A little sodium phosphate and 4 to 5 grms. sodium acetate are then added, and the liquid raised to a boil. The aluminium phosphate is precipitated alone. It is washed with a little boiling water in order to remove all the chromic acid, re-dissolved in nitric acid, and the determination of the alumina is completed as above. The filtrate is raised to a boil, and there is gradually poured into it aluminium nitrate enough to throw down all the phosphoric acid. It is boiled for half an hour and filtered. The filtrate when cold is mixed with lead acetate, when the chromic acid is precipitated and weighed as lead chromate.—*Comptes Rendus.*

LONDON WATER SUPPLY.

REPORT ON THE COMPOSITION AND QUALITY OF DAILY SAMPLES OF THE WATER SUPPLIED TO LONDON, FROM JULY 1ST TO JULY 30TH, 1881.

By WILLIAM CROOKES, F.R.S.,
WILLIAM ODLING, M.B., F.R.S., F.R.C.P.,
Professor of Chemistry at the University of Oxford;
and C. MEYMOTT TIDY, M.B., F.C.S.,
Professor of Chemistry and of Forensic Medicine at the London Hospital; Medical Officer of Health for Islington.

To the RIGHT HONOURABLE THE PRESIDENT OF THE LOCAL GOVERNMENT BOARD.

August 5th, 1881.

SIR,—We beg to lay before you the results of our daily examinations of the water delivered, from the 1st to the 30th of July, by the seven London water companies taking their supply from the Thames and the Lea. These daily examinations, begun on December 20th of last year, are made under instructions from the water companies, and at their cost. The selection of samples, the methods of analysis, and the form and nature of the reports have rested entirely with us. The samples are taken by a man in our service at places and times which we ourselves appoint.

In 1 only of the 182 samples taken during the month were we able to detect by examining the water in large bulk with the naked eye the minutest trace of matter in suspension.

In Table I. we have recorded the analyses in detail of samples, one taken daily from July 1st to July 30th, inclusive. The purity of the water in respect of organic matter has been determined by the Oxygen and the Combustion processes, and the results of our analyses by these methods are stated in columns XIV. to XVIII.

We have recorded in Table II. the tint of the 182 samples of water as determined by the colour-meter we have described in a previous report. Practically the waters differ very little in their appearance (even when examined in large bulk) from distilled water; and the occurrence of any cases of inferior colour or of turbidity must be referred to the condition of the household receptacles, not to the condition of the water as supplied.

Of the 26 samples supplied by the New River Company, the whole were found to be well filtered, clear, and bright.

Of the 26 samples from the mains of the East London Company, all were found to be well filtered, clear, and bright.

Of the 26 samples from the mains of the Chelsea Water Company, all were found to be well filtered, clear, and bright.

Of the 26 samples from the mains of the West Middlesex Company, all were found to be well filtered, clear, and bright.

Of the 26 samples from the mains of the Lambeth Water Company, all were found to be well filtered, clear, and bright.

Of the 26 samples from the mains of the Grand Junction Company, the whole were found to be well filtered, clear, and bright.

Of the 26 samples from the mains of the Southwark and Vauxhall Company, one was noted as "very slightly turbid." The rest were well filtered, clear, and bright.

In Table III. we have recorded the oxygen required to oxidise the organic matter, and the quantities of free oxygen present in the whole of the samples collected.

Our daily examinations of the water delivered to London during the past month satisfy us of its excellent quality, and of its suitability in every way for the supply of the Metropolis.

We remain, Sir,
Your obedient Servants,
WILLIAM CROOKES,
WILLIAM ODLING,
C. MEYMOTT TIDY.

ESTIMATION OF POTASSIUM AS PLATINUM SALT.

By DAVID LINDO.

(Continued from p. 78.)

*General Method.**

WEIGHED the solution of KCl in a small light stoppered bottle. Poured into the dish. Rinsed bottle with measured quantity of distilled water intended for dilution (about ten times the volume of KCl solution employed). Added measured quantity of platinic chloride solution (the weight of platinum introduced being about double the weight of KCl used, and in experiments with KCl and NaCl double the weight of the two salts). Evaporated on water-bath. When crusts began to form, removed the dish occasionally from bath, and by communicating a suitable motion to contents, washed the crusts down.

Towards the end of the evaporation removed dish occasionally, and by inclining it spread contents over the bottom. Continued evaporation, until on inclining dish the mass ceased to flow. Added a few drops of water, and evaporated again to same extent (Tatlock). Removed dish and drenched contents with dilute alcohol (80 per cent absolute by weight). 10 c.c. used to drench with in small estimates, 20 c.c. in larger. Mixed contents by communicating rotatory motion to same. Let rest a few minutes. Started filter-pump. Placed crucible with asbestos in position. Poured drench through crucible. Washed precipitate three or four times carefully by decantation, then removed it from dish to crucible with the aid of a feather carefully cut. Rinsed dish repeatedly with a small quantity of spirit, sweeping the rinsings into crucible with feather. To complete the washings, filled up crucible four or five times with spirit. Dried at 130° C.

Experiments with pure KCl were made by this method; the results are given in Table I. In the last ten experiments the residues were alternately moistened with a few drops of water, and evaporated nearly to dryness five or six times. The same plan was adopted in the experiments recorded in Table III. It was abandoned in the method

* Essentially the process employed by Messrs. Teschemacher and Denham Smith, except that I used Gooch's method of filtration, and spirits of wine 80 per cent to wash with, instead of 85 per cent methylated spirit.

finally employed. Between experiments 13 and 14 fou were made with mixed chlorides of K and Na. Ther results of these are given, with others made after, in Table III. With this exception the experiments are recorded in the Tables in the order in which they were made.

TABLE II.

Analysis of the Results obtained in the Estimation of Potassium when in the form of Pure Chloride.

No. of Expts.	Highest Result.	Lowest Result.	Average.
27	100·26 p.c.	99·75 p.c.	100·00 p.c.

The precipitate from one of the experiments that had given a high result was carefully examined for traces of copper and iron; none were found. The results of two experiments previously tried may be stated here.

1st Experiment.—1·0588 grm. of the chloro-platinate in scales contained in a porcelain crucible was kept at a temperature of 130° C. for four hours. Allowed to cool, and weighed. No loss. It was then reduced to powder in the crucible (taking every precaution to avoid loss of particles), and weighed again. Loss 0·0002. Heated again to 130° C. until weight remained constant. Further loss, 0·0010 gramme.

2nd Experiment.—1·4773 grm. of the salt in scales treated in the same way lost 0·0014 grm.

These experiments show that the scales (sometimes at least) contain small quantities of fluid impurities mechanically confined, as suspected by the Committee.

The general method was considerably modified in the experiments, the results of which are recorded in Table III. I will describe the various modifications employed as briefly as possible; the method finally adopted will be described more fully further on.

1st Modification.—After pouring off the spirit used to drench with, a little more was added to the precipitate; the latter was then crushed to powder with a large glass rod smooth at the end, washed by decantation, and finished as usual. 80 per cent spirit employed.

2nd Modification.—Alcohol 98 per cent employed to wash with. Crushed precipitate, and proceeded as above.

3rd Modification.—Alcohol 98 per cent used to wash with. Precipitate not crushed, but slightly manipulated with the glass rod.

4th Modification.—Used alcohol of 98 per cent: washed by decantation; removed these washings from receiver. Crushed precipitate, transferred it to crucible, finished washing as usual. Returned last washings through the precipitate four times.

5th Modification.—Used 98 per cent alcohol. Proceeded as in 4th modification, except that last washings were only returned once through the precipitate unless they were opalescent, which was rarely the case. This is essentially the method finally adopted, but it will be described more fully further on.

* On turning out this precipitate it was found the scales had been very imperfectly crushed.

† A fresh carboy of alcohol was opened and used from here. It was one of the same stock that had been used from in the former experiments. I examined it carefully, but except that it contained slight traces of organic impurities, such as are met with in most samples, I could detect nothing wrong with it.

It will be seen that most of the results obtained, except by the first modification, are very accurate, but three of the earlier experiments were rejected, the filtrates not being quite brilliant. In dealing with such a dense precipitate the slightest opalescence in the filtrates is inadmissible if we wish to obtain thoroughly reliable results. I therefore felt bound to reject these three experiments, though the turbidity was very slight indeed, and the precipitates, when carried to the balance, showed results according well with theory, viz., No. 41, 100·01; No. 44, 99·93; No. 45, 100·08. I had not yet fully learnt that the filtrate could be returned through the precipitate with impunity, and that the annoyance from turbid filtrates might be almost entirely avoided by washing the precipitate by decantation *before* crushing it.

After the analyses were completed the precipitates from experiments Nos. 71 and 72 were submitted to further washing by passing 20 c.c. of alcohol through each of them *five times*; they were then dried again at 130° C., and weighed. The loss of weight sustained in each case was only 0·0002 grm.

As regards the precipitate from experiments No. 73, before weighing, a thin film of perfectly white saline matter was observed on its surface, which looked very much like NaCl. After weighing this film was removed as completely as possible. It tasted like NaCl, and gave a strong Na reaction in flame.

Precipitate from experiment No. 74 did not taste of NaCl, nor were any white particles observed, even with the aid of a lens; but it gave a Na reaction in flame, though not a strong one, and only seen after K reaction had disappeared.

That the precipitates from No. 71 and No. 72 were practically not reduced in weight by further washing with alcohol seems to indicate that the high results obtained in these experiments were also due to the presence of traces of NaCl in these precipitates. As they had been turned out and mixed with other residues they could not now be further examined.

The solution of platinic chloride employed contained (as previously stated) 1 grm. of metal in 20 c.c. The quantities used in these four experiments were as follows:—

Experiment No. 71, 22 c.c.
" 72, 20 "
" 73, 25 "
" 74, 23 "

The platinum was therefore in decided excess of the quantity required to convert all the KCl and NaCl into platinum salts, and the presence of NaCl in the precipitates is therefore difficult to account for.

I may here state that when these experiments were made the platinum had been recovered for the third time, and had reached a high degree of purity. 5 c.c. of the solution, evaporated as nearly to dryness as possible on the water-bath left a residue which dissolved completely in alcohol. The solution was very brilliant. Left in a corked bottle for twelve hours, not the faintest trace of precipitate was observed, even through a lens.

The NaCl employed in all the experiments was a very pure sample prepared by the process of Margueritte; except that it contained a faint trace of sulphate—only apparent after standing some time mixed with chloride of barium: it was chemically pure. With a 10 per cent solution of this salt the following experiments were made. I will first state the quantities of NaCl and volumes of platinic chloride solution (1 grm. metal in 20 c.c.) used in these experiments. All the evaporations were made on the water-bath. 98 per cent alcohol used to dissolve—

	NaCl taken in Grms.	Solution of Platinic Chloride taken in c.c.
Experiment 1	0·2021	20
" 2	0·2500	10
" 3	0·2382	15
" 4	0·4131	20
" 5	0·4237	20

Experiment 1.—Evaporated as nearly to dryness as possible. Left on water-bath about fifteen minutes longer. Added 80 c.c. alcohol. Complete solution. Very brilliant. Deposited nothing after standing twelve hours in closed bottle.

Experiment 2.—Evaporated just to dryness; added 80 c.c. alcohol. Solution not quite brilliant. Deposited small white precipitate after some hours. Precipitate too minute to examine further.

Experiment 3.—Evaporated to dryness; then heated five hours longer on water-bath. Added 80 c.c. alcohol. Solution turbid, and remained so for hours. NaCl had evidently separated, and appeared struggling to re-combine (even in the midst of the strong alcohol) with platinic chloride, the latter being in large excess. After twenty-four hours a small white precipitate fell. This was separated; it tasted like NaCl. Not further examined.

Experiment 4.—Evaporated just to dryness. Added 80 c.c. alcohol. Solution turbid, and after a time deposited a small perfectly white precipitate. Syphoned off fluid nearly to the bottom. Transferred residue to test-tube. Let settle; drained off alcohol; added a little water. Precipitate dissolved completely. The solution was tested as follows:—

1st. Tasted. Distinct flavour of NaCl.
2nd. Heated in flame on platinum wire. Strong sodium reaction.
3rd. Added nitrate silver. Curdy precipitate.
4th. Added chloride barium to a fresh portion. No reaction.
5th. Added one or two drops solution platinic chloride to a fresh portion. Evaporated on slip of glass until crystals formed. Examined these under microscope by polarised light. Beautiful play of colours (Andrew's test for sodium).

Experiment 5.—Evaporated to dryness. Heated five hours longer on water-bath. Added 80 c.c. alcohol. Solution very turbid. Precipitate deposited after some hours. Collected this on asbestos, washed with alcohol, dried, and weighed. Weight 0·0043 grm. Dissolved out with water and tested. Precipitate proved to be NaCl.

It thus appears evident that even in the presence of excess of platinic chloride, reversion of a small portion of the NaCl will sometimes take place.*

That this might occur may have been suspected by others, but I have nowhere seen it distinctly stated that it ever *does* occur.

Whether the reversion takes place in the dry mass or only on addition of the alcohol it is difficult to determine. Prolonged heating on the water-bath seems to promote the change. From experiments already made and others tried since, I feel satisfied that if in the presence of much NaCl, a somewhat larger excess of platinic chloride is used than was employed in the last four experiments, Table 3, and if the mass is not heated too long after it has become dry, on the water-bath, this reversion of NaCl will either not take place at all, or occur to such a trifling extent as to be of no practical importance in the estimation of potassium, and as to render unnecessary the use of aqueous fluids in washing the chloro-platinate.

It will be observed that the experiments modification 3 gave fairly good results. Five of them, indeed, may be considered accurate, and the remaining three are not greatly in excess of the truth. As the precipitates in these experiments were not crushed, but the scales merely broken down slightly with the glass rod, some may think from these results crushing is hardly necessary. I consider, however, that it is unsafe ever to dispense with it if we wish to obtain thoroughly reliable results, for it seems pretty evident that the crystals will at times entrap impurities which the alcohol can remove if it is allowed to reach them. Moreover, these matters appear to be

* Some may think complete combination does not take place in the first instance. That reversion occurs seems more probable. Therefore I have adopted this view here, where the question as to which is the correct one is of no practical importance.

retained occasionally with considerable force by surface adhesion.* The precipitate when reduced to powder forming a compact mass in the crucible, offers considerable resistance to the passage of the fluid, and under pressure of course this will render thorough cleansing more certain.

As regards minus errors when alcohol of the strength employed by me is used to wash with, I know of nothing in the process that can cause them. Therefore, when they appear, I believe they must be due to faulty manipulation.

ERRATUM.—By an error in copying, the factor on p. 77, col. 2, line 18 from bottom, was given as 0·3050. It should be 0·3056.

(To be continued.)

ON SALT-BUSH AND NATIVE FODDER PLANTS OF NEW SOUTH WALES.†

No. 4 contained or gave up to ether more chlorophyll than any of the others; the quantity of this was generally small, judging from the colour of the solution.

By an unfortunate mistake the whole of the original specimen of No. 6 (the blue-bush) was incinerated. In writing for another specimen, it was suggested that only the more tender parts of the plant need be sent, which suggestion was almost too literally carried out; and as there had been rain between the two gatherings, the plant had entered on its vigorous spring growth, so that the specimen consisted almost entirely of young succulent shoots. This accounts for the high percentage of ash and albumenoids, which are generally higher in immature plants, and the ash would probably be richer in alkaline salts than the ash analysis made on the original specimen shows. Being then in a different stage of development, this analysis does not very well bear comparison with those of the other plants.

The different character of the ash of the cotton-bush from the others was at once shown on charring, as the mass in the crucible slowly burnt away after its removal from the fire, and without further application of heat, and the residue after this spontaneous combustion did not contain above 20 per cent of carbon. It was also noticed that on burning a small portion for the ash determination, it differed somewhat from the other samples, as they all

burned with a luminous and more or less smoky flame, which was particularly the case with No. 7, diffusing at the same time a peculiar, somewhat fishy odour, whilst it exhibited no such peculiarity either as to flame or odour.

To arrive at the value of a fodder plant, there are many properties which have to be taken into consideration, besides the actual nutritive value as ascertained by analysis, in determining their suitability for grazing, such as the rapidity of growth of the plant, ability to withstand drought and constant cropping, and acceptability in respect to flavour to the cattle. On such points it is beyond my power to speak, but it appears to me a subject of sufficient importance and interest to induce some of those who have the opportunity to make accurate notes on the plants in this direction, and publish the results.

The order in which the salt-bushes proper are considered to stand from a grazier's point of view, are 1st, *A. numularia*, or old man salt-bush; 2nd, the dwarf salt-bush, the others not being so much considered. The cotton-bush is considered to be of great value, both from the fact that the sheep get very fat on it, notwithstanding its unpromising appearance, which reminds one of a half-dried European broom-bush, but also from its ability to withstand long protracted drought. The blue-bush (*Kochia*) is not held in much esteem by the sheep, who do not eat it unless pushed by hunger, and their owners naturally place it low down in the list. This must be entirely a question of flavour, as so far as can be judged from the proximate analysis of the immature plant examined, it must have nearly the same nutritive value as the salt-bushes.

An examination of these analyses, and a comparison with the examples of well-known European fodders given, shows that the whole of these plants stand in a good position with regard to nutritive value.

Like the greater number of the plants of the natural order *Chenopodiaceæ* they contain an extraordinary amount of ash, and its preponderance at once strikes one on looking at the analysis, so that they seem well entitled to their popular name of salt-bushes, although there are only three which contain a very large proportion of common salt.

I can only find one analysis of a plant of the same genus, viz., *A. verrucifera* from the Kergis Steppes, which contains 12·5 per cent ash,* whilst in the specimens examined it ranges from 24 per cent to 31·28 per cent; but in species in other genera, of the same order as *Salsola*, the ash sometimes rises as high as from 30 to 42 per cent, as determined by the same author,† and many of these plants were formerly, and in some cases are even now for local use, of much importance as a source of soda.

In the following columns are given the ratios in which the total ash, the common salt, and the potash stand in relation to the total digestible matter taken as 100, including in that term the oil, carbohydrates, and albumenoids. There is also given the average of the salt-bushes properly so called, omitting the blue-bush, as the analysis was made on a specimen at a different and imperfect stage of growth, and the cotton-bush, as it is a plant of an entirely different character.

The great difference between the salt bushes and European fodders is thus shown conspicuously, and the former are placed entirely by themselves, whilst the cotton-bush, as far as the points considered are concerned, ranges itself with the latter.

Ratios of Digestible Matter of Ash, Potash, and Salt.

Oaten hay	100	8	3·277	0·863

These plants being chiefly used for the pasturage of sheep, we may glance at what effects might be expected to take place on the animals, for there seems little doubt that changes in them must occur from a diet so very different to that on which they have been bred from immemorial time in Europe. Youatt, after speaking of the effect of climate on sheep and their wool, says:—

"Pasture has a far greater influence on the fineness of the fleece. The staple of the wool, like every part of the sheep, must increase in length or in bulk when the animal has a superabundance of nutriment; and on the other hand, the secretion from which the wool is formed must decrease like every other when sufficient nourishment is not afforded."*

Sheep in common with other herbivoræ, appear to

* Göbel, "Watts's Dictionary," 1·474.
† "Watts's Dictionary," v., p. 176.

* Youatt on the Sheep, p

require a large quantity of soluble chlorides, which by evolving free hydrochloric acid in the stomach, or rather in the gastric juice, enables them to digest very considerable quantities of cellulose. According to Bidder and Schmidt,* 1000 parts of the gastric juice of the sheep contain 986·148 parts of water, whilst out of the remaining 13·852 parts 6·0 consist of soluble chlorides and 1·557 of hydrochloric acid. It is seen that the salt-bushes supply these chlorides in large proportion, and we might therefore expect the digestion to be active and to effect the assimilation of the nutritive matter with certainty,

It is in the wool, however, that we should expect the greatest effect to take place from such a diet. Youatt says (page 60) "The abundance and healthiness of the wool is proportional to the amount of yolk." The yolk of wool consists partly of fatty matter combined to a greater or less extent with lime and earthy matter in the form of an insoluble soap, but its greater part consists of a peculiar compound containing potash called "suint." This substance forms about one-third of the weight of raw merino wool and about 14 per cent in ordinary wool, and is readily soluble in cold water. It is used to a considerable extent as a source of potash in France,† where 1000 tons per annum of potashes are obtained from it. Hoffman says‡ that 1000 lbs. of wool yield from 70 to 80 lbs. of pure carbonate of potash, and 5 lbs. to 6 lbs. of sulphate and chloride of potassium, the weight of dry suint being from 140 lbs. to 180 lbs.; and this would give, as an average yield from the suint, 17 per cent of actual potash and 1·5 per cent of chloride and sulphate. From the percentage of suint given this evidently refers to ordinary wool, and as merino wool contains twice as much the actual quantity of potash will be double, and 1000 lbs. of greasy merino wool would carry off about 60 lbs. potash. From the ready solubility of this substance in cold water, it appears probable that much of it may be washed out of the wool by rain and dew during its growth, and that the quantity remaining in the shorn fleece may represent only a small portion of that which has been elaborated by the sheep. This would constitute a considerable drain on the potash obtained by the animal from its food, and it appears evident that the plants we are considering, from their richness in that alkali, would enable the sheep, and especially the merinos, to withstand that drain and produce that abundance of yolk on which it appears the fineness of the wool so much depends. That this is so is shown by the high esteem in which Riverina wool is held, and I hope by an examination of the wool itself to come to a definite conclusion on the matter.

The cotton-bush does not differ much in the matter of the ratios just considered from ordinary European fodders, and it evidently owes its value to the high percentage of carbohydrates which it contains, in which it stands above all competitors, and from which it obtains its fattening properties.

In the following columns are given—first the percentage of digestible matter (organic); 2nd, the ratio of albumenoids to oil and carbohydrates, or of flesh-forming material to fat-forming, the former being taken as 100.

	1.	2.	3.
1. Dwarf salt-bush	58·58	100	287

* "Watts's Dictionary," ii., 822.
† Roscoe and Schorlemmer's "Chemistry," vol. ii., pt. i, p. 9.
‡ "Report on Chemical Products in International Exhibition," 1862, p. 42.

It will be observed that in every case the total amount of digestible matter in the salt-bushes falls below that in the European fodders, with the exception of the old man and the cotton-bush; but this in all cases is due to the greatly increased quantity of ash, as in none of them is the quantity of indigestible organic matter so great. The ratios of carbohydrates to albumenoids vary greatly in the different plants, in some cases fully as low as in the leguminosæ, in some rising as high and higher than in the grasses. The exceptionally low ratio in the case of the blue-bush is undoubtedly due to the very immature condition of the specimen examined. I do not feel warranted in drawing any conclusion from these ratios, taken from such a small number of samples, but place them before you in the hope that some one else, by examining the plants from the different standpoints already indicated, may enable us to arrive at the proper composition of a fodder plant to produce the best result in wool or mutton, or both.

In conclusion, my thanks are due to Mr. Mair, of Groongal, Narandera, and to Mr. Wilson, of the Mercantile Bank, for procuring me the plant specimen; and to Mr. Moore for naming them for me.

NOTICES OF BOOKS.

The Retrospect of Medicine. Edited by W. Braithwaite, M.D., and James Braithwaite, M.D. Vol. lxxxiii., January—June, 1881. London: Simpkin, Marshall, and Co.

This volume contains the usual summary of observations relative to medical science. We cannot say that the facts here recorded are of any especial chemical interest. No new compound, whether natural or artificial, mineral or organic, appears to have been introduced into practice as a remedial agent.

A curious physiological fact here noticed is the occurrence of free sulphuretted hydrogen in the urine of a patient, which otherwise presented no anomalous features. During two years this urine, whenever examined—sometimes within a minute of its emission—was found to contain from 1·4 to 1·9 c.c. per litre. About the same time Dr. C. A. Cameron had the opportunity of observing a young lady, in apparently good health, from whose skin sulphuretted hydrogen was exhaled for about three years. Lead test-papers placed in contact with her skin were blackened in a few hours, as were silver coins, thimbles, &c., carried in her pockets. If she exerted herself the odour was distinctly recognised.

Rheumatism: its Nature, its Pathology, and its Successful Treatment. By T. J. Maclagan, M.D. London: Pickering and Co.

In this work the author first combats, by inductive reasoning, the commonly received opinion that acute rheumatism is simply due to exposure to cold and damp. He next discusses the theory of Prout that the *materies morbi* is lactic acid. He admits that acute rheumatism is attended with an excess of lactic acid in the system, such as is met with under no other circumstances, but he argues that this excess, though one of the phenomena of the disease, is not its cause. Dr. Richardson's experimental result, that the injection of lactic acid into the systems of the lower animals is followed by inflammatory changes similar to those occurring in acute rheumatism, is regarded as doubtful. Nor can lactic acid be assigned as the cause of its own excess.

The author's theory is that the rheumatic poison enters the system from without and belongs to the class of miasms. Rheumatic fever is in many respects strikingly analogous to malarial fever, and is speedily arrested by

large doses, not, indeed, of quinine, but of the salicyl compounds. In connection with this subject Dr. Maclagan enters at some length into the characteristics of miasmata and their distinction from contagia. That the poison of rheumatism has ever been isolated the author does not contend.

Dr. Maclagan seems to have been led to use salicine in the treatment of rheumatism by a somewhat curious course of reasoning. He notes that certain maladies are best combatted by remedies peculiar to the districts where they prevail. Thus ipecacuanha grows, or can grow, in climates where dysentery is most common. Intermittents are most deadly and abundant where the Cinchonaceæ grow most readily. In like manner, he argued that the Salicaceæ—the willows—haunt the districts where rheumatism is most likely to arise. Whether this principle will bear generalising we cannot venture to pronounce.

Salicylic acid the author regards as less safe and trustworthy in its action than salicine. The latter evidently does not owe its remedial action to a supposed conversion within the system into salicylic acid, since the administration of salicine relieves the depression and other symptoms to which salicylic acid gives rise.

New Series of Technological Handbooks.

The City and Guilds of London Institute for the Advancement of Technical Training have concluded to issue a series of text-books for the especial use of students who are about to attend their classes or prepare for examinations. Experience has convined the Council of the Institute that existing text-books are too costly, often unfitted by their style for readers who have not enjoyed the benefit of a learned education, and sometimes compiled by writers who, whilst thoroughly acquainted with the scientific principles of the different arts, were little conversant with their practical working, The series now preparing for publication will be edited by Mr. H. Trueman Wood, B.A., the Secretary to the Society of Arts, who has rendered great services to the Institute, and is thoroughly conversant with the requirements of its students. The following volumes are in preparation:—"Calico-printing, Dyeing, and Bleaching," by W. Crookes, F.R.S., &c.; "Iron and Steel Manufacture," by A. K. Huntington, F.C.S., F.I.C., Professor of Metallurgy at King's College, London; "Telegraphs and Telephones," by W. H. Preece, F.R.S., M. Inst. C.E., Electrician to the General Post Office; "Cotton Manufacture: Part I., Spinning; Part II., Weaving," by R. Marsden, Editor of the *Textile Manufacturer*; "Glass Manufacture: Crown, Sheet, and Plate Glass," by H. Chance, M.A., of the firm of Chance Bros., Birmingham; "Flint Glass," by H. Powell, B.A., of the Whitefriars Glass Works; "Optical and Lighthouse Glass, by J. Hopkinson, M.A., LL.D., F.R.S. The price of each volume will be from 3s. 6d. to 5s.

It must be distinctly understood that the manuals in question will not be "cram books." Their object will be to furnish a practical outline of the various arts, capable of standing the test of actual work, and which the student may fill up in detail from his observations in the factory. The principle of the whole series will be practice combined with theory.

CORRESPONDENCE.

TREATMENT OF HYDROFLUORIC ACID WOUNDS.

To the Editor of the Chemical News.

Sir,—In cases of injury arising from the effects of hydrofluoric acid on the skin allow me to recommend to your notice, treatment with a paste of chalk and water, *and afterwards with a mixture of chalk and olive oil.* This latter mixture allays the pain and suffering considerably, and materially hastens the healing process, as I have had occasion to witness a few days ago in reference to an assistant in my employ. He was treated thus, and now the face-wounds (which were very severe and deep) are healing over, forming a perfectly healthy skin.

If you think proper, I should like to give others whatever benefit may be derived from this experience, through the medium of your valuable journal.—I am, &c.,

A. E. Robinson, F.C.S.

CHEMICAL NOTICES FROM FOREIGN SOURCES.

Note.—All degrees of temperature are Centigrade, unless otherwise expressed.

Bulletin de la Société Chimique de Paris.
No. 5, March 5, 1881.

Observations on Pernitric Acid.—M. Berthelot.—Already noticed.

Part Played by Time in the Formation of Salts.—M. Berthelot.—It has been erroneously supposed of late that the reactions of dissolved bases and acids upon dissolved salts are not completed at once, but are, in general, capable of being prolonged for a considerable time, beyond the limit where they cease to be detected by the variations of the thermometer. The chemical equilibrium established so rapidly in dissolved saline systems seems correlated to the electrolytic conductibility which characterises these systems.

Glucoside extracted from Common Ivy.—L. Vernet.—Already noticed.

The Present State of the Rosaniline Question.—A. Rosenstiehl.—The rosaniline question has entered upon a new phase. MM. E. and O. Fischer have arrived at the conclusion that the three NH_2 groups which exist in their molecules, are, over against the carbon of the methane, in the para- position, and in reliance upon the result of direct experiment they deny the formation of rosanilines, either from a mixture of aniline and of pseudo-(ortho) toluidine or from pseudo-toluidine alone. The author takes occasion to distinguish the points upon which he agrees with MM. Fischer, and those which seem to require further examination. The rosaniline which is prepared with a mixture of aniline and ortho-toluidine is always formed in small quantity. In this reaction the aniline plays a part difficult to define, the pseudo-toluidine alone sufficing to produce the red colouring-matter. MM. Fischer consider they have proved that its formation is solely due to the presence of a little para-toluidine in the alkaloid employed. The separation of the last percentages of crystallisable toluidine is not effected without extreme difficulty. It is only by submitting the salts and the aceto-toluide to numerous re-crystallisations that a point is reached where the coloured reactions no longer appear. Such a pseudo-toluidine gives still yields of magenta varying, according to the success of the process, from 5 to 12 per cent. Admitting that the formation of this rosaniline is due to the presence of para-toluidine (at least 3 per cent would be required for such a yield), it results that the alkaloid which escapes the action of the arsenic acid (about 40 per cent) being deprived of its para-toluidine by the first operation would be afterwards unfit for the production of rosaniline. This is not the case. The alkaloid which thus escapes after being freed from small quantities of secondary amines, yields on a second treatment as much magenta as it did the first time. The author has melted pseudo-toluidine which has escaped twice, for the third time along with arsenic acid, and there has been

formed as much magenta as before. This production of colouring-matter is not due to the presence of xylidine or any other analogous body, for the alkaloid employed had distilled over within the interval of single degree Centigrade. From this series of experiments it results that if pseudo-toluidine, alone or mixed with aniline, gives small yields of magenta, these yields are not null. The author does not think that they are due to the presence of para-toluidine, since from 5 to 7 per cent of this base would be needed to produce the 15 to 20 per cent of magenta formed by repeated fusions, which is inadmissible. Either, therefore, the pseudo-toluidine must be transformed during fusion into para-toluidine, or it is capable of forming rosanilines, though to a less degree than its isomer. The author thinks that the conclusion of MM. Fischer, *i.e.*, that the methane of para-toluidine alone is capable of forming rosanilines, is not in absolute agreement with all the facts known. The properties of the different rosanilines are so parallel, as to external appearance, centesimal composition, tinctorial power, and chemical functions, that their non-identity can only be proved by studying the products of their destruction by an energetic reducing agent, hydriodic acid. M. Rosenstiehl considers those rosanilines as distinct which furnish different reduction-products, and inversely. He thus distinguishes para-rosaniline, which is decomposed into aniline and para-toluidine from the rosaniline of commerce, which splits up into aniline, para-toluidine, and pseudo-toluidine. All the conclusions obtained by this method are not, however, trustworthy. The toluene red of Coupier is an instance. Its reduction-products are identical with those of common rosaniline, *i.e.*, aniline, para-toluidine, and pseudo-toluidine. Yet it is obtained from materials free from aniline.

Reserve for Aniline-black.—Horace Kœchlin.—It is known that aniline-black is produced directly upon the fibre by printing a thickened mixture of potassium chlorate, aniline hydrochlorate, and a metallic salt. Rosenstiehl has shown that the reaction is due to the influence of the chlorine produced by the decomposition of the chloric and hydrochloric acids. MM. Storck and Strobel proposed to absorb this chlorine by means of ammonium or potassium sulphocyanide, persulphocyanogen being formed. They prove that by printing upon cotton pieces, colours either with albumen, tannin, or aluminium acetate, mixed in any case with 50 to 60 grms. sulphocyanide per litre, padding in (the materials for) aniline-black, and steaming, the black is not formed where the sulphocyanide has been applied, the latter body acting as a reserve. This process has been in successful action for two years. [A pattern is appended, showing a design with alizarin-red and rose, and Guignet's green (albumen), all mixed with sulphocyanide, then padded in aniline-black, steamed, and soaped.] Sodium hyposulphite, being an antichlore, acts also as a reserve in the dose of 400 grms. at least per litre of colour. Pyrogallic acid, 15 to 20 grms. per litre, also reserves well. The same result is obtained by a process which consists in dyeing the cotton with a manganese bronze, upon which discharge colours are printed, and the bronze is then converted into black by a passage through a salt of aniline. The goods are passed into manganese chloride, then into caustic soda, and oxidised with chloride or chrome. Upon this bronze ground are printed colours containing 400 to 500 grms. per litre of stannous chloride along with the colouring-matter and steamed. The "bistre" styles described by Persoz are thus obtained, and on padding in aniline sulphate the bronze is converted into black. A garnet is obtained in like manner by substituting naphthylamine for aniline.

No. 6, March 20, 1881.

Action of Ozone on the Germs Contained in the Air.—E. Chappuis.—The author has undertaken experiments to show that ozone has the property of destroying the germs capable of occasioning fermentations, putrefactions, and the development of mouldiness. He has filled flasks with beer yeast, and stoppered them, some with cotton which had been exposed to the action of ozone, and the remnant with cotton not so prepared. The latter became turbid in the course of a few days, whilst those stoppered with ozonised cotton remained limpid after twenty days.

Hydrochlorates of the Metallic Chlorates and the Reduction of Chlorides by Hydrogen.—M. Berthelot.—Already noticed.

Fractionated Distillation of Crude Quinoleine and the Oxidation-Products of Lutidine.—Œchsner de Coninck.—The author has obtained lutidine boiling at 165°, and the two collidines boiling at 180° and 195°, in equal quantities. The fraction containing parvoline is about the half of that containing lutidine.

Benzhydrol Acetate.—Camille Vincent.—The author has obtained this compound in crystals, fusible at 41·5°, inodorous, volatile without decomposition, about 300° yielding a colourless liquid, which on cooling solidifies into a crystalline mass.

Russian Chemical Society.—Meeting of Sept. 11/23, 1880.—M. V. J. Ragosine offers the sum of 3000 francs as a prize for the best lamp, capable of burning heavy petroleum oils, of from 0·865 to 0·875 sp. gr.

MM. Beilstein and Kourbatoff announce that they have obtained succinic acid, several liquid acids, and a nitro-product, $C_6H_{11}(NO_2)$, by the action of nitric acid upon that fraction of Caucasian petroleum boiling between 95° and 100°. Hexa-hydro-meta-xylene exists both in American and Caucasian petroleum.

M. Menschoutkine described the influence of isomerism upon the etherification of glycol.

M. Latschinoff announced that a mixture of 4 parts cholalic acid and 1 part of fatty acids is deprived of its taste.

M. Lonatschewsky-Petrounjaka gave the results of the analysis of the water of the Dnieper.

M. Elissafow communicated a memoir on the leucic acid derived from the caproic acid of fermentation.

M. Mendeleeff gave an account of the petroleum deposits of the Caucasus, which he considers the most abundant in the world. He has also explored the sulphur beds of northern Daghestan.

The Influence of Chemical Research upon the Recent Progress of Metallurgy.—V. Deshayes.—The author gives an account of the processes of Hollway and of Thomas and Gilchrist.

Contribution to the History of Sulpholeic Acid.—M. Prud'Homme.—A translation from Runge's *Farben-Chemie*, 1834, describing the preparation of sulpholeic acid and its use as a mordant in cotton dyeing.

No. 7, April 5, 1881.

The Use of the Nitrous Gases in Disinfection and Sanitation.—H. Suilliot.—The author has devised an apparatus for applying the vapours of chamber crystals in disinfection. He finds them more efficacious than ozone.

The Decomposition of Bicalcic Phosphate by Water.—C. Delattre.—On boiling bicalcic phosphate in water the liquid becomes acid, and a notable quantity of phosphoric acid passes into solution. The author has examined the nature of this decomposition, and the limits within which it takes place. The products of the reaction are mono-calcic and tri-calcic phosphates, but the decomposition never becomes complete, as these substances tend to re-combine, forming bicalcic phosphate. A cold solution of the bicalcic salt may be completely decomposed by boiling.

A New Method of Preparing Silicium Oxy-chlorides.—L. Troost and P. Hautefeuille.—The authors caused a current of chlorine mixed with half to one-fifth its volume of oxygen to act upon crystallised silicium in a glass tube.

Magnetic Oxide of Iron.—M. Berthelot.—According to the recent researches of M. Moissan, there exist several

distinct isomeric states of magnetic oxide, differing in the facility with which they are attacked by acids. The author has determined the formation-heat of the most soluble of these compounds.

The Vapour-Density of Iodine.—M. Berthelot.—The laws of Dulong and Petit, of Gay-Lussac, and of Mariotte, constitute the sole scientific base upon which rests the physical determination of molecular weights, and consequently the numeration of the atoms in present theories. In case these laws should not hold good for certain elements the physical definition of the molecular weights of their atoms would become mere conventions. The author has already shown that the experiments of MM. Kundt and Warburg, on the speed of sound in mercurial vapour, are irreconcilable with the totality of the three fundamental laws above mentioned. The experiments of M. V. Meyer, on the decrease of the gaseous density of iodine and the halogens, under constant pressure, but at temperatures widely remote from each other, are still more contrary to the admitted laws. The only law absolutely and universally applicable to the elements is the invariability of the relations of weight, according to which they combine. This notion and that of the energy brought into play in their reactions are the sole firm foundations of chemical science.

On Basic Salts and on Atacamite.—M. Berthelot.—The author considers that atacamite (copper oxychloride) does not result from the substitution of the metallic oxide for the water of hydration of cupric chloride.

The Transformation of Glucose into Dextrine.—MM. Musculus and Meyer.—The substance which the authors formerly obtained on dissolving glucose in sulphuric acid and adding alcohol to the solution presents all the properties, physical, chemical, and organoleptic of a dextrine.

A Cellular Yeast which does not Secrete an Inversive Ferment.—E. Roux.—This new yeast is incapable of setting up fermentation in a solution of cane-sugar.

The Products of Oxidation of Cholalic Acid.—P. T. Cléve.—Not adapted for useful abstraction.

Russian Chemical Society.—Session of October 2/14, 1880.—M. Mendeleeff read the conditions for the Ragosine prize.

M. W. Alexeeff described his experiments on the preparation of pure phenol. Being unable to succeed by Calvert's process he operates as follows:—He adds to commercial phenol 5 per cent of water, and after having melted it, leaves it to stand. The crystals first formed are drained, and after this operation has been repeated three or four times, the product is distilled.

M. Setchenoff gave an account of a relation which he has discovered between the variations in the composition of the air exhaled from the lungs, and the elastic force of the oxygen which it contains.

M. Czech gave in communications on the quantitative valuation of hops and on the wines of the Caucasus.

M. Potilitzine described the deposits of petroleum in the district of Kuban.

No. 8, April 20, 1881.

Certain Facts towards the History of Phosphorescence.—J. Chappuis.—Phosphorus in an atmosphere of pure oxygen is not luminous, but the introduction of a bubble of ozone sets up phosphorescence for a moment. Oil of turpentine prevents phosphorescence, and it possesses the property of destroying ozone. The illumination of phosphorus in oxygen by means of ozone is a means of detecting the presence of the latter.

Contribution to the Study of the Phospho-platinic Compounds.—E. Pomey.—Not suitable for abstraction.

Preparation of Meta-toluidine.—MM. Vienne and Steiner.—The authors have followed the process indicated by M. O. Widman in the *Berichte* of the Berlin Chemical Society, but without obtaining the compound sought.

Formation-Heat and the Combustion-Heat of the Principal Hydrocarbonic Gases and Vapours.—M. Berthelot.—Already noticed.

The Products of Oxidation of Cholalic Acid.—P. T. Cléve.—A continuation of the memoir continued in the last number.

Moniteur Scientifique, Quesneville.
March, 1881.

Process for the Total Destruction of Organic Matters in the Detection of Mineral Poisons.—Dr. A. G. Pouchet.—This process has been already described in the Chemical News.

Hydrometric Method for the Determination of Butter in Milk.—Dr. F. Soxhlet.—This process cannot be intelligibly described without the aid of the accompanying illustration.

Principal Properties of Celluloid.—F. Boekmann.—The various specimens of celluloid examined by the author do not contain true gun-cotton (hexa-nitrocellulose), but the pyroxyline of collodion, perfectly soluble at common temperatures in a mixture of ether and alcohol. Celluloid is not a true definite chemical combination.

The Petroleum Springs.—E. Poulichambaroff.—An account of the petroleum wells of the Caucasus, from an engineering point of view.

Industrial Society of Mulhouse.—Session of December 8th, 1880.—M. Vaucher presented some specimens of Japanese algæ. The best qualities of these weeds resemble what has long been sold under the name of vegetable gelatine for finishing tissues.

M. Noelting presented some notes on anthragallol, on behalf of MM. Bourcart and Georgivies, students in the laboratory of the Chemical School. If anthragallol is heated for twenty-four hours with a large excess of ammonia in a sealed tube to 150°, it forms two derivatives. The one, which constitutes three-fourths of the product, is black, amorphous, and insoluble in all solvents except sulphuric acid. The other crystallises in alcohol in long red needles, and dyes a brownish violet with iron mordants and a reddish violet with alumina, but the shades produced do not bear soaping.

MM. Noelting and Salis have obtained ortho-binitro-cresylol, which they prepared by means of ortho-toluidine, sulpho-conjugating pure ortho-cresylol, and treating the sulphacid formed with nitric acid. They are studying the ethers of the binitro-crysylols and their reduction-products.

M. Noelting presented specimens of garnet and violet colouring-matters prepared by the action of chloro-binitrated and trinitrated benzol, and of chloro-binitro-naphthaline upon rosaniline.

Session of January 12th.—The President read a paper by M. Scheurer, on the imperfection of saponification in the manufacture of soaps. He maintains that a portion both of the fatty acid and of the alkali remain uncombined, and that the latter dulls and impoverishes colours. He recommends that saponification should be effected under pressure.

MM. Noelting and Bourcart, on heating together protocatechuic and benzoic acids, have obtained a colouring-matter which dyes like alizarin, though differing from it in some features.

New Uses of Quasssia Wood.—A decoction of this wood is recommended as a preservative against the bites of mosquitoes, flies, &c., and as a valuable agent for protecting choice fruit trees, &c., from insects.

Two New (?) Colouring-Matters Drawn from the Vegetable Kingdom.—Alneine is an extract obtained from the alder, and "in general from all trees whose sap contains tannic, gallic, saccharine, or mucilaginous principles." It is recommended as superior to the best catechu. [The bark of recently-felled alders was formerly used as a dye for silks.] Ercine is said to be found in the

common heath and the branches of the poplar, and is "destined to displace the extracts of yellow woods used in dyeing."

Antizymotic Action of Benzoic Acid.—M. Schorm.—The author does not describe any experiments on the antizymotic power of this acid, but treats of its different sources, and of the impurities found in its salts.

April, 1881.

Indigotin and its Derivatives.—O. N. Witt and E. Noelting.

Researches on the Affinities of Carbon.—A. Geuther and B. Rose.

Inuline.—H. Kiliani.—These papers are taken from the *Annalen der Chemie*.

Industrial Society of Mulhouse.—At the February meeting, M. C. Koechlin stated that in making soda-soaps by the cold process with emulsive oil, the agitation should not be kept up for more than two or three minutes. It is then necessary for the soap to stand for four or five days to effect complete combination. With potash soaps prolonged agitation is requisite.

MM. Noelting and de Salis have obtained a yellow colouring-matter of the chrysoidine group by the action of diazo-benzol chloride upon para-binitro-cresylol.

MM. Noelting and Witt communicated a summary of the discovery of artificial indigotin and on its future prospects. They consider that ortho-nitro-phenyl-propiolic acid, by means of which indigo can be formed directly upon cloth, may be very serviceable, but that artificial indigotin has little or no chance of competing with the natural product.

Legal Means to be Opposed to the Adulteration of Food.—Dr. E. Vidal.—A summary of legislation on the adulteration question.

Berichte der Deutschen Chemischen Gesellschaft zu Berlin. Vol. 13, No. 11.

Certain Para-chlor-benzyl Compounds.—C. L. Jackson and J. Fleming White.

Certain Ortho-brom-benzyl Compounds.—C. L. Jackson and J. Fleming White.—These two papers were read before the American Academy of Science, respectively, March 12 and November 12, 1879.

Amido-phenyl-mercaptan, or Sulph-hydraniline.—A. W. Hofmann.—This treatise does not admit of useful abridgment.

MISCELLANEOUS.

The late M. F. Kuhlmann.—We regret to learn, by a courteous communication from the friends of the deceased, the untimely death of this distinguished technical chemist, who has been well styled the worthy successor of his illustrious father.

The Fraudulent Alteration of Cheques.—A recent occurrence is again drawing public attention to this important subject. Early in the year we made favourable mention of the patented process of Mr. A. Nesbitt, F.C.S., who prints upon the cheques grounds or designs capable of being attacked either by acids or alkalies, if such are applied with a view of effacing the writing. We learn that a further and different attempt at the solution of the problem has been made by Dr. Dupré, F.R.S., and M. Hehner, F.C.S., who we believe are chemists to the well-known cheque-printers, Messrs. Skipper and East. The patentees incorporate with the paper-pulp, or print upon the cheque, a mixture of zinc sulphide and lead carbonate. This mixture, white to begin with, retains its colour so long as kept dry, or moistened merely with water. If the cheque is treated with an acid or an alkali, the theory of the inventors is that the zinc sulphide will be decomposed, with the production, respectively, of sulphuretted hydrogen or an alkaline sulphide, and that in either case black sulphide of lead will be produced.

TO CORRESPONDENTS.

Subscriber.—Alizarin is slightly soluble in alkalies; more so in alcohol, and readily soluble in ether, wood-spirit, benzol, petroleum, turpentine, disulphide of carbon, glycerin, chloroform, and acetic acid.

NOTICE.

The Actien-Gesellschaft für Anilin-Fabrikation of Berlin, having been informed that statements are being made to their customers to the effect that the sale and use of ACID RUBINE manufactured by the said Company according to Dr. Jacobsen's Patent, No. 2828, of 11th July, 1879, would constitute an infringment of other patents, they hereby assert that there is no foundation whatever in any such statements, the use and sale of their ACID RUBINE being in no way an infringement of any other Patent.

OWENS COLLEGE, VICTORIA UNIVERSITY (MANCHESTER).

SESSION 1881-2.

I. Department of Arts and Law.
II. Department of Science and Engineering.

The Session will commence in these Departments on Tuesday, October 4th. Students will be admitted on and after Wednesday, September 28th. Candidates for admission must not be under 14 years of age, and those under 16 will be required to pass a Preliminary Examination in English, Arithmetic, and Elementary Latin, to be held on the 30th September.

III. Department of Medicine and Surgery.

The Session will commence on Saturday, October 1st. Students are required before entering to have passed one of the Preliminary Examinations prescribed by the General Medical Council.

IV. Evening Classes.

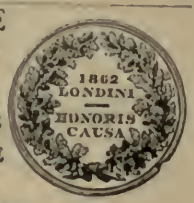
The Session will commence on Monday, October 10th. New students will be admitted on the Wednesday, Thursday, and Friday preceding, between 6.30 and 9 p.m.

Prospectuses of the several Departments may be obtained at Mr. Cornish's, Piccadilly, and at other Booksellers in Manchester, and they will be forwarded from the College on application.

J. HOLME NICHOLSON, Registrar.

SAINT PAUL'S SCHOOLS.—About Ten Scholarships will be awarded next Term.—For information, address Clerk to the Governors, Mercers' Hall, E.C.

BISULPHIDE OF CARBON
PROTOSULPHATE
RED OXIDE
OXYCHLORIDE
Sulphocyanide,



And every other Mercurial Preparation.

BISULPHITE OF LIME, TETRACHLORIDE OF CARBON.

MANUFACTURED BY

WILLIAM BAILEY & SON,

HORSELEY FIELDS CHEMICAL WORKS,
WOLVERHAMPTON.

IRISH HILL BAUXITE (Alum Clay).

The IRISH HILL MINING CO. are now, and always have been, the LARGEST PRODUCERS OF THIS CLAY, of Superior Quality, and supply the Manufacturers of Alum, Sulphate of Alumina, and Alum-Cake, of the United Kingdom, America, and the Continent, almost exclusively.

Analysis by John Pattinson, Esq.

Supplies over 90 % of the Bauxite (Alum Clay) used.

	Dried at 212° F.		
	Gertrude (extra qual.)	1st Quality.	2nd Quality.
Alumina	59·00	53·83	52·00
Peroxide of Iron	0·47	1·57	4·57
Silica	18·00	8·67	12·00
Titanic Acid		5·80	6·20
Lime, Magnesia, Potash, Soda, and Sulphuric Acid	0·23	0·83	1·14
Combined Water	22·30	29·27	24·00
	100·00	99·97	99·91

Supplies over 90 % of the Bauxite (Alum Clay) used.

Our MINES, DRYING KILNS, and GRINDING MILLS are situated very close to the Shipping Ports of BELFAST and LARNE, and adjacent to Railways running alongside both Steamers and Sailing Vessels at both Ports, from either of which shipping is abundant and cheap, therefore we can guarantee Regular Delivery as Buyers require it, and are prepared to quote prices f.o.b. c.i.f., or delivered at any Port, in Bulk or Bags, Lump or Ground.

GEO. G. BLACKWELL, *Managing Director.*

Richmond Buildings, 26, Chapel St.,
Liverpool.

Established 1798.

ROBERT DAGLISH & CO.,

ENGINEERS, BOILER AND BRIDGE MAKERS, MILLWRIGHTS,
BRASS AND IRON FOUNDERS.

Manufacturers of every description of Condensing, or High-pressure Blowing, Pumping, Rolling, Winding, and Patent Steam-engines, of any required power, for Irrigating, Draining, Mining, Rolling Mills, or Water Works purposes, and Manufacturers of every description of Chemical, Colliery, Copper Ore, Gold Mining, Glass, and Rock-salt Machinery.

Black-ash Revolving Furnaces of the Most Approved Type.
Bessemer Steel-Rail Plant.
Compressing-Engines for Collieries, Iron Works, and Weldon's Patent Bleaching-Powder Process.
Caustic, Chlorate, Decomposing, Nitre Nitro-Glycerine, Iodine Potash, Sulphur, Acid, and Oxalic Pans.
Gas Producers Patent for Heating and other Purposes.
Pyrites Burners for Irish, Norwegian, and Spanish Ores of Improved Construction.
Patent Rousing Machinery for Brewers.
Retorts, Acid, Gas, Iodine, Nitric, Nitre Nitro-Glycerine and Vitriol Refining.
Steam Superheaters improved for Oil Tar, and Resin Refining.
Steam Sulphur Melter.
Stills for Oil, Resin, and Tar.
Wheels, Bevel Mitre, and Spur Moulded on the Shortest Notice by Patent Machinery.
Makers of Mactear's Patent Carbonating Furnace, Jones and Walsh's Patent Sulphate of Soda Furnace, Parnell and Simpson's Patent Causticiser, and Kynaston's Patent Alum Plan

Lists sent on Application.

Photographs, Plans, and other information supplied on receipt of Order.

ST HELEN'S ENGINE, BOILER, AND BRIDGE WORKS AND FOUNDRY,
LANCASHIRE.

BAILEY'S FLY WHEEL STEAM PUMPS
SIMPLE & STRONG,
WITH NO MYSTERIOUS VALVES.
W.H. BAILEY & Co. HYDRAULIC ENGINEERS
ALBION WORKS, SALFORD, MANCHESTER.

These Pumps are especially adapted for MINES, QUARRIES, DYE WORKS, BREWERIES, &c.

They are so simple in construction that repairs can be done by an ordinary mechanic.

MINERAL OIL REFINERY.

TO BE SOLD, as a Going Concern, a Works producing first class Lubricating Oils for Spindles and other purposes, Paraffin Scales, &c., which have obtained a high standard in the market, and for which there exists a good selling connection in London, Manchester, and other districts. The Works adjoin the North Staffordshire Railway, with siding accommodation, and are also conveniently situated for water carriage by canal. The plant consists of steam engines, boilers, stills, agitators, modern filter-presses, double freezing machine, hydraulic press, complete laboratory, &c., and is capable of working about fifty tons of raw material per week. Satisfactory reasons given for disposing of business.—For cards to views or further particulars apply to Mr. J. R. Wain Tunstall, Staff.

THE CHEMICAL NEWS.

Vol. XLIV. No. 1135.

ESTIMATION OF POTASSIUM AS PLATINUM SALT.

By DAVID LINDO.

(Continued from p. 89.)

I will now describe fully the

Method Finally Adopted.

Diluted solutions as usual. Mixed with platinic chloride. Evaporated just to apparent dryness, then allowed to remain two or three minutes longer on water-bath.* Removed dish and drenched contents at once with 20 c.c. 98 per cent alcohol. Mixed by communicating rotatory motion; started filter-pump; placed crucible with asbestos in position; connected with pump; poured the fluid through the asbestos. Washed precipitate three or four times by decantation with a small quantity of alcohol, stirring the precipitate up with a feather.† Cleansed dish at the same time of excess of platinic chloride and sodium salt. Poured a little alcohol on precipitate in dish and set it aside. Removed crucible. Stirred up filtrate from the bottom with feather, and examined carefully. If the faintest opalescence was observed, passed filtrate again through the asbestos. Having obtained it quite bright, the filtrate was removed from the receiver. Crushed the precipitate in the dish to powder with a large glass rod, the end of which had been fused before the blowpipe. In crushing the precipitate care was taken to break down even the smallest aggregations.‡ Rinsed the rod with alcohol, and waited a minute or two for precipitate to settle somewhat. Started pump again, connected it with receiver and crucible, poured the fluid through the asbestos, and transferred precipitate with the aid of the feather to crucible. Particles of precipitate adhering to the feather were washed into the crucible with alcohol delivered from a small dropping bottle. Rinsed dish repeatedly with small quantities of alcohol, sweeping the rinsings with all remaining traces of precipitate into crucible with the feather. Filled up crucible two or three times with alcohol. These last washings were found to measure 25 to 35 c.c., and had a faint yellow tinge; they were removed from the receiver, and passed again slowly through the precipitate, filling up crucible by pouring gently down the side, allowing fluid to drain off, and pump to suck precipitate a few seconds before adding a fresh portion of fluid. Removed crucible, stirred up filtrate with feather, and examined carefully; if the slightest opalescence was noticed, the filtrate was passed again through the precipitate, when it was always obtained beautifully bright. Finished by filling crucible once with alcohol. Dried at 130° C. Although the absolute necessity for passing the last washings through the precipitate twice will rarely occur, it might always be done with advantage, as it ensures thorough washing and can never do harm.‖

The results obtained by this method (which differs very slightly from Modifications 2, 4, and 5) are given in Table IV. 4½ in. dishes were used in all these experiments. The total washings, including the drench, were found to average 60 c.c. I have given in the table the volumes of platinic chloride solution employed. Strength 1 grm. of metal to 20 c.c. The manipulations are very simple, and rapidly performed. Working with two crucibles, I have easily made six estimates in a day.

I consider these results justify the conclusion that the error in excess when this method is employed will rarely reach 0·15 of one per cent in the separation of KCl from considerable quantities of NaCl (up to 50 per cent), and seldom amount to 0·10 when smaller quantities (up to 20 per cent) of NaCl are present, the quantity of mixed chlorides taken for analysis in each case being about 0·5 grm., and the results compared with 100 parts of potassium salt taken.

The KCl taken may be stated as constituting so much per cent of the mixture of the two chlorides employed, and the KCl found may be stated in the same manner. In practice it must be reported in this way. The extent to which the errors will appear reduced by this method of comparing the results is shown in Table V.

* I have confirmed the observation of Precht that when the evaporation is carried to dryness, the chloro-platinate of sodium is more readily dissolved by the alcohol, but *prolonged* heating of the dry mass must be avoided, for the reason already given.

† A stiff feather should be selected, best from the wing of a duck. It is stripped to within 2 inches of the tip, and then carefully trimmed with a sharp pair of scissors.

‡ I suppose I need hardly point out that reducing the chloro-platinate to the state of a crystalline powder, after it has been deposited slowly by evaporation from a dilute solution, and washed by decantation, is a very different thing to precipitating it in a pulverulent state in the midst of extraneous matters from a concentrated solution.

‖ That the filtrate appears colourless is not a certain indication that the washing has been sufficient.

The highest result obtained in nine experiments published by the committee on the separation of KCl from large quantities of NaCl by Tatlock's process is 99·97 and the lowest 99·20, the average being 99·58. It should be observed, however, that in four of these experiments the quantities of material taken for analysis were measured, instead of being weighed. In four experiments with smaller quantities of NaCl the results obtained were slightly above the truth. The results obtained in five experiments made with *pure* KCl by the same process were accurate. The committee concludes from these, that the chloro-platinate is practically insoluble in a strong aqueous solution of platinic chloride, prepared, I presume, by the method described in the report.

I employed the same process, and freed the reagent of HCl, as completely as this could be done at the temperature of the water-bath. It certainly was not quite neutral, nor, I presume, was that employed by the committee. My solution contained 5 grms. of metal in 100 c.c., the committee's about 6 grms. in the same volume.

Ten experiments were made with pure KCl by Tatlock's method. In the first six I digested the precipitate in the solution containing 1 grm. platinum in 20 c.c.; in the last four, in a solution double this strength, made by concentrating the other. The manipulations will be described as briefly as possible.

Diluted solution. Mixed with excess of platinic chloride (platinum about double the weight of KCl employed). Evaporated just to dryness. Moistened with water. Evaporated to same extent again. Added 40 m.m. platinic chloride solution. Mixed well. Left to digest in the cold (in first two experiments for half an hour, in the others for an hour or an hour and a quarter), stirring occasionally with a thin glass rod. Poured the aqueous fluid through the asbestos, and washed with 10 minims more platinic solution. Let the pump suck well. *Removed aqueous filtrate from receiver*, and rinsed out latter with alcohol. Washed precipitate by decantation with 98 per cent. alcohol, and transferred it to the crucible. Washed with more alcohol. Last washings returned once through precipitates. The latter were never crushed. The results are given in Table 6. The alcoholic washings averaged about 42 c.c.

The aqueous filtrates vere very brilliant, but invariably produced marked turbidity when mixed with a sufficient volume of alcohol. After a time a small precipitate of chloro-platinate subsided, showing, of course, that a small quantity of the original precipitate had been dissolved. If the aqueous filtrate is allowed to mix with the alcoholic washings, a turbid fluid will result. If the volume of alcohol is sufficient, if time is allowed for the precipitate to form, the fluid stirred up, and returned through the bulk of the precipitate until it passes clear, accurate results may be reached at last, but this would be rather an awkward way of arriving at them.

Having found by repeated trials that it was quite unnecessary to place the crucible and precipitate in a desiccator to cool before weighing, the method adopted in all the experiments Tables 3, 4, 6, and in most of those in Table 1, was to place the crucible and contents, after removal from the air-bath, under a glass shade to cool. When quite cold, wiped the outside of the crucible with a soft dry cloth, and weighed deliberately. The weighings in experiments (further on) on the solubility of chloro-platinate, and in taking the tare of the crucibles and feltings in all experiments, were made in the same manner.

The precipitate is not in the slightest degree hygroscopic, and the constancy in weight which it exhibits is very remarkable. I have repeatedly left it (in scales or powder) in a crucible loosely covered, under a glass shade from one day to the next, and sometimes longer (the amount of moisture in the atmosphere varying considerably), and as a rule found the weight remain constant to 0·0001 grm. I have done the same with the asbestos feltings with particles of the precipitate adhering to them, and with the same result.

(To be continued.)

ON A

MODIFICATION OF THE ELECTRIC LAMP.

By M. JAMIN.

THE lamp which the author has made known is of very small bulk and can be placed either in a vacuum or in inert gases within a globe entirely closed. Among the gases which have no action on the carbons rank nitrogen, carbonic oxide, marsh-gas, and probably carbon disulphide. The majority of the others are decomposed. Common air behaves in a peculiar manner. The vessel is first filled with ruddy vapours from the combination of oxygen and nitrogen under the electric influence. This compound is soon destroyed and the gas becomes colourless again. It is evident that the hyponitric acid is decomposed to supply oxygen to the carbon. Ultimately nothing remains but nitrogen and carbonic oxide.

During this time the electric arc undergoes corresponding changes. As long as there are red vapours, it varies at once in its intensity and its colour, rising and descending along the points. As the gas becomes decolourised the flame becomes fixed and changes its colour. When all the chemical transformations are completed, it is reduced to a well-defined arc of a bluish-green, unmixed with other colours. It becomes absolutely fixed without any fading in its intensity or variation in its colour or position. In no other case has the author remarked so complete a fixity which necessarily involves the same invariability in the lustre of the points. This circumstance will probably obviate the irregularities met with in all points.

This spectrum is traversed by an incredible quantity of very fine and almost regular lines. It presents a very unequal brightness in its different parts. There are seen four great maxima, which begin abruptly on the less refrangible side with a very brilliant line, which is repeated at equal distances, growing feebler. These maxima are in the yellow-green, the green, the blue, and the violet. They alone remain visible if the light is diminished. We recognise then the spectrum of the blue flame of alcohol or of gas; that of the carburetted gases traversed by the spark of Ruhmkorff's coil, and lastly, that of the recent comet, as studied by M. Thollon: it is the electric spectrum of the vapour of carbon rendered incandescent without burning.

In the air the case is different; the carbon burns, the arc is red, and we see alternating at regular intervals the foregoing spectrum and another due to combustion and totally different; it presents a splendid assemblage of brilliant rays due to the combustion of the metals present in the carbon. It is evident that in an inert gas, we have a simple and purely electric phenomenon; that the arc is a current; that we can direct it and keep it invariably at the points by electro-magnetic action. Hence the remarkable fixity of the light. In the free air, on the contrary, the phenomenon is complex. There is still a current which we may fix, but there is also the combustion of the carbons over which we have no power, and which varies from moment to moment from the want of homogeneity in the carbons, occasioning those oscillations with which the electric light is justly charged.

If we operate in confined air, we observe at first the spectrum of combustion. As soon as the chemical transformations begin, the electric spectrum appears; the two are never seen at once, but succeed each other alternately; little by little the duration of the combustion spectrum decreases, whilst the electric spectrum is prolonged, and finally becomes persistent.

It is very remarkable that in the two cases the arc is characterised by spectra so dissimilar, and that the oscillations of the light are merely indications of the passage from one spectrum to the other.

It is still more important that as the carbons cease to burn they cease to wear out. When operating in the air with a medium current, there is expended 0·16 metre "candle" per hour, and as there are five candles of 0·32 metre per lamp, it lasts 10 hours, or one night. In the closed apparatus, as the gas is transformed, the consumption decreases rapidly, and is reduced to 0·002 metre per hour. Each candle lasts 100 hours; each lamp 800 hours, or 80 nights of 10 hours each. We may say that the electric light is rendered perpetual; that it is enough to replace the carbons when the lamp requires cleaning; that their cost is almost abolished, and their quality rendered indifferent; that all daily attention is suppressed, and then the light acquires a steadiness hitherto unknown. It must be added that the lamp becomes ignited spontaneously as soon as the current is closed.

In practice, it is requisite to reduce as much as possible the dimensions of the glass globe containing the burner; carefully to prevent the outer air from entering when the apparatus is cold, whilst allowing the interior gas to escape by means of a valve, when the lamp is in action.—*Comptes Rendus.*

NOTE CONCERNING THE ACTION OF THE ORGANIC MATTER NOT SUGAR OCCURRING IN CANE AND BEET PRODUCTS, ON ALKALINE SOLUTION OF COPPER OXIDE.

By J. H. TUCKER.

IT has been asserted that the organic matters present in impure commercial sugars and syrups have a considerable reductive effect on the copper solution employed in Fehling's method and its various modifications for the estimation of invert sugar. To avoid this supposed source of error, it has accordingly been recommended that sugar solution, before testing, should be treated with excess of basic lead acetate, filtered, the metallic salt remaining in solution precipitated with sulphurous acid, and the resulting liquid after filtering again used for the sugar determination.

In order to prove whether the organic matters acted as asserted with Fehling's solution, the author has made some experiments on the most impure saccharine material obtainable from a variety of sources. The manner of conducting the experiments was as follows:—The hot solution of the substance operated upon was treated with excess of basic lead acetate and the precipitate washed thoroughly with a large excess of hot water. To be assured that no sugar should remain in the precipitate as lead sucrate, the washed magma, after diffusion through water, was saturated with carbonic acid by allowing the gas to bubble through the diffused mass for six or eight hours, or longer. After this treatment the precipitate was again well washed, and then, after mixing with water, decomposed by sulphuretted hydrogen, the lead sulphide filtered off, and the resultant dissolved organic matters evaporated to dryness at a gentle heat and weighed. The substance thus separated was heated with Fehling's solution (Violette's), near the boiling-point, for some minutes, the resulting cuprous oxide, converted into cupric oxide, and weighed, special correction being made for the filter-ash on account of the amount of copper retained.

The results are given below; 0·100 gramme organic matter of the different origins given caused the reduction of the following amounts of copper oxide:—

West India molasses	0·027	gramme	CuO
Residual syrup from sugar-refining	0·030	,,	,,
Beet molasses	0·0124	,,	,,
Muscovado raw sugar	0·0246	,,	,,
Manilla	0·0170	,,	,,
0·100 gramme invert-sugar reduces	0·2206	,,	,,

In order to test whether any sugar might have been retained in the precipitates before decomposition with

lead, a control experiment was made by adding tartrate of soda and potash to a solution of pure invert-sugar, and precipitating with basic acetate of lead. This produced a voluminous precipitate similar to that thrown down from impure sugar solutions. The tartrate of lead was treated in the same manner as the compounds of lead and organic matter, as detailed above, and the tartaric acid obtained after the decomposition with sulphuretted hydrogen was heated with the copper solution.

0·100 gramme reduced 0·002 gramme CuO.

From this it may be concluded that little or no sugar was retained in the organic lead compounds operated upon.

As a general result of these experiments, it may be proved by calculation that organic matters in impure sugars have too small an influence upon the results of the copper test to make it necessary to remove them from the sugar solutions in most cases. When the saccharine material contains a considerable proportion of these compounds, for very accurate work such removal may be desirable.

ON THE RELATION OF MOISTURE IN AIR TO HEALTH AND COMFORT.

By ROBERT BRIGGS, C.E., Cor. Mem. Am. Inst. of Architects.

IN continuation of the paper read before the American Institute of Architects,* it is desirable to support the argument for the impracticability of attaining the full summer condition of humidity, for air in winter which has been warmed to the temperature of comfort, by more extended computations than could be presented to an audience, or brought within the scope of comprehension of the listener or the casual reader. The single example with specified relations which was taken showed, on calculation, that nearly as much heat would be expended in supplying vapour for the usual hydration of air of usual humidity and of 34° temperature (which air was heated to 70°) as was expended in heating the air itself.

The temperatures and humid condition of about 69 per cent assumed, being the averages of nature, out of doors for three warm or three cold months in the city of Philadelphia, in 1844, as reported by Prof. Bache. It occurs, accidentally, that the exact conditions of temperature and humidity chosen for an example give the ratio of heat demanded for the two purposes incident to warming air as unity, white this ratio, for other temperatures and degrees of humidity, will be found to vary materially. For the purpose of exhibiting more completely the general case, the accompanying table has been prepared to show what quantities of heat are demanded for heating, or are given out in cooling air of 70 per cent humidity, from various temperatures (from 0° to 100°) to 70°, in direct comparison to the quantities for vapourisation or condensation of water to procure the condition of 70 per cent humidity to the air of 70°. When 70° and 70 per cent humidity may be accepted as the American summer condition of comfort for the air, it being asserted that 70°, with 80 per cent, or more, of humidity, is close and enervating, while 70°, with 60 per cent, or less, of humidity, is fresh and cool, and demands heavy clothing to preserve the comfort of the individual—a proper and necessary demand in winter.

The figures relating to weights in the table (see next page) refer to 1000 cubic feet (a cube of 10 feet side) for a unit, to avoid the repetition of 0's in decimals; by multiplying any value by 7, the weights per cubic foot in grains will be found. All the weights are in pounds avoirdupois and decimals. The volumes are in cubic feet.

Columns II. and III. are derived from Regnault's data; weight of one cubic foot of dry air = 0·080728 pound = 12·387 cubic feet per pound; and rate of expansion = 0·002039 volume for each degree Fahrenheit from 32° = 0·025315 cubic foot per pound from 32°.

Column IV. is taken from Guyot's tables, Regnault's data, slightly corrected by differences.

Column V. is derived from $W = \frac{0{\cdot}622}{29{\cdot}922} \times$ value of Column III. × value of Column IV., where 0·622 = specific gravity of vapour in air of the same tension; and 29·922 = inches of mercury column which measures the tension of air in Column II.

Column VI. is obtained directly from Column V., as indicated in caption.

Column VII. is obtained by taking the difference of weight of the volume of vapour in the air from that of the air which it displaces, and deducting their difference from the respective values in Column III. The values in Column VII. agree as closely as could be expected with results in Glaisher's tables.

Column VIII. is obtained by deducting weight of vapour. Column V. from Column VII.

Column IX. is obtained by taking the ratio of quantity of dry air in the several values of Column IX., with the value at 70° (= 73·63 pounds) as a unit, and dividing by this ratio the values in Column VI.

Column X. is obtained by taking 70 per cent of $\frac{F}{29{\cdot}922}$, where F is the tension of vapour possible to exist at the given temperature, as given in Column IV., and 29·922 is the tension of the atmosphere. It should noticed that this column has its units in percentages: the first value for instance, is 11·100 of a per cent.

Column XI. is obtained by making a computation of three columns for saturated air, like VII., VIII., and IX., and thus ascertaining at what degree of temperature the values in Column IX. coincide with those in the same column for saturated air. This column closely agrees with Glaisher's, varying two degrees higher at 15° and corresponding at 80°.

Column XII. is taken from Glaisher's tables at 70 per cent., and is sufficiently exact for use.

Column XIII. is obtained by taking the difference between the quantity of vapour in air of 70° Fahrenheit, and that in the several values given in Column IX.

Column XIV. is obtained by multiplying 0·07363 pound (the quantity of dry in a cubic foot of air of 70° Fahrenheit and 70 per cent. humidity) by 0·238 (the specific heat of air), adding to this value that of the amount of the several values in Column IX. multiplied by 0·475 (the specific heat of vapour), and then multiply the sums of the above by the number of degrees from 70° which the air is to be heated or cooled.

Column XV. is obtained by multiplying the values of Column IX. (the vapour to be supplied or removed) by 1065 °= the latent heat of steam from and at 70° and dividing the result by 1000, so as to give the heat of vapourisation belonging to one cubic foot of air at 70°.

A careful study of the table, with comparisons of the values given in the several columns, will readily allow any student to find the fullest corroboration of the views expressed in the original paper; but for the convenience of the general reader it may be well to exhibit some of the results. Thus, calling attention to Column XI. it will be seen that the air of saturation at 60° becomes, by heating, that of 70° and 70 per cent humidity; showing a close approach of English and American humid conditions to the comfortable condition in either case. Again, the temperature of saturation for air of 80°, with 70 per cent humidity, is 69·5°; consequently, air of above 80° of the usual humid condition of our climate in summer, will become a mist and rain, unless its moisture be absorbed by some non heat-giving absorbent. If such air is to be reduced to the 70° standard of comfort, by means of surfaces cooled by currents of water, such surfaces must have a temperature at least below 60°, and probably 10° below that point, to abstract, by condensation, the moisture from the air. The heat demanded for condensation, therefore, will be increased some 20° below that of cooling the air, but as the latent heat of

* See CHEMICAL NEWS, vol. xliii. p. 253 *et seq.*

vapour of water is nearly constant, the difference of quantity of heat for cooling is not materially changed.

A study of the last two columns will demonstrate that as the quantity of moisture present in air falls off much more rapidly than the temperature, the quantity which is requisite to make up the moisture in air at 70° and 70 per cent humidity, from the condition at the various temperatures with the same ratio of humidity, becomes more and more nearly the same as the temperatures fall off. The great heat demanded for changing water into vapour accordingly, is nearly constant for the low temperatures, and the heat demanded for warming air gains on that for vapourisation of water; and after passing a greatest difference at between 55° and 60°, attaining an equality at about 36°, it becomes about one-half greater at 0°.

The tabular values here given have, it is thought, been first grouped together in this, or any form, and they will be found a ready and convenient basis for the application of the various meteorological conditions to warming and ventilation.

Royal Polytechnic Institution.—Mr. William Stokes is introducing some valuable new suggestions in his Lectures upon the Improvement of the Memory, and is explaining the practical application of his system for teaching the multiplication table by means of easily remembered pictures, the extended table being placed at the ready command of children and accountants by an agreeable and expeditious process.

THE SPIRAL BALANCE.

By C. F. CROSS.

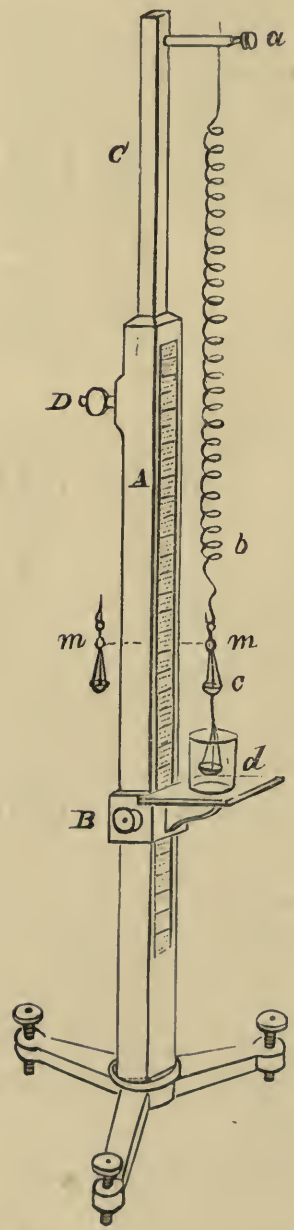
In my researches on the Rehydration of Metallic Oxides and Salts,* I was met by the necessity of frequent and rapid weighings of a substance in an atmosphere saturated with aqueous vapour. Having carefully considered the adaptability of the beam balance to this purpose and found it wanting, or rather perhaps inferior to the balance I am about to describe, my choice fell upon the latter. Jolly's Federwaage or spiral balance boasts of no new principle, but by a refined application of the well-known property of a metal spiral of undergoing elongations when stretched by weights, up to a certain limit, which are in the simple ratio of those weights, has given us an instrument whose advantages should secure its adoption in every laboratory. The balance in its original form is represented in Fig. 1. (*Sitzungsber. Baey. Akad.*, 1864, i., 162).

The spiral is fastened by means of a binding screw at *a*, and carries below, suspended at *b*, two small pans, *c* and *d*, connected as shown in the drawing. Of these, *d*, which is of glass, is kept immersed in water, and serves to steady the whole and bring the spiral, together with the index *m*, rapidly to rest after displacement, and is also used in cases of weighing beneath the surface of a liquid, as in determination of sp. gr.

* *Jour. Chem. Soc.*, 35, 796.

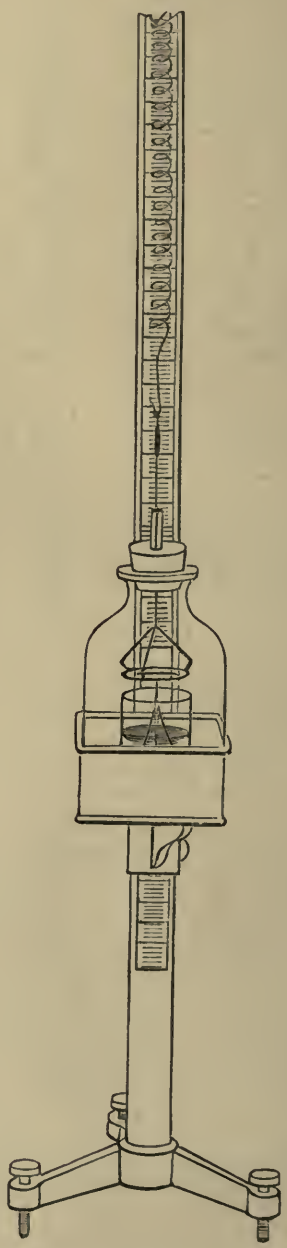
The glass containing the water in which *d* is immersed is supported on a bracket, B, which is movable over the hollow upright, A, and may be fixed at any height by means of a binding screw. C, the rod which carries the spiral, fits loosely into the hollow portion of A, and is of the same length; it can be raised out of A by any portion

FIG. 1.



of its length, and is fixed by means of the binding screw, D. The base of the instrument is a tripod, provided with levelling screws, as shown in the figure. The elongations of the spiral are observed by means of the index, *m*, which is a small bead of opaque white glass, and a mirror scale (millimetre), which is let into one of the sides of A. The position of *m* is read off with accuracy with the naked eye by bringing *m* exactly to cover its image in the mirror, which, occurring upon a graduation or between two, is easily observed to ½ m.m. Previously to making an observation it is necessary to adjust *m* by moving C, either to the zero of the scale or to a point sufficiently high to allow of the elongation to be followed on the scale.

FIG. 2.



The following examples are given by Prof. V. Jolly in his original paper:—

(*a*) *Determination of Absolute Weight.*—The spiral consisted of 36 turns of piano-wire (No. 6).

Original reading of *m*..	2·5
With a load of 1 grm...	374·7
With the object to be weighed..	213·6

The absolute weight of the latter is—

$$\frac{213{\cdot}6-2{\cdot}5}{374{\cdot}7-2{\cdot}5}=0{\cdot}5611 \text{ grm.}$$

with the probable error in the fourth place of decimals.

(β) *Determination of Specific Gravity of a Solid.*—

Original reading of *m*	64·2
Loaded with a crystal placed in pan, *c* ..	275·3
" " " " " *d* ..	220·8

$$\text{Sp. gr.} = \frac{\text{Absolute weight}}{\text{Loss of wt. in water}} = \frac{275{\cdot}3-64{\cdot}2}{275{\cdot}3-220{\cdot}8} = 3{\cdot}85,$$

with the probable error in the second decimal place.

(γ) *Determination of Specific Gravity of a Liquid.*—In this case the lower pan, *d*, is removed and replaced by a small cylinder of glass of about 1 c.c. capacity. The loss of weight experienced on submerging the latter beneath the surfaces of the respective liquids is expressed in scale divisions, as in the preceding instances, and the quotients of such numbers are the relative weights.

Since the publication of the original paper there have been certain modifications of the above details. For the plain spirals of piano-wire, spirals of brass of slightly conical form have been substituted, which although difficult to prepare, are a great improvement upon the old; and in determinations of the sp. gr. of liquids, the scale pan arrangement is altogether removed, and replaced by a simple contrivance, of which the glass cylinder and the index on the suspending wire are the chief features.

I will now give a brief account of the application of the instrument to the work of investigating the phenomenon of rehydration.

It would have been advantageous could I have kept the spirals continuously stretched by the substances under examination, but a series of blank experiments established the fact that the spirals, when stretched by a constant weight, are perpetually undergoing slight elongation. It was necessary, therefore, to adopt the discontinuous method of observation, and even then to be watchful against displacements of the o point, sometimes observable after a long series of weighings, especially in the case of new spirals.

On the strictness of the ratio of elongation to stretching weight and its comparative inalterability, I submit the following observation from amongst many similar: α, with the original spiral (of brass wire, 0·5 m.m. diameter, 111 turns wound conically); β, with the same spiral after two months constant use.

	α.		β.	
Stretching Wt. Grms.	Elongation. M.m.	Per Centigrm. M.m.	Elongation. M.m.	Per Centigrm. M.m.
0·5	46·5	0·93	47	0·93
0·55	51	"		
1·0	92	0·92	93	0·93
1·5	140	0·93	139·5	0·93
1·55	144·5	"		
2·0	186	"	186	0·93
2·5	232	"		
2·55	237	"	231	0·925
3·0	279	"	277·5	0·928
3·5	324·5	"	323·5	0·925
3·55	329·5	"		
4·0	371	"	369·5	0·93
4·5	417	"		
4·55	421·5	"		
5·0	463	"	460·5	0·924

The error, therefore, due to the imperfect elasticity of the spiral, vanishes in respect of an average weighing; that due to change of elasticity as the result of superficial oxidation and molecular change, has also proved so far barely recognisable; that due to change of temperature, as well also as the preceding, is easily controlled by readjustment of the index to zero. This was done, I need scarcely say, before each of the series of observations recorded in the above tables.

In further illustration of the reliability of the instrument I may cite an extended series of observations, ranging over a period of 282 hours, during which time no readjustment took place. This was an investigation of the hydration of potassium bichromate by the method to be presently described, and involved 75 weighings by one and the same spiral. The initial elongation due to the anhydrous salt was 89 m.m. The limit of hydration I observed to be $2K_2Cr_2O_7{\cdot}7H_2O$, and to be attained at the 147th hour of its exposure to the space saturated with aqueous vapour (temp., 18° to 20°). After this point the observations were continued to the 283rd hour, 30 weighings being made; all the readings fell between 107 and 108 m.m., showing the constancy of the hydration and of the spiral. At the 283rd hour the bell jar surrounding the salt was removed, and the result of this exposure to the ordinary air observed. The reading taken after the lapse of 1 hour (temp., 16°) was 93 m.m.; after 2 hours, 90 m.m, *i.e.*, the initial position was virtually regained. This is a typical example of the nature of my researches and the capabilities of the balance.

It only remains for me to describe the modification of the instrument necessitated by my work, and ably carried out by Herr Berberich, the Präparator of München.

The scale pan, *c*, in its original form, I found inconveniently small, and in all respects unsuitable. After several phases of development, the following modification was adopted as altogether satisfactory. A circular mica plate, extremely thin and perfectly smooth, is supported by means of a tri-radial arrangement of thin wire. This carries, below, suspended from the centre, a small disc of thin metal, the substitute for the heavy watch-glass, *d*, of the original, and, above, the index bead, *m*. Both the wire skeleton of the pan and the lower disc have a triple suspension of the finest platinum wire.* The mica plate is easily slipped into and out of the wire support, and supplies a movable scale pan of 70 m.m. diameter, amply large enough, therefore, for the purposes of my research. The whole arrangement, moreover, weighing less than 3 grms., allows some 2 to 3 grms. of substance to be placed under observation without exceeding the limits of elasticity of the spirals. Fig. 2 is a sketch of the apparatus thus modified and adapted to observations of hydration; the spiral is shown connected with the scale pan ready for observation. This completed, it is disconnected, and the terminal wire of the scale pan is placed upon a hook, which is carried below by a thimble-shaped cap; this is then placed upon the glass tube which passes through the cork of the bell-jar, and so the saturated air within is cut off from the outer air. The trough, which is carried by the bracket, is filled to the height of about 1 inch with water, and this completes the sealing of the bell-jar below.

In conclusion I would inform my fellow chemists of yet another advantage of this instrument, viz., its cheapness. In its original form it costs something under 30 shillings, and with the improvements above detailed, together with a supply of wire, &c., for repairs, it can be had, delivered free, for less than £2.†

Revision of Analytical Methods.—The "Central Society of Chemical and Commercial Industries" has nominated a commission for the revision of the analytical processes used in determining the value or the purity of commercial products.—*Moniteur Scientifique.*

---

* The construction is so simple that I am able in a few minutes to complete the mounting of the mica plate, the only materials required being copper and platinum wires, tin-foil, and bugle beads of white glass.

† Those who wish to supply themselves with this balance should apply to the maker, Herr K. Berberich, Präparator, K. Universität, München, and, if they require the improved scale pan, to say so. I believe Messrs. Woolley, of Manchester, are about to be entrusted with the agency.

CORRESPONDENCE.

THE HISTORY OF CHEMISTRY.

To the Editor of the Chemical News.

SIR,—I incline to put before chemists the following idea, and shall be glad if you think it well to assist me by inserting it in the CHEMICAL NEWS. I sent it last year to the British Association Chemical Committee, but Dr. Gilbert, who was then President, tells me that little interest was shown. My interest in the matter is not less, although my time for attention to it is so.—I am, &c.,

R. ANGUS SMITH.

MY DEAR DR. GILBERT,—As you are going to the British Association Meeting at Swansea I am inclined to put before you an idea which has long been in my mind, regarding a method of obtaining for chemists a better knowledge than they now have of the early writings of those who first made attempts to learn something of the qualities of matter at present called chemical, as differing from those usually called physical. We have fine histories of chemistry; we can scarcely wish a better than Kopp's as one, especially if supplemented by Hoefer's; but none of these volumes can give the spirit of these old writers so well as the books of the old writers themselves, whilst the number of the latter is so great that few chemists have time to read them; still many of the volumes are only in a few places attainable, and the languages are such as all chemists cannot be expected to learn, whilst in some cases the difficulty of translation is very great, and perhaps insurmountable in others.

I proposed to the late Prof. Graham that the Cavendish Society should form a small library of chemical history. I forget the exact words which I used; but the Society was not flourishing, and had given up all idea of doing more than finishing the translation of Gmelin's "Chemistry."

My proposal was and is to publish the earliest chemical works; one or two from even the earlier centuries may be found. There will be great disputes as to their value, their meaning, their age, the purity of the text, and so on; but it would be well if they were in the hands of chemists, so that each should judge for himself: one volume will hold many of the less wordy writers, and we need order, arrangement, and modern handling. Again, one part of the plan is to have printed all that obscure portion which is found in Greek manuscripts in various libraries in Europe,—writings which were more attended to by the older chemists, but which have been again brought more into notice in later years, first by Hoefer in France, and afterwards by a fuller account in a separate volume by Prof. Kopp.

At present, however, the knowledge of them is imperfect, and it would require the combined skill of many persons to bring out of them all that seems possible. The text may be obscure, but the allusions may be, and I believe they are, in some cases sufficient to lead us to the origin of the writings, or at least the source from which the writers took some of their ideas. A small expression may connect itself with a philosophy or a religion which may have been acting on the minds of these early thinkers; and a minute study of the language, and the very quality of its corruptions, may reveal much interesting knowledge.

I only hint at these things. I feel inclined to think that chemists will consider a hint quite sufficient, and that the importance of the work will be seen at once.

After these very early writings are printed, and the yet unpublished Greek ones, whether early or otherwise, a good specimen of each succeeding period would be found perhaps enough. The few Greek MSS. which I have seen were in excellent condition, but the various copies might be collated. Some may be more difficult to read.

I have failed to rouse any interest in this subject in the minds of Greek scholars. I have had the pleasure of assisting my friend Dr. Young, F.R.S., to make a collection of chemical and alchemical books printed before the year 1800, but the difficulty of obtaining many of the volumes is very great, and it is constantly increasing. Books which were sold almost as waste paper in my youth are scarcely now to be had to purchase.

But, independently of all this, no one can obtain a clear idea of the writings of the earlier gropers after chemistry without an amount of labour which is equal to the study of a separate science.

Is it not possible to make such a short collection, and to arrange it in such a manner as to enable us to learn more clearly the links of connection with other departments of human thought and history? I believe it is: I should be glad if the British Association felt interested in the subject. Editors would be sought from any country that would supply them; and without asking too much from Prof. Kopp, the great historian of chemistry, we might fairly hope that he would take an interest in the matter; he could of all men best give guidance.

Prof. Graham liked the plan, and wished me to begin; but I had not time, and it is not work for a private man or for one man.

It is true that the subject might be brought before the Chemical Society, but I am inclined to think the British Association better suited. This, however, is a point on which you will give an opinion, and I leave the matter in your hands.—I am, yours sincerely,

(Signed) R. ANGUS SMITH.

Dr. GILBERT, F.R.S.,
Pres. Chem. Sect. Brit. Assoc., Swansea.

PS. It might be well to form a committee to consider, and, if agreeable, to make preliminary arrangements. It might be called the Chemical History Committee.

To this I may add I was desirous of not allowing to die a plan formed many—perhaps twenty-five—years ago. I have never lost sight of it; and my recent enquiries into the origin of the word Chemistry have given me a further proof that the Science has been closely connected with much of the higher—that is, the philosophical and religious—thought of man, as well as with the mysticism of a portion of his history.

It must not be supposed that I expect to find any fact of any value in Chemical Research as encouraged by this Society. The value is one which arises from the assistance which is promised in making clearer to us the origin and progress of thought and of feeling in man. It is a portion of the work to be done in attaining a full history of humanity and the philosophy of man.

I cannot expect merely practical chemists to take an interest in it. I cannot expect even to find an interest in it raised in men whose sole object is to find new chemical compounds. I will even go farther, and say that I cannot expect the merely scientific chemist to interest himself in such matters; but I do expect an interest in those men who look to our Chemistry as a part only of the science with which Philosophy works, using its results as simple tools to gain her ends. I think we shall find among chemists a sufficient breadth of education and of unselfish interest to give great encouragement to the plan. I do not at all doubt this, but there may be a difficulty to find a man fitted to edit the works as they ought to be, one which is capable of finding the fulness or emptiness of the writers. For the Greek manuscripts he would require to familiarise himself for a while with the style of language not merely of the manuscripts, but of the writers of the Greek Empire. He would require to be very well versed in classic knowledge, and the more he knew of Egypt and the East the easier would be his task; but one thing also is essential,—he must not only have read the history of religions and philosophies, but he must have lived in them

sufficiently to have gained full sympathy with certain portions, and good reasons for refusing sympathy with others; he must know something of chemistry.

All these qualities are required in a perfect editor, and many classes of thinkers will be interested in such works; still it is probable that we do enough at first by publishing—perfect editing will be gradual. I cannot doubt that in time help will come in from various quarters, and a united attempt will be made to clear up the still dark portions of the history of the science, and the effects of its study in the mind of the various generations of mystic philosophers, and also artisans, through many ages back to its natural birthplace.

R. A. S.

December, 1880.

THE FRAUDULENT ALTERATION OF CHEQUES.

To the Editor of the Chemical News.

Sir,—On reading the Specification of Messrs. Dupré and Hehner's proposed safety-cheques, it at once occurred to me that they could still be altered by means of a device familiar to colour-mixers. If the cheque is first steeped in cadmium nitrate, and then treated with an acid, there is produced not the black lead sulphide, but the yellow cadmium sulphide. So small is the quantity required that the yellow tone is scarcely perceptible, and can be quite overcome by a slight blue wash. If the forger applies an alkaline solution to remove the ink, he needs merely add a certain quantity of sodium hydrocarbonate, when there will be no change of colour at all.

Even sulphuric acid at a certain strength may be safely applied; the result will be not black lead sulphide, but white lead sulphate.

I have seen these experiments actually exhibited by a chemist of my acquaintance, who assures me that he made a complete trial, three years ago, of this mixture of zinc sulphide and lead carbonate, but abandoned it as inefficient.—I am, &c.,

Calico-Printer.

DISULPHIDE OF CARBON IN COMMERCIAL BENZOL, AND ITS UTILISATION.

To the Editor of the Chemical News.

Sir,—In the Chemical News, vol. xliii., p. 148, Mr. Nickels points out a very simple method of removing carbon disulphide from commercial benzols, further suggesting that the plan indicated might be employed on the large scale for a similar purpose. Now as the question of this compound in benzols is continually cropping up and intruding itself as a fertile source of complaint, it might just be worth the while of those interested in the problem to give the matter some little consideration, especially as it is one that might be a means of considerable profit, so far at least as disulphide is concerned.

Assuming the quantity present in ordinary make of "90 per cent" to be 1½ per cent by weight, 1000 gallons would contain 132 lbs. disulphide, and which, converted into potassium xanthate, would furnish 278 lbs. of that substance. This product, now widely known as potassium ethyl-sulpho-carbonate, represents a compound that has been made and used in large quantity for the destruction of the Phylloxera, or "Vine pest," and for other forms of insect life noxious to vegetation. As such its formation and removal from commercial benzols would not only greatly improve their quality, but supply a new source of a highly valuable compound, and which could be separated and utilised at a very handsome profit on the operation.—I am, &c.,

X. X.

CHEMICAL NOTICES FROM FOREIGN SOURCES.

Note.—All degrees of temperature are Centigrade, unless otherwise expressed.

Comptes Rendus Hebdomadaires des Séances, de l'Académie des Sciences. No. 2, July 11, 1881.

Speed of Propagation of Explosive Phenomena in Gases.—M. Berthelot.—The propagation of explosive phenomena appears due to the transmission of successive shocks of the gaseous molecules brought to a more intense vibratory state by the heat liberated in their combination, and transformed at once, or more correctly speaking, after a slight relative displacement. This circumstance assimilates it to the propagation of detonations in solid matters. Consequently the speed of the propagation of explosion in a gas becomes comparable to the speed of sound, which is likewise propagated in virtue of an undulatory movement; the speed of these two movements being of the same order as the speed of the translation of gaseous molecules.

Influence of Phosphoric Acid upon the Phenomena of Vegetation.—M. de Gasparin.—The writer explains that he has been led astray by a mistranslation of the memoir of Prof. Ricciardi.

Attempt at an Explanation of the Tails of Comets.—A. Picart.—Until lately there have been admitted only three states of matter, the solid, the liquid, and the gaseous. Recently there has been added a fourth state, the radiant,—that of a gas so rarefied that each of its molecules, in its movement, according to the dynamic hypothesis of Bernouilli, experiences merely few shocks from other molecules, and describes a trajectory composed of rectilineal elements. These are the states of so-called ponderable matter, obeying the law of gravitation. But there is another matter, imponderable, diffused uniformly in the universe, forming a sort of substratum, in which ponderable matter moves, and which is perhaps the only matter, becoming transformed by the movement, and the varied grouping of its atoms of different forms into the different states of ponderable matter. When this matter is agitated in any point, this point becomes a focus of light, so that if it is in vibration for a certain extent it presents the appearance of a luminous body. It is then, as it were, a new state of matter, which may be called the luminous state, consisting in the vibratory condition of an accumulation, more or less extensive, of the ethereal matter. But the peculiarity of the ether, as of all fluid matter, is that the intermittent repulsion of its atoms produced by the shocks which they impart in their mutual movements, may be ideally expressed as a permanent repulsion between these atoms supposed to be immovable—a repulsion which varies according to a certain function of the distance, decreasing as the latter increases. This new imponderable matter possesses the characteristic property that a repulsive action is exerted between its elements. The author explains certain cosmic phenomena by means of this form of matter.

Absolute Measurement of Currents by Electrolysis.—M. Mascart.—With the number 107·93, given by M. Stas as the atomic weight of silver, and adopting the unities of Weber, the author finds the electro-chemical equivalent of water as 0·009373 milligrm. If, on the contrary, we take the practical units of the British Association, it results that a current, the electro-magnetic intensity of which is represented by 1 weber, decomposes in one second a weight of water = 0·09373 milligrm., or more generally a fraction equal to 0·010415 of the atomic weight of the body expressed in milligrms. The intensity of a current capable of producing in one second the electrolysis of one atom of a body expressed in milligrms. would be equal to 96·01 webers.

Chlorides of Iron.—P. Sabatier.—A thermo-chemical study of the two hydrated ferrous chlorides, $FeCl,2H_2O$ and $FeCl_4H_2O$; of the two hydrated ferric chlorides, $Fe_2Cl_3,5H_2O$ and $Fe_2Cl_312H_2O$; and of the hydrochlorate of ferric chloride.

Strontium and Barium Oxy-chlorides.—M. André.—A thermo-chemical study. The formation-heat of strontium oxy-chloride exceeds that of barium oxy-chloride. Hence strontia has a greater tendency to form an oxy-chloride than baryta. This tendency is still more marked in lime, which forms a more basic oxy-chloride, and with a still more considerable liberation of heat.

Experimental Researches on the Decomposition of Potassium Picrate, and an Analysis of the Products.—MM. Sarrau and Vieille.—The gases yielded by the explosion in the order of their relative quantities are carbonic oxide, nitrogen, carbonic acid, and hydrogen, with smaller quantities of hydrocyanic acid and marsh-gas.

Decipium and Samarium.—M. Delafontaine.—Inserted in full.

Action of Plumbic Peroxide on Alkaline Iodides.—A. Ditte.—Not adapted for abstraction.

Ethers of Morphine considered as a Phenol.—E. Grimaux.—The author refers to his announcement in a former memoir that morphine presents a phenolic character, and furnishes ethers of the same type as does phenol, and to his description of a methylic ether identical with codeine, and an ethylic ether, or codethyline. He has since examined the action of various alcoholic chlorides, bromides, iodides, and analogous bodies, and has discovered that the reaction is general.

Researches on the Tertiary Monamines. Action of Tri-ethylamine on the Hydracid Ethers of the Secondary and Tertiary Alcohols.—E. Reboul.—In this paper the author describes the action of tri-ethylamine upon iso-propyl iodide, and pseudo-propyl bromide.

Cyanised Camphor.—A. Haller.—This compound, in alcoholic solution, is partly resolved into hydrocyanic and camphic acids.

Composition of Sodium Hydrosulphite and Hydrosulphurous Acid.—A. Bernthsen.—The author maintains that the composition of this salt is not expressed by the formula of M. Schützenberger, $NaHSO_2$, but by $NaSO_2$, leaving the constitutional or hydration water out of sight. The anhydrous acid is S_2O_3 and not SO, as M. Schützenberger considers.

Two Facts Concerning Decilene (Essence of Turpentine.—E. J. Maumené.—Sulphuric acid can be mixed in equal weights with this hydrocarbon cooled to 0°, and set in motion in the author's apparatus ("Théorie Générale, p. 5). The mixture may be obtained colourless; if it is allowed to rise to the ordinary temperature there is no speedy action. It must be heated not merely in the water-bath, where there is no action, but in the sand-bath. After two or three hours scarcely a few grains can be collected; the rest forms a black mass, a product of polymerisation. All the results are foreseen by the author's theory. The action of mercuric chloride gives also results predicted by theory. The mixture may be heated up to 180°. If distilled in alcohol, or in a mixture of ether and alcohol, the vapours carry along with them a notable quantity of a compound, which, if introduced into the pulmonary organs would occasion incurable poisoning.

Viscose, the Gummy Substance of Viscous Fermentation.—A. Béchamp.—Viscose is a white substance, easily powdered, and has not at all the appearance of gum. It dissolves in cold water, rendering it glutinous, like gum. It does not reduce the cupro-potassic reagent. Alcohol precipitates it entirely from its solution as a mass which can be drawn into threads. Its elementary composition is: carbon, 44·97; hydrogen, 6·26. The solutions of viscose are not coloured blue or violet by iodine. Viscose yields two nitro-derivatives which are characteristic. Sulphuric acid acts upon viscose as a starch, forming dextrins and a glucose. The dextrins do not ferment under the influence of beer yeast.

Determination of Urea by means of Standard Sodium Hypobromite.—M. Quinquand.—When sodium hypobromite reacts upon urea the latter is decomposed into nitrogen and carbonic acid. Three molecules of hypobromite are necessary for the decomposition of 1 mol. of urea. Hence it is sufficient to determine the hypobromite used in order to know the quantity of urea decomposed. To determine the hypobromite we make use of an alkaline decinormal solution of sodium arsenite. On adding to such a solution a drop of sulphate of indigo, the latter takes a yellowish green colouration. On running in the hypobromite the colour decreases in intensity, and when the point of saturation is reached, it disappears entirely. The reaction may be rendered more sensitive by adding another drop of indigo before reaching the end of the reaction. To determine hypobromite used in the decomposition of the urea it is dropped into the latter till there is no longer any escape of gas; a small excess of hypobromite is added, and a small excess of a known quantity of standard sodium arsenite, an excess denoted by the decolouration of the liquid, and verified by adding one or two more drops of sulphate of indigo, which should remain yellow. Hypobromite is then again added until the indigo is decolourised; if from the total quantity of the hypobromite used we deduct the arsenite added in excess, and expressed as hypobromite, we have the quantity of hypobromite which has reacted upon the urea and consequently the latter. By repeated experiments we have demonstrated that a solution of hypobromite made in any manner does not give the theoretic figure $3NaBrO$. The solutions which give the theoretic figure are: water, 28 c.c.; soda-lye 100 c.c.; bromine, 2·8 c.c.; or soda-lye, 100; bromine, 3 c.c.

Chemical Researches on the Secretion of the Ink Pouch in the Cephalopods.—P. Girod.—The black matter purified by successive digestions in alcohol, ether, glacial acetic acid, sodium carbonate, to which a little potassa has been added, and dilute hydrochloric acid gave on ultimate analysis:—Carbon, 53·6; hydrogen, 4·04; nitrogen, 8·8, the remainder being oxygen.

Annales de la Société des Sciences Industrielles de Lyon. No. 4, 1881.

This publication persistently avoids those branches of chemical technology which are chiefly connected with the trade of Lyon. The only matter at all connected with chemistry is an anonymous report on experiments with chemical manures. The "complete manure" of M. Ville seems to have given the best results.

Bulletin de la Société d'Encouragement pour l'Industrie Nationale. May, 1881.

Report Presented by M. Vincent on Behalf of the Committee of Chemical Arts, on a Communication from the French Celluloid Company.—In this report it is admitted that celluloid must be preserved from any notable elevation of temperature, even momentary, in order to avoid serious accidents. It ought only to be stored up in limited quantity. Cold mineral acids only attack it slightly, but it is quickly destroyed by nitric and sulphuric acids if hot. It is quickly dissolved, even in the cold, in a mixture of alcohol and ether. The nitro-cellulose, which is the basis of this product, is prepared from cigarette paper.

Report Presented by M. Schützenberger on Behalf of the Committee of the Chemical Arts, on a Method Proposed by M. Maistrasse for Detecting the Impurity of Tin Used in the Manufacture of Tin Plate.—The process of M. Maistrasse is based on the difference of

aspect of the *moiré metallique*, obtained on metallic surfaces according to the degree of impurity of the tin. The only manipulation required is washing the surface with dilute hydrochloric acid, either pure or mixed with nitric acid. If lead is present in a quantity exceeding 5 per cent the appearance of the *moiré* is distinctly altered.

Journal für Praktische Chemie.
No. 7, 1881.

My Share in the Development of Theoretical Chemistry.—H. Kolbe.—The first part of a historical survey, characterised by equal ability and severity. To give any detached portions of a discussion entering so largely into personal considerations would lay us open to the charge of unfairness.

The Compounds of Certain Solid Dioxide Hydrates with Acids, Salts, and Alkalies.—J. M. van Bemmelen.—The author considers, after a series of experiments on the action of amorphous hydroxides upon solutions of salts, acids, and alkalies, that most of these phenomena can be reckoned among the formative processes of feeble chemical combinations which are in a state of dissociation, and that they depend upon chemical laws. He was first led to these researches by the results of an earlier investigation on the absorptive power of arable soil, and of silicic acid as regards solutions of alkalies and alkaline salts.

Preparation of Sulphuryl-chloride.—H. Schulze.—A preliminary communication. The author has observed that a liquid mixture of camphor and sulphurous acid yields sulphuryl-chloride on treatment with free chlorine.

Reply to a "Monitum."—F. Beilstein.—The author gives an explanation of his seeming omission of Professor Kolbe's researches in his recent work on organic chemistry.

Le Génie Civil. No. 11, April 1, 1881.

Extraction of the Precious Metals by Electro-Chemical Amalgamation.—An account of the Designolle process. The treatment of the ores consists of eight successive processes:—Fracture, grinding, suspension in water, trituration to a pulp, electro-chemical amalgamation, the filtration of the amalgam, its concentration and distillation, and lastly, the fusion of the precious metal obtained. Each of these operations is described at length and with reference to illustrations.

Moniteur Scientifique, Quesneville.
May, 1881.

Points of Contact between Art and Science in the Manufactures of Earthenware and Porcelain.—Prof. A. H. Church.—A translation of lectures delivered before the Society of Arts.

Cinchonidine and Hæmo-cinchonidine.—Dr. O. Hesse.

Cinchonine.—Dr. O. Hesse.

Determination of Cinchonidine Sulphate in Quinine Sulphate.—Dr. O. Hesse.—These three memoirs are taken from *Liebig's Annalen*.

The Question of the Rosanilines.—J. A. Pabst.—The author criticises the present theoretical views on the formation and constitution of the rosanilines, especially the views put forward by MM. Fischer. He holds that rosaniline may be a secondary triamine, possessing a hydrozoic or di-imidic structure. If leucaniline is derived from triphenyl-methan the transformation is effected by a simple molecular transposition.

Cotton-seed Oil.—M. Wideman.—Cotton-seed oil at 0° has the sp. gr. 0·9406; at 30° it is only 0·9206. With oil of vitriol it takes a violet tint, which increases on stirring. At the end of twenty-four hours the mixture becomes thick and deep brown. With sulphuric acid and potassium bichromate there is a violent reaction; sulphurous acid is evolved, and the oil takes a blood-red colour. At the end of twenty-four hours it has become a black solid mass. With caustic alkalies (sp. gr. 1·24) the oil thickens, becomes a straw-yellow, while the alkaline solution separates, and takes a deeper colour. If the mixture is stirred with a glass rod the upper layers take a blue colour, which gradually passes into a violet.

Industrial Society of Mulhouse.—Session of March 9, 1881.—MM. Pfeiffer and Jugenohl gave a description of a machine for printing several colours, upon a quite new system.

M. Benner proposes to print aniline-black along with dyed alizarin violets without fear of running or spreading. He adds to the violet mordant a large excess of acetate of lime.

Alkalimetric Determination of Sulphate of Soda in Crude Salt-cake.—Armand Bertrand.—The author dissolves 1 grm. of the sample in hot water, precipitates with an excess of baryta water, lets cool, and filters. He passes an excess of carbonic acid into the filtrate, heats to a boil, and lets cool; filters, and in the filtrate he determines the carbonate of soda (corresponding to the original sulphate of soda) with normal sulphuric acid.

Determination of Nitrates.—A. Bertrand.—The author modifies Bolley's process by determining the chlorides and deducting from the total carbonates the quantity formed by the decomposition of the chlorides.

Iodal.—A. Bertrand.—The author has obtained this compound by passing hydriodic acid into anhydrous chloral or bromal.

June, 1881.

New Mechanical Furnace for the Continuous Manufacture of Salt-cake.—James Mactear.—From the *Journal of the Society of Arts*.

Review of Chemical Researches Published in Germany.—A series of extracts from the *Berichte der Deutsch. Chem. Gesellschaft*.

Water and Air.—Lectures delivered by Dr. J. Tyndall.—A reprint from the *Journal of Science*.

Salicylic Acid.—E. Robinet.—Strictures on the report by Dr. Dubrisay, drawn up in the name of the Consulting Committee of Hygiene.

Notes by M. E. Maumené.—A reply to the criticisms of Spencer Pickering, and two notes on the action of nitric acid upon metals, and on the decomposition of mercury and silver cyanide, both already noticed.

Industrial Society of Mulhouse.—Session of the Chemical Committee, April 6th.—Certain prizes were announced, but no new results in the tinctorial arts were brought forward.

Creosote.—A. Kopp.—Not adapted for abstraction.

July, 1881.

Determination of Urea by Means of a Standard Solution of Sodium Hypobromite.—A memoir extending over upwards of thirty pages, and not capable of useful reproduction without the illustrations and the accompanying tables.

Vaccination for "Charbon."—In the course of a discussion which took place at the meeting of the Academy of Medicine, June 14, M. Pasteur announced that the operation had been performed on apes with very satisfactory results. The discussion had its usually warm character.

SILICATE OF SODA, Solid and in Solutions of Various Degrees of Concentration: the finest quality obtainable, and especially adapted for the use of Soap Makers and other Consumers.—JOSEPH CROSFIELD and SONS, Soap Makers, &c., Warrington.

London Agent—H. B. CLARKE, Great Tower Street, E.C.

IRISH HILL BAUXITE (Alum Clay).

THE IRISH HILL MINING CO. are now, and always have been, the LARGEST PRODUCERS OF THIS CLAY, of Superior Quality, and supply the Manufacturers of Alum, Sulphate of Alumina, and Alum-Cake, of the United Kingdom, America, and the Continent, almost exclusively.

ANALYSIS BY JOHN PATTINSON, ESQ.

Supplies over 90 % of the Bauxite (Alum Clay) used.

	Gertrude (extra qual.)	Dried at 212° F. 1st Quality.	2nd Quality.
Alumina	59·00	53·83	52·00
Peroxide of Iron	0·47	1·57	4·57
Silica	18·00	8·67	12·00
Titanic Acid		5·80	6·20
Lime, Magnesia, Potash, Soda, and Sulphuric Acid	0·23	0·83	1·14
Combined Water	22·30	29·27	24·00
	100·00	99·97	99·91

Supplies over 90 % of the Bauxite (Alum Clay) used.

Our MINES, DRYING KILNS, and GRINDING MILLS are situated very close to the Shipping Ports of BELFAST and LARNE, and adjacent to Railways running alongside both Steamers and Sailing Vessels at both Ports, from either of which shipping is abundant and cheap, therefore we can guarantee Regular Delivery as Buyers require it, and are prepared to quote prices f.o.b. c.i.f., or delivered at any Port, in Bulk or Bags, Lump or Ground.

NOTICE.

The Actien-Gesellschaft für Anilin-Fabrikation of Berlin, having been informed that statements are being made to their customers to the effect that the sale and use of ACID RUBINE manufactured by the said Company according to Dr. Jacobsen's Patent, No. 2828, of 11th July, 1879, would constitute an infringment of other patents, they hereby assert that there is no foundation whatever in any such statements, the use and sale of their ACID RUBINE being in no way an infringement of any other Patent.

THE CHEMICAL NEWS.

Vol. XLIV. No. 1136.

BRITISH ASSOCIATION FOR THE ADVANCEMENT OF SCIENCE.

York Meeting, August 31, 1881.

INAUGURAL ADDRESS OF THE PRESIDENT,

Sir John Lubbock, Bart., M.P., F.R.S., D.C.L., LL.D., Pres. Linn. Soc.

In the name of the British Association, which for the time I very unworthily represent, I beg to tender to you, my Lord Mayor, and through you to the City of York, our cordial thanks for your hospitable invitation and hearty welcome.

We feel, indeed, that in coming to York we are coming home: gratefully as we acknowledge and much as we appreciate the kindness we have experienced elsewhere, and the friendly relations which exist between this Association and most—I might even say all—our great cities, yet Sir R. Murchison truly observed at the close of our first meeting in 1831, that to York, "as the cradle of the Association, we shall ever look back with gratitude; and whether we meet hereafter on the banks of the Isis, the Cam, or the Forth, to this spot we shall still fondly revert." Indeed, it would have been a matter of much regret to all of us if we had not been able on this, our fiftieth anniversary, to hold our meeting in our mother city.

My Lord Mayor, before going further, I must express my regret, especially when I call to mind the illustrious men who have preceded me in this chair, that it has not fallen to one of my eminent friends around me to preside on this auspicious occasion. Conscious, however, as I am of my own deficiencies, I feel that I must not waste time in dwelling on them, more especially as in doing so I should but give them greater prominence. I will, therefore, only make one earnest appeal to your kind indulgence.

The connection of the British Association with the City of York does not depend merely on the fact that our first meeting was held here. It originated in a letter addressed by Sir D. Brewster to Professor Phillips, as Secretary to your York Philosophical Society, by whom the idea was warmly taken up. The first meeting was held on September 26, 1831, the chair being taken by Lord Milton, who delivered an address.

Of those who organised and took part in that first meeting few, alas! remain. Brewster and Phillips, Harcourt and Lord Milton, Lyell and Murchison, all have passed away, but their memories live among us. Some few, indeed, of those present at our first meeting we rejoice to see here to-day, including one of the five members constituting the original organising Committee, our venerable Vice-President, Archdeacon Creyke.

The constitution and objects of the Association were so ably described by Mr. Spottiswoode, at Dublin, and are so well known to you, that I will not dwell on them this evening. The excellent President of the Royal Society, in the same address, suggested that the past history of the Association would form an appropriate theme for the present meeting. The history of the Association, however, is really the history of science, and I long shrunk from the attempt to give even a panoramic survey of a subject so vast and so difficult; nor should I have ventured to make any such attempt, but that I knew I could rely on the assistance of friends in every department of science.

Certainly, however, this is an opportunity on which it may be well for us to consider what have been the principal scientific results of the last half century, dwelling especially on those with which this Association is more directly concerned, either as being the work of our own members, or as having been made known at our meetings. It is of course impossible within the limits of a single address to do more than allude to a few of these, and that very briefly. In dealing with so large a subject I first hoped that I might take our annual volumes as a text-book. This, however, I at once found to be quite impossible. For instance, the first volume commences with a Report on Astronomy by Sir G. Airy: I may be pardoned, I trust, for expressing my pleasure at finding that the second was one by my father, on the Tides, prepared like the preceding at the request of the Council; then comes one on Meteorology by Forbes, Radiant Heat by Baden Powell, Optics by Brewster, Mineralogy by Whewell, and so on. My best course will therefore be to take our different Sections one by one, and endeavour to bring before you a few of the principal results which have been obtained in each department.

The Biological Section is that with which I have been most intimately associated, and with which it is, perhaps, natural that I should begin.

Fifty years ago it was the general opinion that animals and plants came into existence just as we now see them. We took pleasure in their beauty; their adaptation to their habits and mode of life in many cases could not be overlooked or misunderstood. Nevertheless, the book of Nature was like some richly illuminated missal, written in an unknown tongue; the graceful forms of the letters, the beauty of the colouring, excited our wonder and admiration; but of the true meaning little was known to us; indeed, we scarcely realised that there was any meaning to decipher. Now glimpses of the truth are gradually revealing themselves; we perceive that there is a reason—and in many cases we know what that reason is—for every difference in form, in size, and in colour; for every bone and every feather, almost for every hair. Moreover, each problem which is solved opens out vistas, as it were, of others perhaps even more interesting. With this great change the name of our illustrious countryman, Darwin, is intimately associated, and the year 1859 will always be memorable in science as having produced his great work on the "Origin of Species." In the previous year he and Wallace had published short papers, in which they clearly state the theory of natural selection, at which they had simultaneously and independently arrived. We cannot wonder that Darwin's views should have at first excited great opposition. Nevertheless from the first they met with powerful support, especially, in this country, from Hooker, Huxley, and Herbert Spencer. The theory is based on four axioms:—

"1. That no two animals or plants in nature are identical in all respects.

"2. That the offspring tend to inherit the peculiarities of their parents.

"3. That of those which come into existence, only a small number reach maturity.

"4. That those which are, on the whole, best adapted to the circumstances in which they are placed are most likely to leave descendants."

Darwin commenced his work by discussing the causes and extent of variability in animals, and the origin of domestic varieties: he showed the impossibility of distinguishing between varieties and species, and pointed out the wide differences which man has produced in some cases—as, for instance, in our domestic pigeons, all unquestionably descended from a common stock. He dwelt on the struggle for existence (which has since become a household world), and which, inevitably resulting in the survival of the fittest, tends gradually to adapt any race of animals to the conditions in which it occurs.

While thus, however, showing the great importance of natural selection, he attributed it to no exclusive influence,

but fully admitted that other causes—the use and disuse of organs, sexual selection, &c.—had to be taken into consideration. Passing on to the difficulties of his theory, he accounted for the absence of intermediate varieties between species, to a great extent, by the imperfection of the geological record.

But if the geological record be imperfect, it is still very instructive. The further palæontology has progressed the more it has tended to fill up the gaps between existing groups and species, while the careful study of living forms has brought into prominence the variations dependent on food, climate, habitat, and other conditions, and shown that many species long supposed to be absolutely distinct are so closely linked together by intermediate forms that it is difficult to draw a satisfactory line between them.

The principles of classification point also in the same direction, and are based more and more on the theory of descent. Biologists endeavour to arrange animals on what is called the "natural" system. No one now places whales among fish, bats among birds, or shrews with mice, notwithstanding their external similarity; and Darwin maintained that "community of descent was the hidden bond which naturalists had been unconsciously seeking." How else, indeed, can we explain the fact that the framework of bones is so similar in the arm of a man, the wing of a bat, the fore-leg of a horse, and the fin of a porpoise —that the neck of a giraffe and that of an elephant contain the same number of vertebræ?

Strong evidence is, moreover, afforded by embryology; by the presence of rudimentary organs and transient characters, as, for instance, the existence in the calf of certain teeth which never cut the gums, the shrivelled and useless wings of some beetles, the presence of a series of arteries in the embryos of the higher Vertebrata exactly similar to those which supply the gills in fishes, even the spots on the young blackbird, the stripes on the lion's cub; these, and innumerable other facts of the same character, appear to be incompatible with the idea that each species was specially and independently created: and to prove, on the contrary, that the embryonic stages of species show us more or less clearly the structure of their ancestors.

Darwin's views, however, are still much misunderstood. I believe there are thousands who consider that according to his theory a sheep might turn into a cow, or a zebra into a horse. No one would more confidently withstand any such hypothesis, his view being, of course, not that the one could be changed into the other, but that both are descended from one common ancestor.

No one, at any rate, will question the immense impulse which Darwin has given to the study of natural history, the number of new views he has opened up, and the additional interest which he has aroused in, and contributed to, Biology. When we were young we knew that the leopard had spots, the tiger was striped, and the lion tawny; but why this was so it did not occur to us to ask; and if we had asked no one would have answered. Now we see at a glance that the stripes of the tiger have reference to its life among jungle-grasses; the lion is sandy, like the desert; while the markings of the leopard resemble spots of sunshine glancing through the leaves.

The science of embryology may almost be said to have been created in the last half century. Fifty years ago it was a very general opinion that animals which are unlike when mature were dissimilar from the beginning. It is to Von Baer, the discoverer of the mammalian ovum, that we owe the great generalisation that the development of the egg is in the main a progress from the general to the special,—in fact, that embryology is the key to the laws of animal development.

Thus the young of existing species resemble in many cases the mature forms which flourished in ancient times. Huxley has traced up the genealogy of the horse to the Miocene Anchitherium. In the same way Gaudry has called attention to the fact that just as the individual stag gradually acquires more and more complex antlers: having at first only a single prong, in the next year two points, in the following three, and so on; so the genus, as a whole, in Middle Miocene times, had two pronged horns; in the Upper Miocene, three; and that it is not till the Upper Pliocene that we find any species with the magnificent antlers of our modern deer. It seems to be now generally admitted that birds have come down to us through the Dinosaurians, and, as Huxley has shown, the profound break once supposed to exist between birds and reptiles has been bridged over by the discovery of reptilian birds and bird-like reptiles; so that, in fact, birds are modified reptiles. Again, the remarkable genus Peripatus, so well studied by Moseley, tends to connect the annulose and articulate types.

Again, the structural resemblances between Amphioxus and the Ascidians had been pointed out by Goodsir; and Kowalevsky in 1866 showed that these were not mere analogies, but indicated a real affinity. These observations, in the words of Allen Thomson, "have produced a change little short of revolutionary in embryological and zoological views, leading as they do to the support of the hypothesis that the Ascidian is an earlier stage in the phylogenetic history of the mammal and other vertebrates."

The larval forms which occur in so many groups, and of which the Insects afford us the most familiar examples, are, in the words of Quatrefages, embryos, which lead an independent life. In such cases as these external conditions act upon the larvæ as they do upon the mature form; hence we have two classes of changes, adaptional or adaptive, and developmental. These and many other facts must be taken into consideration; nevertheless naturalists are now generally agreed that embryological characters are of high value as guides in classification, and it may, I think, be regarded as well established that, just as the contents and sequence of rocks teach us the past history of the earth, so is the gradual development of the species indicated by the structure of the embryo and its developmental changes.

When the supporters of Darwin are told that his theory is incredible, they may fairly ask why it is impossible that a species in the course of hundreds of thousands of years should have passed through changes which occupy only a few day or weeks in the life history of each individual?

The phenomena of yolk-segmentation, first observed by Prevost and Dumas, are now known to be in some form or other invariably the precursors of embryonic development; while they reproduce, as the first stages in the formation of the higher animals, the main and essential features in the life-history of the lowest forms. The "blastoderm," as it is called, or first germ of embryo in the egg, divides itself into two layers, corresponding, as Huxley has shown, to the two layers into which the body of the Cœlenterata may be divided. Not only so, but most embyros at an early stage of development have the form of a cup, the walls of which are formed by the two layers of the blastoderm. Kowalevsky was the first to show the prevalence of this embryonic form, and subsequently Lankester and Hæckel put forward the hypothesis that it was the embryonic repetition of an ancestral type, from which all the higher forms are descended. The cavity of the cup is supposed to be the stomach of this simple organism, and the opening of the cup the mouth. The inner layer of the wall of the cup constitutes the digestive membrane, and the outer the skin. To this form Hæckel gave the name Gastræa. It is, perhaps, doubtful whether the theory of Lankester and Hæckel can be accepted in precisely the form they propounded it; but it has had an important influence on the progress of embryology. I cannot quit the science of embryology without alluding to the very admirable work on "Comparative Embryology" by our new General Secretary, Mr. Balfour, and also the "Elements of Embryology" which he had previously published in conjunction with Dr. M. Foster.

In 1842, Steenstrup published his celebrated work on the "Alternation of Generations," in which he showed that many species are represented by two perfectly distinct types or broods, differing in form, structure, and

habits; that in one of them males are entirely wanting, and that the reproduction is effected by fission, or by buds, which, however, are in some cases structurally indistinguishable from eggs. Steenstrup's illustrations were mainly taken from marine or parasitic species, of very great interest, but not generally familiar, excepting to naturalists. It has since been shown that the common Cynips or Gallfly is also a case in point. It had long been known that in some genera belonging to this group, males are entirely wanting, and it has now been shown by Bassett, and more thoroughly by Adler, that some of these species are double-brooded; the two broods having been considered as distinct genera.

Thus an insect known as *Neuroterus lenticularis*, of which females only occur, produces the familiar oak-spangles so common on the under sides of oak leaves, from which emerge, not *Neuroterus lenticularis*, but an insect hitherto considered as a distinct species, belonging even to a different genus, *Spathegaster baccarum*. In *Spathegaster* both sexes occur; they produce the currant-like galls found on oaks, and from these galls *Neuroterus* is again developed. So, also, the King Charles oak apples produce a species known as *Teras terminalis*, which descends to the ground, and makes small galls on the roots of the oak. From these emerge an insect known as *Biorhiza aptera*, which again gives rise to the common oak apple.

It might seem that such enquiries as these could hardly have any practical bearing. Yet it is not improbable that they may lead to very important results. For instance, it would appear that the fluke which produces the rot in sheep, passes one phase of its existence in the black slug, and we are not without hopes that the researches, in which our lamented friend Prof. Rolleston was engaged at the time of his death, which we all so much deplore, will lead, if not to the extirpation, at any rate to the diminution, of a pest from which our farmers have so grievously suffered.

It was in the year 1839 that Schwann and Schleiden demonstrated the intimate relation in which animals and plants stand to each other, by showing the identity of the laws of development of the elementary parts in the two kingdoms of organic nature.

As regards descriptive biology, by far the greater number of species now recorded have been named and described within the last half century.

Dr. Günther has been good enough to make a calculation for me. The numbers, of course, are only approximate, but it appears that while the total number of animals described up to 1831 was not more than 70,000, the number now is at least 320,000.

Lastly, to show how large a field still remains for exploration, I may add that Mr. Waterhouse estimates that the British Museum alone contains not fewer than 12,000 species of insects which have not yet been described, while our collections do not probably contain anything like one-half of those actually in existence. Further than this, the anatomy and habits even of those which have been described offer an inexhaustible field for research, and it is not going too far to say that there is not a single species which would not amply repay the devotion of a lifetime.

One remarkable feature in the modern progress of biological science has been the application of improved methods of observation and experiment; and the employment in physiological research of the exact measurements employed by the experimental physicist. Our microscopes have been greatly improved. The use of chemical reagents in microscopical investigations has proved most instructive, and another very important method of investigation has been the power of obtaining very thin slices by imbedding the object to be examined in paraffin or some other soft substance. In this manner we can now obtain, say, fifty separate sections of the egg of a beetle, or the brain of a bee.

At the close of the last century, Sprengel published a most suggestive work on flowers, in which he pointed out the curious relation existing between these and insects, and showed that the latter carry the pollen from flower to flower. His observations, however, attracted little notice until Darwin called attention to the subject in 1862. It had long been known that the cowslip and primrose exist under two forms, about equally numerous, and differing from one another in the arrangements of their stamens and pistils; the one form having the stamens on the summit of the flower and the stigma half-way down; while in the other the relative positions are reversed, the stigma being at the summit of the tube and the stamens half-way down. This difference had, however, been regarded as a case of mere variability; but Darwin showed it to be a beautiful provision, the result of which is that insects fertilise each flower with pollen brought from a different plant; and he proved that flowers fertilised with pollen from the other form yield more seed than if fertilised with pollen of the same form, even if taken from a different plant.

Attention having been thus directed to the question an astonishing variety of most beautiful contrivances have been observed and described by many botanists, especially Hooker, Axel, Delpino, Hildebrand, Bennett, Fritz Müller, and, above all, Hermann Müller, and Darwin himself. The general result is that to insects, and especially to bees, we owe the beauty of our gardens, the sweetness of our fields. To their beneficent, though unconscious action, flowers owe their scent and colour, their honey—nay, in many cases, even their form. Their present shape and varied arrangements, their brilliant colours, their honey, and their sweet scent are all due to the selection exercised by insects.

In these cases the relation between plants and insects is one of mutual advantage. In many species, however, plants present us with complex arrangements adapted to protect them from insects; such, for instance, are in many cases the resinous glands which render leaves unpalatable; the thickets of hairs and other precautions which prevent flowers from being robbed of their honey by ants. Again, more than a century ago, our countryman, Ellis, described an American plant, Dionæa, in which the leaves are somewhat concave, with long lateral spines and a joint in the middle; close up with a jerk, like a rat-trap, the moment any unwary insect alights on them. The plant, in fact, actually captures and devours insects. This observation also remained as an isolated fact until within the last few years, when Darwin, Hooker, and others have shown that many other species have curious and very varied contrivances for supplying themselves with animal food.

Some of the most fascinating branches of botany—morphology, histology, and physiology—scarcely existed before 1830. In the two former branches the discoveries of von Mohl are pre-eminent. He first observed cell-division in 1835, and detected the presence of starch in chlorophyll-corpuscles in 1837, while he first described protoplasm, now so familiar to us, at least by name, in 1846. In the same year Amici discovered the existence of the embryonic vesicle in the embryo sac, which develops into the embryo when fertilised by the entrance of the pollen tube into the micropyle. The existence of sexual reproduction in the lower plants was doubtful, or at least doubted by some eminent authorities, as recently as 1853, when the actual process of fertilisation in the common bladderwrack of our shores was observed by Thuret, while the reproduction of the larger fungi was first worked out by De Bary in 1863.

As regards lichens, Schwendener proposed, in 1869, the startling theory, now however accepted by some of the highest authorities, that lichens are not autonomous organisms, but commensal associations of a fungus parasitic on an alga. With reference to the higher Cryptogams it is hardly too much to say that the whole of our exact knowledge of their life-history has been obtained during the last half-century. Thus, in the case of ferns the male organs, or antheridia, were first discovered by Nägeli in 1844, and the archegonia, or female organs, by Suminski

in 1848. The early stages in the development of mosses were worked out by Valentine in 1833. Lastly, the principle of Alternation of Generations in plants was discovered by Hofmeister. This eminent naturalist also, in 1851-4, pointed out the homologies of the reproductive processes in mosses, vascular cryptogams, gymnosperms, and angiosperms.

Nothing could have appeared less likely than that researches into the theory of spontaneous generation should have led to practical improvements in medical science. Yet such has been the case. Only a few years ago Bacteria seemed mere scientific curiosities. It had long been known that an infusion—say, of hay—would, if exposed to the atmosphere, be found, after a certain time, to teem with living forms. Even those few who still believe that life would be spontaneously generated in such an infusion, will admit that these minute organisms are, if not entirely, yet mainly, derived from germs floating in our atmosphere; and if precautions are taken to exclude such germs, as in the careful experiments especially of Pasteur, Tyndall, and Roberts, everyone will grant that in ninety-nine cases out of a hundred no such development of life will take place.

These facts have led to most important results in Surgery. One reason why compound fractures are so dangerous, is because, the skin being broken, the air obtains access to the wound, bringing with it innumerable germs, which too often set up putrefying action. Lister first made a practical application of these observations. He set himself to find some substance capable of killing the germs without being itself too potent a caustic, and he found that dilute carbolic acid fulfilled these conditions. This discovery has enabled many operations to be performed which would previously have been almost hopeless.

The same idea seems destined to prove as useful in Medicine as in Surgery. There is great reason to suppose that many diseases, especially those of a zymotic character, have their origin in the germs of special organisms. We know that fevers run a certain definite course. The parasitic organisms are at first few, but gradually multiply at the expense of the patient, and then die out again. Indeed, it seems to be thoroughly established that many diseases are due to the excessive multiplication of microscopic organisms, and we are not without hope that means will be discovered by which, without injury to the patient, these terrible, though minute, enemies may be destroyed, and the disease thus stayed. The interesting researches of Burdon Sanderson, Greenfield, Koch, Pasteur, Toussaint, and others, seem to justify the hope that we may be able to modify these and other germs, and then by appropriate inoculation to protect ourselves against fever and other acute diseases.

The history of Anæsthetics is a most remarkable illustration how long we may be on the very verge of a most important discovery. Ether, which, as we all know, produces perfect insensibility to pain, was discovered as long ago as 1540. The anæsthetic property of nitrous oxide, now so extensively used, was observed in 1800 by Sir H. Davy, who actually experimented on himself, and had one of his teeth painlessly extracted when under its influence. He even suggests that "as nitrous oxide gas seems capable of destroying pain, it could probably be used with advantage in surgical operations." Nay, this property of nitrous oxide was habitually explained and illustrated in the chemical lectures given in hospitals, and yet for fifty years the gas was never used in actual operations.

Few branches of science have made more rapid progress in the last half-century than that which deals with the ancient condition of man. When our Association was founded it was generally considered that the human race suddenly appeared on the scene, about 6000 years ago, after the disappearance of the extinct mammalia, and when Europe, both as regards physical conditions and the other animals by which it was inhabited, was pretty much in the same condition as in the period covered by Greek and Roman history. Since then the persevering researches of Layard, Rawlinson, Botta, and others have made known to us, not only the statutes and palaces of the ancient Assyrian monarchs, but even their libraries; the cuneiform characters have been deciphered, and we can not only see, but read in the British Museum, the actual contemporary records, on burnt clay cylinders, of the events recorded in the historical books of the Old Testament and in the pages of Herodotus. The researches in Egypt also seem to have satisfactorily established the fact that the pyramids themselves are at least 6000 years old, while it is obvious that the Assyrian and Egyptian monarchies cannot suddenly have attained to the wealth and power, the state of social organisation, and progress in the arts, of which we have before us, preserved by the sand of the desert from the ravages of man, such wonderful proofs.

In Europe, the writings of the earliest historians and poets indicated that, before iron came into general use, there was a time when bronze was the ordinary material of weapons, axes, and other cutting implements, and though it seemed *à priori* improbable that a compound of copper and tin should have preceded the simple metal iron, nevertheless the researches of archæologists have shown that there really was in Europe a "Bronze Age," which at the dawn of history was just giving way to that of "Iron."

The contents of ancient graves, buried in many cases so that their owner might carry some at least of his wealth with him to the world of spirits, have proved very instructive. More especially the results obtained by Nilsson in Scandinavia, by Hoare and Borlase, Bateman and Greenwell, in our own country, and the contents of the rich cemetery at Hallstadt, left no room for doubt as to the existence of a Bronze Age; but we get a completer idea of the condition of Man at this period from the Swiss lake-villages, first made known to us by Keller, and subsequently studied by Morlot, Troyon, Desor, Rütimeyer, Heer, and other Swiss archæologists. Along the shallow edges of the Swiss lakes there flourished, once upon a time, many populous villages or towns, built on platforms supported by piles, exactly as many Malayan villages are now. Under these circumstances innumerable objects were one by one dropped into the water; sometimes whole villages were burnt, and their contents submerged; and thus we have been able to recover, from the waters of oblivion in which they had rested for more than 2000 years, not only the arms and tools of this ancient people, the bones of their animals, their pottery and their ornaments, but the stuffs they wore, the grain they had stored up for future use, even fruits and cakes of bread.

But this bronze-using people were not the earliest occupants of Europe. The contents of ancient tombs give evidence of a time when metal was unknown. This also was confirmed by the evidence then unexpectedly received from the Swiss lakes. By the side of the bronze-age villages were others, not less extensive, in which, while implements of stone and bone were discovered literally by thousands, not a trace of metal was met with. The shell-mounds or refuse-heaps accumulated by the ancient fishermen along the shores of Denmark, fully confirmed the existence of a "Stone Age."

No bones of the reindeer, no fragment of any of the extinct mammalia have been found in any of the Swiss lake villages or in any of the thousands of tumuli which have been opened in our own country or in Central and Southern Europe. Yet the contents of caves and of river-gravels afford abundant evidence that there was a time when the mammoth and rhinoceros, the musk-ox and reindeer, the cave lion and hyena, the great bear and the gigantic Irish elk wandered in our woods and valleys, and the hippopotamus floated in our rivers; when England and France were united, and the Thames and the Rhine had a common estuary. This was long supposed to be before the advent of man. At length, however, the discoveries of Boucher de Perthes in the valley of the Somme,

supported as they are by the researches of many Continental naturalists, and in our own country of MacEnery and Godwin-Austen, Prestwich and Lyell, Vivian and Pengelly, Christy, Evans, and many more, have proved that man formed a humble part of this strange assembly.

Nay, even at this early period there were at least two distinct races of men in Europe; one of them—as Boyd Dawkins has pointed out—closely resembling the modern Esquimaux in form, in his weapons and implements, probably in his clothing, as well as in so many of the animals with which he was associated.

At this stage Man appears to have been ignorant of pottery, to have had no knowledge of agriculture, no domestic animals, except perhaps the dog. His weapons were the axe, the spear, and the javelin; I do not believe he knew the use of the bow, though he was probably acquainted with the lance. He was, of course, ignorant of metal, and his stone implements, though skilfully formed, were of quite different shapes from those of the second Stone Age, and were never ground. This earlier Stone period, when man co-existed with these extinct mammalia, is known as the Palæolithic, or Early Stone Age, in opposition to the Neolithic, or Newer Stone Age.

The remains of the mammalia which co-existed with man in pre-historic times have been most carefully studied by Owen, Lartet, Rütimeyer, Falconer, Busk, Boyd-Dawkins, and others. The presence of the mammoth, the reindeer, and especially of the musk-ox, indicates a severe, not to say an arctic, climate, the existence of which, moreover, was proved by other considerations; while, on the contrary, the hippopotamus requires considerable warmth. How, then, is this association to be explained?

While the climate of the globe is, no doubt, much affected by geographical conditions, the cold of the glacial period was, I believe, mainly due to the excentricity of the earth's orbit, combined with the obliquity of the ecliptic. The result of the latter condition is a period of 21,000 years, during one-half of which the northern hemisphere is warmer than the southern, while during the other 10,500 years the reverse is the case. At present we are in the former phase, and there is, we know, a vast accumulation of ice at the south pole. But when the earth's orbit is nearly circular, as it is at present, the difference between the two hemispheres is not very great; on the contrary, as the excentricity of the orbit increases the contrast between them increases also. This excentricity is continually oscillating within certain limits, which Croll and subsequently Stone have calculated out for the last million years. At present the excentricity is 0·016, and the mean temperature of the coldest month in London is about 40°. Such has been the state of things for nearly 100,000 years; but before that there was a period, beginning 300,000 years ago, when the excentricity of the orbit varied from 0·26 to 0·57. The result of this would be greatly to increase the effect due to the obliquity of the orbit; at certain periods the climate would be much warmer than at present, while at others the number of days in winter would be twenty more, and of summer twenty less than now, while the mean temperature of the coldest month would be lowered 20°. We thus get something like a date for the last glacial epoch, and we see that it was not simply a period of cold but rather one of extremes, each beat of the pendulum of temperature lasting for no less than 21,000 years. This explains the fact that, as Morlot showed in 1854, the glacial deposits of Switzerland, and, as we now know, those of Scotland, are not a single uniform layer, but a succession of strata indicating very different conditions. I agree also with Croll and Geikie in thinking that these considerations explain the apparent anomaly of the co-existence in the same gravels of arctic and tropical animals; the former having lived in the cold, while the latter flourished in the hot, periods.

It is, I think, now well established that man inhabited Europe during the milder periods of the glacial epoch. Some high authorities, indeed, consider that we have evidence of his presence in pre-glacial and even in Miocene times, but I confess that I am not satisfied on this point. Even the more recent period carries back the record of man's existence to a distance so great as altogether to change our views of ancient history.

Nor is it only as regards the antiquity and material condition of man in pre-historic times that great progress has been made. If time permitted I should have been glad to have dwelt on the origin and development of language, of custom, and of law. On all of these the comparison of the various lower races still inhabiting so large a portion of the earth's surface, has thrown much light; while even in the most cultivated nations we find survivals, curious fancies, and lingering ideas; the fossil remains as it were of former customs and religions embedded in our modern civilisation, like the relics of extinct animals in the crust of the earth.

In geology the formation of our association coincided with the appearance of Lyell's "Principles of Geology," the first volume of which was published in 1830 and the second in 1832. At that time the received opinion was that the phenomena of Geology could only be explained by violent periodical convulsions, and a high intensity of terrestrial energy culminating in repeated catastrophes. Hutton and Playfair had indeed maintained that such causes as those now in operation would, if only time enough were allowed, account for the geological structure of the earth; nevertheless the opposite view generally prevailed, until Lyell, with rare sagacity and great eloquence, with a wealth of illustration and most powerful reasoning, convinced geologists that the forces now in action are powerful enough, if only time be given, to produce results quite as stupendous as those which Science records.

As regards stratigraphical geology, at the time of the first meeting of the British Association at York, the strata between the carboniferous limestone and the chalk had been mainly reduced to order and classified, chiefly through the labours of William Smith. But the classification of all the strata lying above the chalk and below the carboniferous limestone, respectively, remained in a state of the greatest confusion. The year 1831 marks the period of the commencement of the joint labours of Sedgwick and Murchison, which resulted in the establishment of the Cambrian, Silurian, and Devonian systems. Our Pre-Cambrian strata have recently been divided by Hicks into four great groups of immense thickness, and implying, therefore, a great lapse of time; but no fossils have yet been discovered in them. Lyell's classification of the Tertiary deposits, the result of the studies which he carried on with the assistance of Deshayes and others, was published in the third volume of the "Principles of Geology" in 1833. The establishment of Lyell's divisions of Eocene, Miocene, and Pliocene, was the starting-point of a most important series of investigations by Prestwich and others of these younger deposits; as well as of the post tertiary, quaternary, or drift beds, which are of special interest from the light they have thrown on the early history of man.

As regards the physical character of the earth, two theories have been held: one, that of a fluid interior covered by a thin crust; the other, of a practically solid sphere. The former is now very generally admitted, both by astronomers and geologists, to be untenable. The prevailing feeling of geologists on this subject has been well expressed by Prof. Le Comte, who says "the whole theory of igneous agencies—which is little less than the whole foundation of theoretic geology—must be reconstructed on the basis of a solid earth."

In 1837 Agassiz startled the scientific world by his "Discours sur l'ancienne extension des Glaciers," in which, developing the observation already made by Charpentier and Venetz, that boulders had been transported to great distances, and that rocks far away from, or high

above, existing glaciers, are polished and scratched by the action of ice, he boldly asserted the existence of a "glacial period," during which Switzerland and the North of Europe were subjected to great cold, and buried under a vast sheet of ice.

The ancient poets described certain gifted mortals as privileged to descend into the interior of the earth, and have exercised their imagination in recounting the wonders there revealed. As in other cases, however, the realities of science have proved more varied and surprising than the dreams of fiction. Of the gigantic and extraordinary animals thus revealed to us, by far the greatest number have been described during the period now under review. For instance, the gigantic Cetiosaurus was described by Owen in 1838, the Dinornis of New Zealand by the same distinguished naturalist in 1839, the Mylodon in the same year, and the Archæopteryx in 1862.

In America a large number of remarkable forms have been described, mainly by Marsh, Leidy, and Cope. Marsh has made known to us the Titanosaurus, of the American (Colorado) Jurassic beds, which is, perhaps, the largest land animal yet known, being 100 feet in length, and at least 30 in height, though it seems possible that even these vast dimensions were exceeded by those of the Atlantosaurus. Nor must I omit the Hesperornis, described by Marsh in 1872, as a carnivorous, swimming ostrich, provided with teeth, which he regards as a character inherited from reptilian ancestors; the Ichthyornis, stranger still, with biconcave vertebræ, like those of fishes, and teeth set in sockets.

As giving, in a few words, an idea of the rapid progress in this department, I may mention that Morris's "Catalogue of British Fossils," published in 1843, contained 5300 species, while that now in preparation by Mr. Etheridge enumerates 15,000.

But if these figures show how rapid our recent progress has been, they also very forcibly illustrate the imperfection of the geological record, and give us, I will not say a measure, but an idea, of the imperfection of the geological record. The number of all the described recent species is over 300,000, but certainly not half are yet on our lists, and we may safely take the total number of recent species as being not less than 700,000. But in former times there have been at the very least twelve periods, in each of which by far the greater number of species were distinct. True the number of species was probably not so large in the earlier periods as at present; but if we make a liberal allowance for this, we shall have a total of more than 2,000,000 species, of which about 25,000 only are as yet upon record; and many of these are only represented by a few, some only by a single specimen, or even only by a fragment.

The progress of palæontology may also be marked by the extent to which the existence of groups has been, if I may so say, carried back in time. Thus I believe that in 1830 the earliest known quadrupeds were small marsupials belonging to the Stonesfield slates; the most ancient mammal now known is *Microlestes antiquus* from the Keuper of Würtemberg: the oldest bird known in 1831 belonged to the period of the London Clay; the oldest now known is the Archæopteryx of the Solenhofen slates, though it is probable that some at any rate of the footsteps on the Triassic rocks are those of birds. So again the Amphibia have been carried back from the Trias to the Coal-measures; Fish from the Old Red Sandstone to the Upper Silurian; Reptiles to the Trias; Insects from the Cretaceous to the Devonian; Mollusca and Crustacea from the Silurian to the Lower Cambrian. The rocks below the Cambrian, though of immense thickness, have afforded no relics of animal life, if we except the problematical *Eozoon Canadense*, so ably studied by Dawson and Carpenter. But if palæontology as yet throws no light on the original forms of life, we must remember that the simplest and the lowest organisms are so soft and perishable that they would leave "not a wrack behind."

Passing to the science of Geography, Mr. Clements Markham has recently published an excellent summary of what has been accomplished during the half-century.

But the progress in our knowledge of geography is, and has been, by no means confined to the improvement of our maps, or to the discovery and description of new regions of the earth, but has extended to the causes which have led to the present configuration of the surface. To a great extent, indeed, this part of the subject falls rather within the scope of geology; but I may here refer, in illustration, to the distribution of lakes, the phenomena of glaciers, the formation of volcanic mountains, and the structure and distribution of coral islands.

The origin and distribution of lakes is one of the most interesting problems in physical geography. That they are not scattered at random a glance at the map is sufficient to show. They abound in mountain districts, are comparatively rare in equatorial regions, increasing in number as we go north, so that in Scotland and the northern parts of America they are sown broadcast.

Perhaps *à priori* the first explanation of the origin of lakes which would suggest itself, would be that they were formed in hollows resulting from a disturbance of the strata, which had thrown them into a basin-shaped form. Lake-basins, however, of this character are, as a matter of fact, very rare; as a general rule lakes have not the form of basin-shaped synclinal hollows, but, on the contrary, the strike of the strata often runs right across them. My eminent predecessor, Prof. Ramsay, divides lakes into three classes:—(1) Those which are due to irregular accumulations of drift, and which are generally quite shallow; (2) those which are formed by moraines; and (3) those which occupy true basins scooped by glacier-ice out of the solid rock. To the latter class belong most of the great Swiss and Italian lakes. Prof. Ramsay attributes their excavation to glaciers, because it is of course obvious that rivers cannot make basin-shaped hollows surrounded by rocks on all sides. Now the Lake of Geneva, 1230 feet above the sea, is 984 feet deep; the Lake of Brienz is 1850 feet above the sea, and 2000 feet deep, so that its bottom is really below the sea-level. The Italian lakes are even more remarkable. The Lake of Como, 700 feet above the sea, is 1929 feet deep. Lago Maggiore, 685 feet above the sea, is no less than 2625 feet deep. It will be observed that these lakes, like many others in mountain regions,—those of Scandinavia, for instance,—lie in the direct channels of the great old glaciers. If the mind is at first staggered at the magnitude of the scale, we must remember that the ice which scooped out the valley in which the Lake of Geneva now reposes was once at least 2700 feet thick, while the moraines were also of gigantic magnitude—that of Ivrea, for instance, being no less than 1500 feet in height. Prof. Ramsay's theory seems, therefore, to account beautifully for a large number of interesting facts.

Passing from lakes to mountains, two rival theories with reference to the structure and origin of volcanoes long struggled for supremacy.

The more general view was that the sheets of lava and scoriæ which form volcanic zones—such, for instance, as Ætna or Vesuvius—were originally nearly horizontal, and that subsequently a force operating from below, and exerting a pressure both upwards and outwards from a central axis towards all points of the compass, uplifted the whole stratified mass and made it assume a conical form, giving rise at the same time, in many cases, to a wide and deep circular opening at the top of the cone, called by the advocates of this hypothesis a "crater of elevation."

This theory, though—as it seems to us now—it had already received its death-blow from the admirable memoirs of Scrope, was yet that most generally adopted fifty years ago, because it was considered that compact and crystalline lavas could not have consolidated on a slope exceeding 1° or 2°. In 1858, however, Sir C. Lyell conclusively showed that in fact such lavas could consolidate at a con-

siderable angle, even in some cases at more than 30°, and it is now generally admitted that though the beds of lava, &c., may have sustained a slight angular elevation since their deposition, still, in the main, volcanic cones have acquired their form by the accumulation of lava and ashes ejected from one or more craters.

The problems presented by glaciers are of very great interest. In 1843 Agassiz and Forbes proved that the centre of a glacier, like that of a river, moves more rapidly than its sides. But how and why do glaciers move at all? Rendu, afterwards Bishop of Annecy, in 1841 endeavoured to explain the facts by supposing that glacier ice enjoys a kind of ductility. The "viscous theory" of glaciers was also adopted, and most ably advocated, by Forbes, who compared the condition of a glacier to that of the contents of a tar-barrel poured into a sloping channel. We have all, however, seen long narrow fissures, a mere fraction of an inch in width, stretching far across glaciers—a condition incompatible with the ordinary idea of viscosity. The phenomenon of regelation was afterwards applied to the explanation of glacier-motion. An observation of Faraday's supplied the clue. He noticed, in 1850, that when two pieces of thawing ice are placed together they unite by freezing at the place of contact. Following up this suggestion, Tyndall found that if he compressed a block of ice in a mould it could be made to assume any shape he pleased. A straight prism, for instance, placed in a groove and submitted to hydraulic pressure, was bent into a transparent semicircle of ice. These experiments seem to have proved that a glacial valley is a mould through which the ice is forced, and to which it will accommodate itself, while, as Tyndall and Huxley also pointed out, the "veined structure of ice" is produced by pressure, in the same manner as the cleavage of slate rocks.

It was in the year 1842 that Darwin published his great work on "Coral Islands." The fringing reefs of coral presented no special difficulty. They could be obviously accounted for by an elevation of the land, so that the coral, which had originally grown under water, had been raised above the sea-level. The circular or oval shape of so many reefs, however, each having a lagoon in the centre, closely surrounded by a deep ocean, and rising but a few feet above the sea-level, had long been a puzzle to the physical geographer. The favourite theory was that these were the summits of submarine volcanoes on which the coral had grown. But as the reef-making coral does not live at greater depths than about 25 fathoms, the immense number of these reefs formed an almost insuperable objection to this theory. The Laccadives and Maldives, for instance,—meaning literally the "lac of islands" and the "thousand islands,"—are a series of such atolls, and it was impossible to imagine so great a number of craters, all so nearly of the same altitude. Darwin showed, moreover, that so far from the ring of corals resting on a corresponding ridge of rock, the lagoons, on the contrary, now occupy the place which was once the highest land. He pointed out that some lagoons—as, for instance, that of Vanikoro—contain an island in the middle; while other islands, such as Tahiti, are surrounded by a margin of smooth water, separated from the ocean by a coral reef. Now, if we suppose that Tahiti were to sink slowly, it would gradually approximate to the condition of Vanikoro; and if Vanikoro gradually sank, the central island would disappear, while on the contrary the growth of the coral might neutralise the subsidence of the reef, so that we should simply have an atoll, with its lagoon. The same considerations explain the origin of the "barrier reefs," such as that which runs, for nearly 1000 miles, along the north-east coast of Australia. Thus Darwin's theory explained the form and the approximate identity of altitude of these coral islands. But it did more than this, because it showed us that there were great areas in process of subsidence, which, though slow, was of great importance in physical geography.*

* I ought to mention that Darwin's views have recently been questioned by Semper and Murray.

Much information has also been acquired with reference to the abysses of the ocean, especially from the voyages of the *Porcupine* and the *Challenger*. The greatest depth yet recorded is near the Ladrone Islands, where a sounding of 4575 fathoms was obtained.

Ehrenberg long ago pointed out the similarity of the calcareous mud now accumulating in our recent seas to the chalk, and showed that the green sands of the geologist are largely made up of casts of Foraminifera. Clay, however, had been looked on, until the recent expeditions, as essentially a product of the disintegration of older rocks. Not only, however, are a large proportion of siliceous and calcareous rocks either directly or indirectly derived from material which has once formed a portion of living organisms, but Sir Wyville Thomson maintains that this is the case with some clays also. In that case the striking remark of Linnæus, that "fossils are not the children but the parents of rocks," will have received remarkable confirmation. I should have thought it, I confess, probable that these clays are, to a considerable extent, composed of volcanic dust.

It would appear that calcareous deposits resembling our chalk do not occur at a greater depth than 3000 fathoms; they have not been met with in the abysses of the ocean. Here the bottom consists of exceedingly fine clay, sometimes coloured red by oxide of iron, sometimes chocolate by manganese oxide, and containing with Foraminifera occasionally large numbers of siliceous Radiolaria. These strata seem to accumulate with extreme slowness: this is inferred from the comparative abundance of whales' bones and fishes' teeth, and from the presence of minute spherical particles, supposed by Mr. Murray to be of cosmic origin—in fact, to be the dust of meteorites, which in the course of ages have fallen on the ocean. Such particles no doubt occur over the whole surface of the earth, but on land they soon oxidise, and in shallow water they are covered up by other deposits. Another interesting result of recent deep-sea explorations has been to show that the depths of the ocean are no mere barren solitudes, as was until recent years confidently believed, but, on the contrary, present as many remarkable forms of life. We have, however, as yet but thrown here and there a ray of light down into the ocean abysses:—

> "Nor can so short a time sufficient be
> To fathom the vast depths of Nature's sea."

In Astronomy, the discovery in 1845 of the planet Neptune, made independently and almost simultaneously by Adams and by Le Verrier, was certainly one of the very greatest triumphs of mathematical genius. Of the minor planets four only were known in 1831, whilst the number now on the roll amounts to 220. Many astronomers believe in the existence of an intra-mercurial planet or planets, but this is still an open question. The Solar System has also been enriched by the discovery of an inner ring to Saturn, of satellites to Mars, and of additional satellites to Saturn, Uranus, and Neptune.

The most unexpected progress, however, in our astronomical knowledge during the past half-century has been due to spectrum analysis.

The dark lines in the spectrum were first seen by Wollaston, who noticed a few of them; but they were independently discovered by Fraunhofer, after whom they are justly named, and who, in 1814, mapped no fewer than 576. The first steps in "spectrum analysis," properly so called, were made by Sir J. Herschel, Fox Talbot, and by Wheatstone, in a paper read before this Association in 1835. The latter showed that the spectrum emitted by the incandescent vapour of metals was formed by bright lines, and that these lines, while, as he then supposed, constant for each metal, differed for different metals. "We have here," he said, "a mode of discriminating metallic bodies more readily than that of chemical examination, and which may hereafter be employed for useful purposes." Nay, not only can bodies thus be more readily discriminated, but, as we now know, the presence of

extremely minute portions can be detected, the 1-5,000,000th of a grain being in some cases easily perceptible.

It is also easy to see that the presence of any new simple substance might be detected, and in this manner already several new elements have been discovered, as I shall mention when we come to Chemistry.

But spectrum analysis has led to even grander and more unexpected triumphs. Fraunhofer himself noticed the coincidence between the double dark line D of the solar spectrum and a double line which he observed in the spectra of ordinary flames, while Stokes pointed out to Sir W. Thomson, who taught it in his lectures, that in both cases these lines were due to the presence of sodium. To Kirchhoff and Bunsen, however, is due the independent conception and the credit of having first systematically investigated the relation which exists between Fraunhofer's lines and the bright liner in the spectra of incandescent metals. In order to get some fixed measure by which they might determine and record the lines characterising any given substance, it occurred to them that they might use for comparison the spectrum of the sun. They accordingly arranged their spectroscope so that one-half of the slit was lighted by the sun, and the other by the luminous gases they proposed to examine. It immediately struck them that the bright lines in the one corresponded with the dark lines in the other—the bright line of sodium, for instance, with the line, or rather lines, D in the sun's spectrum. The conclusion was obvious. There was sodium in the sun! It must indeed have been a glorious moment when that thought flashed across them, and even by itself well worth all their labour.

Kirchhoff and Bunsen thus proved the existence in the sun of hydrogen, sodium, magnesium, calcium, iron, nickel, chromium, manganese, titanium, and cobalt; since which Angström, Thalen, and Lockyer have considerably increased the list.

But it is not merely the chemistry of the heavenly bodies on which light is thrown by the spectroscope; their physical structure and evolutional history are also illuminated by this wonderful instrument of research.

It used to be supposed that the sun was a dark body enveloped in a luminous atmosphere. The reverse now appears to be the truth. The body of the sun, or photosphere, is intensely brilliant; round it lies the solar atmosphere of comparatively cool gases, which cause the dark lines in the spectrum; thirdly, a chromosphere,—a sphere principally of hydrogen, jets of which are said sometimes to reach to a height of 100,000 miles or more, into the outer coating or corona, the nature of which is still very doubtful.

Formerly the red flames which represent the higher regions of the chromosphere could be seen only on the rare occasions of a total solar eclipse. Janssen and Lockyer, by the application of the spectroscope, have enabled us to study this region of the sun at all times.

It is, moreover, obvious that the powerful engine of investigation afforded us by the spectroscope is by no means confined to the substances which form part of our system. The incandescent body can thus be examined, no matter how great its distance, so long only as the light is strong enough. That this method was theoretically applicable to the light of the stars was indeed obvious, but the practical difficulties were very great. Sirius, the brightest of all, is, in round numbers, a hundred millions of millions of miles from us; and, though as big as sixty of our suns, his light when it reaches us, after a journey of sixteen years, is at most one two-thousandth-millionth part as bright. Nevertheless, as long ago as 1815 Fraunhofer recognised the fixed lines in the light of four of the stars, and in 1863 Miller and Huggins, in our own country, and Rutherford, in America, succeeded in determining the dark lines in the spectrum of some of the brighter stars, thus showing that these beautiful and mysterious lights contain many of the material substances with which we are familiar. In Aldebaran, for instance, we may infer the presence of hydrogen, sodium, magnesium, iron, calcium, tellurium, antimony, bismuth, and mercury; some of which are not yet known to occur in the sun. As might have been expected, the composition of the stars is not uniform, and it would appear that they may be arranged in a few well-marked classes, indicating differences of temperature, or, in other words, of age. Some recent photographic spectra of stars obtained by Huggins go very far to justify this view.

Thus, we can make the stars teach us their own composition with light which started from its source before we were born—light older than our Association itself.

But spectrum analysis has even more than this to tell us. The old methods of observation could determine the movements of the stars so far only as they were transverse to us; they afforded no means of measuring motion either directly towards or away from us. Now Döppler suggested in 1841 that the colours of the stars would assist us in this respect, because they would be affected by their motion to and from the earth, just as a steam-whistle is raised or lowered as it approaches or recedes from us. Everyone has observed that if a train whistles as it passes us, the sound appears to alter at the moment the engine goes by. This arises, of course, not from any change in the whistle itself, but because the number of vibrations which reach the ear in a given time are increased by the speed of the train as it approaches, and diminished as it recedes. So, like the sound, the colour would be affected by such a movement; but Döppler's method was practically inapplicable, because the amount of effect on the colour would be utterly insensible; and even if it were otherwise the method could not be applied, because, as we did not know the true colour of the stars, we have no datum line by which to measure.

A change of refrangibility of light, however, does occur in consequence of relative motion, and Huggins successfully applied the spectroscope to solve the problem. He took in the first place the spectroscope of Sirius, and chose a line known as F, which is due to hydrogen. Now, if Sirius was motionless, or rather if it retained a constant distance from the earth, the line F would occupy exactly the same position in the spectrum of Sirius as in that of the sun. On the contrary, if Sirius were approaching or receding from us, this line would be slightly shifted either towards the blue or red end of the spectrum. He found that the line had moved very slightly towards the red, indicating that the distance between us and Sirius is increasing at the rate of about twenty miles a second. So also Betelgeux, Rigel, Castor, and Regulus are increasing their distance; while, on the contrary, that of others, as for instance of Vega, Arcturus, and Pollux, is diminishing. The results obtained by Huggins on about twenty stars have since been confirmed and extended by Mr. Christie, now Astronomer Royal, in succession to Sir G. Airy, who has long occupied the post with so much honour to himself and advantage to science.

To examine the spectrum of a shooting star would seem even more difficult; yet Alexander Herschel has succeeded in doing so, and finds that their nuclei are incandescent solid bodies: he has recognised the lines of potassium, sodium, lithium, and other substances, and considers that the shooting stars are bodies similar in character and composition to the stony masses which sometimes reach the earth as aërolites.

No element has yet been found in any meteorite which was not previously known as existing in the earth, but the phenomena which they exhibit indicate that they must have been formed under conditions very different from those which prevail on the earth's surface. I may mention, for instance, the peculiar form of crystallised silica, called by Maskelyne, Asmanite; and the whole class of meteorites, consisting of iron generally alloyed with nickel, which Daubrée terms Holosiderites. The interesting discovery, however, by Nordenskiöld, in 1870, at Ovifak, of a number of blocks of iron alloyed with nickel and cobalt, in connection with basalts containing disseminated iron, has, in the words of Judd, "afforded a very important

link, placing the terrestrial and extra-terrestrial rocks in closer relations with one another."

We have as yet no sufficient evidence to justify a conclusion as to whether any substances exist in the heavenly bodies which do not occur in our earth, though there are many lines which cannot yet be satisfactorily referred to any terrestrial element. On the other hand, some substances which occur on our earth have not yet been detected in the sun's atmosphere.

Such discoveries as these seemed, not long ago, entirely beyond our hopes. M. Comte, indeed, in his "Cours de Philosophie Positive," as recently as 1842, laid it down as an axiom regarding the heavenly bodies, that "Nous concevons la possibilité de déterminer leurs formes, leurs distances, leurs grandeurs et leurs mouvements, tandis que nous ne saurions jamais étudier par aucun moyen leur composition chimique ou leur structure minéralogique." Yet within a few years this supposed impossibility has been actually accomplished, showing how unsafe it is to limit the possibilities of science.

It is hardly necessary to point out that, while the spectrum has taught us so much, we have still even more to learn. Why should some substances give few, and others many, lines? Why should the same substance give different lines at different temperatures? What are the relations between the lines and the physical or chemical properties?

We may certainly look for much new knowledge of the hidden actions of atoms and molecules from future researches with the spectroscope. It may even, perhaps, teach us to modify our views of the so-called simple substances. Prout long ago, struck by the remarkable fact that nearly all atomic weights are simple multiples of the atomic weight of hydrogen, suggested that hydrogen must be the primordial substances. Brodie's researches also naturally fell in with the supposition that the so-called simple substances are in reality complex, and that their constituents occur separately in the hottest regions of the solar atmosphere. Lockyer considers that his researches lend great probability to this view. The whole subject is one of intense interest, and we may rejoice that it is occupying the attention, not only of such men as Abney, Dewar, Hartley, Liveing, Roscoe, and Schuster in our own country, but also of many foreign observers.

When geology so greatly extended our ideas of past time, the continued heat of the sun became a question of greater interest than ever. Helmholtz has shown that, while adopting the nebular hypothesis, we need not assume that the nebulous matter was originally incandescent; but that its present high temperature may be, and probably is, mainly due to gravitation between its parts. It follows that the potential energy of the sun is far from exhausted, and that with continued shrinking it will continue to give out light and heat, with little, if any, diminution for several millions of years.

Like the sand of the sea, the stars of heaven have ever been used as effective symbols of number, and the improvements in our methods of observation have added fresh force to our original impressions. We now know that our earth is but a fraction of one out of at least 75,000,000 worlds.

But this is not all. In addition to the luminous heavenly bodies, we cannot doubt that there are countless others, invisible to us from their greater distance, smaller size, or feebler light; indeed, we know that there are many dark bodies which now emit no light or comparatively little. Thus, in the case of Procyon, the existence of an invisible body is proved by the movement of the visible star. Again, I may refer to the curious phenomena presented by Algol, a bright star in the head of Medusa. This star shines without change for two days and thirteen hours; then, in three hours and a half, dwindles from a star of the second to one of the fourth magnitude; and then, in another three and a half hours, re-assumes its original brilliancy. These changes seem certainly to indicate the presence of an opaque body, which intercepts at regular intervals a part of the light emitted by Algol.

Thus, the floor of heaven is not only "thick inlaid with patines of bright gold," but studded also with extinct stars; once probably as brilliant as our own sun, but now dead and cold, as Helmholtz tells us that our sun itself will be, some seventeen millions of years hence.

The general result of astronomical researches has been thus eloquently summed up by Proctor:—"The sidereal system is altogether more complicated and more varied in structure than has hitherto been supposed; in the same region of the stellar depths co exist stars of many orders of real magnitude; all orders of nebulæ, gaseous or stellar planetary, ring-formed, elliptical, and spiral, exist within the limits of the galaxy; and lastly, the whole system is alive with movements, the laws of which may one day be recognised, though at present they appear too complex to be understood."

We can, I think, scarcely claim the establishment of the undulatory theory of light as falling within the last fifty years; for though Brewster, in his "Report on Optics," published in our first volume, treats the question as open, and expresses himself still unconvinced, he was, I believe, almost alone in his preference for the emission theory. The phenomena of interference, in fact left hardly any—if any—room for doubt, and the subject was finally set at rest by Foucault's celebrated experiments in 1850. According to the undulatory theory the velocity of light ought to be greater in air than in water, while if the emission theory were correct, the reverse would be the case. The velocity of light—186,000 miles in a second—is, however, so great that, to determine its rate in air, as compared with that in water, might seem almost hopeless.

The velocity in air was, nevertheless, determined by Fizeau in 1849, by means of a rapidly revolving wheel. In the following year Foucault, by means of a revolving mirror, demonstrated that the velocity of light is greater in air than in water—thus completing the evidence in favour of the undulatory theory of light.

The idea is now gaining ground, that, as maintained by Clerk-Maxwell, light itself is an electro-magnetic disturbance, the luminiferous ether being the vehicle of both light and electricity.

Wünsch, as long ago as 1792, had clearly shown that the three primary colours were red, green, and violet; but his results attracted little notice, and the general view used to be that there were seven principal colours—red, orange, yellow, green, blue, indigo, and violet; four of which—namely, orange, green, indigo, and violet—were considered to arise from mixtures of the other three. Red, yellow, and blue were therefore called the primary colours, and it was supposed that in order to produce white light these three colours must always be present.

Helmholtz, however, again showed, in 1852, that a colour to our unaided eyes identical with white, was produced by combining yellow with indigo. At that time yellow was considered to be a simple colour, and this, therefore, was regarded as an exception to the general rule, that a combination of three simple colours is required to produce white. Again, it was, and indeed still is, the general impression that a combination of blue and yellow makes green. This, however, is entirely a mistake. Of course we all know that yellow paint and blue paint make green paint; but this results from absorption of light by the semi-transparent solid particles of the pigments, and is not a mere mixture of the colours proceeding unaltered from the yellow and the blue particles: moreover, as can easily be shown by two sheets of coloured paper and a piece of window glass, blue and yellow light, when combined, do not give a trace of green, but if pure would produce the effect of white. Green, therefore, is after all not produced by a mixture of blue and yellow. On the other hand, Clerk-Maxwell proved, in 1860, that yellow could be produced by a mixture of red and green, which put an end to the pretension of yellow to be considered a

primary element of colour. From these and other considerations it would seem, therefore, that the three primary colours—if such an expression be retained—are red, green, and violet.

The existence of rays beyond the violet, though almost invisible to our eyes, had long been demonstrated by their chemical action. Stokes, however, showed in 1852 that their existence might be proved in another manner, for that there are certain substances which, when excited by them, emit light visible to our eyes. To this phenomenon he gave the name of fluorescence. At the other end of the spectrum Abney has recently succeeded in photographing a large number of lines in the infra-red portion, the existence of which was first proved by Sir William Herschel.

From the rarity, and in many cases the entire absence, of reference to blue, in ancient literature, Geiger—adopting and extending a suggestion first thrown out by Mr. Gladstone—has maintained that, even as recently as the time of Homer, our ancestors were blue-blind. Though for my part I am unable to adopt this view, it is certainly very remarkable that neither the Rigveda, which consists almost entirely of hymns to heaven, nor the Zendavesta, the Bible of the Parsees or fire-worshippers, nor the Old Testament, nor the Homeric poems, ever allude to the sky as blue.

On the other hand, from the dawn of poetry, the splendours of the morning and evening skies have excited the admiration of mankind. As Ruskin says, in language almost as brilliant as the sky itself, the whole heaven, "from the zenith to the horizon, becomes one molten, mantling sea of colour and fire; every black bar turns into massy gold, every ripple and wave into unsullied shadowless crimson, and purple, and scarlet, and colours for which there are no words in language, and no ideas in the mind—things which can only be conceived while they are visible; the intense hollow blue of the upper sky melting through it all, showing here deep, and pure, and lightness; there, modulated by the filmy, formless body of the transparent vapour, till it is lost imperceptibly in its crimson and gold."

But what is the explanation of these gorgeous colours? Why is the sky blue? and why are the sunrise and sunset crimson and gold? It may be said that the air is blue, but if so how can the clouds assume their varied tints? Brücke showed that very minute particles suspended in water are blue by reflected light. Tyndall has taught us that the blue of the sky is due to the reflection of the blue rays by the minute particles floating in the atmosphere. Now, if from the white light of the sun, the blue rays are thus selected, those which are transmitted will be yellow, orange, and red. Where the distance is short the transmitted light will appear yellowish. But as the sun sinks towards the horizon the atmospheric distance increases, and consequently the number of the scattering particles. They weaken in succession the violet, the indigo, the blue, and even disturb the proportions of green. The transmitted light under such circumstances must pass from yellow through orange to red, and thus, while we at noon are admiring the deep blue of the sky, the same rays, robbed of their blue, are elsewhere lighting up the evening sky with all the glories of sunset.

Another remarkable triumph of the last half-century has been the discovery of photography. At the commencement of the century Wedgwood and Davy observed the effect produced by throwing the images of the objects on paper or leather prepared with nitrate of silver, but no means were known by which such images could be fixed. This was first effected by Niepce, but his processes were open to objections, which prevented them from coming into general use, and it was not till 1839 that Daguerre invented the process which was justly named after him. Very soon a further improvement was effected by our countryman Talbot. He not only fixed his "Talbotypes" on paper—in itself a great convenience—but, by obtaining a negative, rendered it possible to take off any number of positive, or natural, copies from one original picture.

We owe to Wheatstone the conception that the idea of solidity is derived from the combination of two pictures of the same object in slightly different perspective. This he proved in 1833 by drawing two outlines of some geometrical figure or other simple object, as they would appear to either eye respectively, and then placing them so that they might be seen, one by each eye. The "stereoscope," thus produced, has been greatly popularised by photography.

For 2000 years the art of lighting had made little if any progress. Until the close of the last century, for instance, our lighthouses contained mere fires of wood or coal, though the construction had vastly improved. The Eddystone lighthouse, for instance, was built by Smeaton, in 1759; but for forty years its light consisted in a row of tallow candles stuck in a hoop. The Argand lamp was the first great improvement, followed by gas, and in 1863 by the electric light.

Just as light was long supposed to be due to the emission of material particles, so heat was regarded as a material, though ethereal, substance, which was added to bodies when their temperature was raised.

Davy's celebrated experiment of melting two pieces of ice by rubbing them against one another in the exhausted receiver of an air-pump had convinced him that the cause of heat was the motion of the invisible particles of bodies, as had been long before suggested by Newton, Boyle, and Hooke. Rumford and Young also advocated the same view. Nevertheless, the general opinion, even until the middle of the present century, was that heat was due to the presence of a subtle fluid known as "caloric," a theory which is now entirely abandoned.

The determination of the mechanical equivalent of heat is mainly due to the researches of Mayer and Joule. Mayer, in 1842, pointed out the mechanical equivalent of heat as a fundamental datum to be determined by experiment. Taking the heat produced by the condensation of air as the equivalent of the work done in compressing the air, he obtained a numerical value of the mechanical equivalent of heat. There was, however, in these experiments one weak point. The matter operated on did not go through a cycle of changes. He assumed that the production of heat was the only effect of the work done in compressing the air. Joule had the merit of being the first to meet this possible source of error. He ascertained that a weight of 1 lb. would have to fall 772 feet in order to raise the temperature of 1 lb. of water by 1° F. Hirn subsequently attacked the problem from the other side, and showed that if all the heat passing through a steam-engine was turned into work, for every degree Fahr. added to the temperature of a pound of water enough work could be done to raise a weight of 1 lb. to a height of 772 feet. The general result is that, though we cannot create energy we may help ourselves to any extent from the great storehouse of Nature. Wind and water, the coal-bed and the forest, afford man an inexhaustible supply of available energy.

It used to be considered that there was an absolute break between the different states of matter. The continuity of the gaseous, liquid, and solid conditions was first demonstrated by Andrews in 1862.

Oxygen and nitrogen have been liquefied independently and at the same time by Cailletet and Raoul Pictet. Cailletet also succeeded in liquefying air, and soon afterwards hydrogen was liquefied by Pictet under a pressure of 650 atmospheres, and a cold of 170° C. below zero. It even became partly solidified, and he assures us that it fell on the floor with "the shrill noise of metallic hail." Thus then it was shown experimentally that there are no such things as absolutely permanent gases.

The kinetic theory of gases, now generally accepted, refers the elasticity of gases to a motion of translation of their molecules, and we are assured that in the case of hydrogen, at a temperature of 60° F., they move at an

average rate of 6225 feet in a second; while as regards their size, Loschmidt, who had since been confirmed by Stoney and Sir W. Thomson, calculates that each is at most 1-50,000,000th of an inch in diameter.

We cannot, it would seem at present, hope for any increase of our knowledge of atoms by any improvement in the microscope. With our present instruments we can perceive lines ruled on glass of 1-90,000th of an inch apart. But, owing to the properties of life itself, the fringes due to interference begin to produce confusion at distances of 1-74,000. It would seem then that, owing to the physical characters of light, we can, as Sorby has pointed out, scarcely hope for any great improvement so far as the mere visibility of structure is concerned, though in other respects no doubt much may be hoped for.

Sorby is of opinion that in a length of 1-80,000th of an inch there would probably be from 500 to 2000 molecules —500, for instance, in albumen, and 2000 in water. Even, then, if we could construct microscopes far more powerful than any we now possess, they would not enable us to obtain by direct vision any idea of the ultimate molecules of matter. Sorby calculates that the smallest sphere of organic matter which could be clearly defined with our most powerful microscopes would contain many millions of molecules of albumen and water, and it follows that there may be an almost infinite number of structural characters in organic tissues, which we can at present foresee no mode of examining.

Electricity in the year 1831 may be considered to have just been ripe for its adaptation to practical purposes: it was but a few years previously, in 1819, that Oersted had discovered the deflective action of the current on the magnetic needle, that Ampère had laid the foundation of electro-dynamics, that Schweizzer had devised the electric coil or multiplier, and that Sturgeon had constructed the first electro-magnet. It was in 1831 that Faraday, the prince of pure experimentalists, announced his discoveries of voltaic induction and magneto-electricity, which with the other three discoveries constitute the principles of nearly all the telegraph instruments now in use; and in 1834 our knowledge of the nature of the electric current had been much advanced by the interesting experiment of Sir Charles Wheatstone, proving the velocity of the current in a metallic conductor to approach that of the wave of light.

Practical applications of these discoveries were not long in coming to the fore, and the first telegraph line on the Great Western Railway from Paddington to West Drayton was set up in 1838. In America Morse is said to have commenced to develop his recording instrument between the years 1832 and 1837.

In 1851 submarine telegraphy became an accomplished fact through the successful establishment of telegraphic communication between Dover and Calais. Submarine lines followed in rapid succession, crossing the English Channel and the German Ocean, threading their way through the Mediterranean, Black and Red Seas, until in 1866, after two abortive attempts, telegraphic communication was successfully established between the Old and New Worlds, beneath the Atlantic Ocean.

Duplex and quadruplex telegraphy, one of the most striking achievements of modern telegraphy, the result of the labours of several inventors, should not be passed over in silence. It not only serves for the simultaneous communication of telegraphic intelligence in both directions, but renders it possible for four instruments to be worked irrespectively of one another, through one and the same wire connecting two distant places.

Another more recent and perhaps still more wonderful achievement in modern telegraphy is the invention of the telephone and microphone, by means of which the human voice is transmitted through the electric conductor, by mechanism that imposes through its extreme simplicity. In this connection the names of Reiss, Graham Bell, Edison, and Hughes, are those chiefly deserving to be recorded.

By the electric transmission of power we may hope some day to utilise at a distance such natural sources of energy as the Falls of Niagara, and to work our cranes, lifts, and machinery of every description by means of sources of power arranged at convenient centres. To these applications the Brothers Siemens have more recently added the propulsion of trains by currents passing through the rails, the fusion in considerable quantities of highly refractory substances, and the use of electric centres of light in horticulture as proposed by Werner and William Siemens. By an essential improvement by Faure of the Planté Secondary Battery, the problem of storing electrical energy appears to have received a practical solution, the real importance of which is clearly proved by Sir W. Thomson's recent investigation of the subject.

It would be difficult to assign the limits to which this development of electrical energy may not be rendered serviceable for the purposes of man.

As regards Mathematics I have felt that it would be impossible, even with the kindest help, to write anything myself. Mr. Spottiswoode, however, has been so good as to supply me with the following memorandum.

In a complete survey of the progress of Science during the half-century which has intervened between our first and our present meeting, the part played by mathematics would form no insignificant feature. To those indeed who are outside its enchanted circle it is difficult to realise the intense intellectual energy which actuates its devotees, or the wide expanse over which that energy ranges.

In the extension of mathematics it has happened more than once that laws have been established so simple in form, and so obvious in their necessity, as scarcely to require proof. And yet their application is often of the highest importance in checking conclusions which have been drawn from other considerations, as well as in leading to conclusions which, without their aid, might have been difficult of attainment. The same thing has occurred also in physics; and notably in the recognition of what has been termed the "Law of the Conservation of Energy."

Energy has been defined to be "The capacity, or power, of any body, or system of bodies, when in a given condition, to do a measureable quantity of work." Such work may either change the condition of the bodies in question, or it may affect other bodies; but in either case energy is expended by the agent upon the recipient in performance of the work. The law then states that the total amount of energy in the agents and recipients taken together remains unaltered by the changes in question.

Now the principle on which the law depends is this: that every kind of change among the bodies may be expressed numerically in one standard unit of change, viz., work done, in such wise that the result of the passage of any system from one condition to another may be calculated by mere additions and subtractions, even when we do not know how the change came about.

The history of a discovery, or invention, so simple at first sight, is often found to be more complicated the more thoroughly it is examined. That which at first seems to have been due to a single mind proves to have been the result of the successive action of many minds. Attempts more or less successful in the same direction are frequently traced out; and even unsuccessful efforts may not have been without influence on minds turned towards the same object. Lastly also, germs of thought, originally not fully understood, sometimes prove in the end to have been the first stages of growth towards ultimate fruit. The history of the law of the conservation of energy forms no exception to this order of events. There are those who discern even in the writings of Newton expressions which show that he was in possession of some ideas which, if followed out in a direct line of thought, would lead to those now entertained on the subjects of energy and of work. But however this may be, and whosoever might

be reckoned among the earlier contributors to the general subjects of energy, and to the establishment of its laws, it is certain that within the period of which I am now speaking, the names of Seguin, Clausius, Helmholtz, Mayer, and Colding, on the Continent, and those of Grove, Joule, Rankine, and Thomson, in this country, will always be associated with this great work.

Prof. Frankland has been so good as to draw up for me the following account of the progress of chemistry during the last half century.

Most of the elements had been discovered before 1830, the majority of the rarer elements since the beginning of the century. In addition to these the following five have been discovered, three of them by Mosander, viz.:—Lanthanum in 1839, didymium in 1842, and erbium in 1843. Ruthenium was discovered by Claus in 1843, and niobium by Rose in 1844. Spectrum Analysis has added five to the list, viz.:—Cæsium and rubidium, which were discovered by Bunsen and Kirchhoff in 1860; thallium, by Crookes in 1861; indium, by Reich and Richter in 1863; and gallium, by Lecoq de Boisdaudran in 1875.

In organic chemistry the views most generally held about the year 1830 were expressed in the radical theory of Berzelius. This theory, which was first stated in its electro-chemical and dualistic form by its author in 1817, received a further development at his hands in 1834 after the discovery of the benzoyl-radical by Liebig and Wöhler. In the same year (1834), however, a discovery was made by Dumas, which was destined profoundly to modify the electro-chemical portion of the theory, and even to overthrow the form of it put forth by Berzelius. Dumas showed that an electro-negative element, such as chlorine, might replace, atom for atom, an electro-positive element like hydrogen, in some cases without much alteration in the character of the compound. This law of substitution has formed a necessary portion of every chemical theory which has been proposed since its discovery, and its importance has increased with the progress of the science.

Chemists have been engaged in determining, by means of decompositions, the molecular architecture, or *constitution* as it is called, of various compounds, natural and artificial, and in verifying by synthesis the correctness of the views thus arrived at.

It was long supposed that an impassable barrier existed between inorganic and organic substances: that the chemist could make the former in his laboratory, while the latter could only be produced in the living bodies of animals or plants,—requiring for their construction not only chemical attractions, but a supposed "vital force." It was not until 1828 that Wöhler broke down this barrier by the synthetic production of urea, and since his time this branch of science in the hands of Hofmann has made great strides.

In connection with the rectification of the atomic weights it may be mentioned that a so-called natural system of the elements has been introduced by Mendelejeff (1869), in which the properties of the elements appear as a periodic function of their atomic weights. By the aid of this system it has been possible to predict the properties and atomic weights of undiscovered elements, and in the case of known elements to determine many atomic weights which had not been fixed by any of the usual methods. Several of these predictions have been verified in a remarkable manner. A periodicity in the atomic weights of elements belonging to the same class had been pointed out by Newlands about four years before the publication of Mendelejeff's memoir.

In mechanical science the progress has not been less remarkable than in other branches. Indeed to the improvements in mechanics we owe no small part of our advance in practical civilisation, and of the increase of our national prosperity during the last fifty years.

This immense development of mechanical science has been to a great extent a consequence of the new processes which have been adopted in the manufacture of iron, for the following data with reference to which I am indebted to Captain Douglas Galton. About 1830, Neilson introduced the hot blast in the smelting of iron. At first a temperature of 600° or 700° Fahrenheit was obtained, but Cowper subsequently applied Siemens's regenerative furnace for heating the blast, chiefly by means of fumes from the black furnace, which were formerly wasted; and the temperature now practically in use is as much as 1400° or even more: the result is a very great economy of fuel and an increase of the output.

Bessemer, by his brilliant discovery, which he first brought before the British Association at Cheltenham in 1856, showed that Iron and Steel could be produced by forcing currents of atmospheric air through fluid pig-metal, thus avoiding for the first time the intermediate process of puddling iron, and converting it by cementation into steel.

The inventions of Cort and others were known long before 1830, but we were then still without the most powerful tool in the hands of the practical metallurgist, viz., Nasmyth's steam hammer.

Steel can now be produced as cheaply as iron was formerly; and its substitution for iron as railway material and in shipbuilding, has resulted in increased safety in railway travelling, as well as in economy, from its vastly greater durability.

The introduction of iron has, moreover, had a vast influence on the works of both the civil and military engineer. Before 1830, Telford had constructed an iron suspension turnpike-road bridge of 560 feet over the Menai Straits; but this bridge was not adapted to the heavy weights of locomotive engines. At the present time, with steel at his command, Mr. Fowler is engaged in carrying out the design for a railway bridge over the Forth, of two spans of 1700 feet each; that is to say, of nearly one third of a mile in length.

As regards railways, the Stockton and Darlington Railway was opened in 1825, but the Liverpool and Manchester Railway, perhaps the first truly passenger line, dates from 1830, while the present mileage of railways is over 200,000 miles, costing nearly £4,000,000,000 sterling. It was not until 1838 that the *Sirius* and *Great Western* first steamed across the Atlantic. The steamer, in fact, is an excellent epitome of the progress of the half-century; the paddle has been superseded by the screw; the compound has replaced the simple engine; wood has given place to iron, and iron in its turn to steel. The saving in dead weight, by this improvement alone, is from 10 to 16 per cent. The speed has been increased from 9 knots to 15, or even more. Lastly, the steam-pressure has been increased from less than 5lbs. to 70lbs. per square inch, while the consumption of coal has been brought down from 5 or 6lbs. per horse-power to less than 2. It is a remarkable fact that not only is our British shipping rapidly on the increase, but it is increasing relatively to that of the rest of the world. In 1860 our tonnage was 5,700,000 against 7,200,000; while it may now be placed as 8,500,000 against 8,200,000; so that considerably more than half the whole shipping of the world belongs to this country.

If I say little with reference to economic science and and statistics it is because time, not materials, are wanting.

I scarcely think that in the present state of the question I can be accused of wandering into politics if I observe that the establishment of the doctrine of free trade as a scientific truth falls within the period under review.

In education some progress has been made towards a more rational system. When I was at a public school, neither science, modern languages, nor arithmetic formed any part of the school system. This is now happily changed. Much, however, still remains to be done. Too little time is still devoted to French and German, and it

is much to be regretted that even in some of our best schools they are taught as dead languages. Lastly, with few exceptions, only one or two hours on an average are devoted to science. We have, I am sure, none of us any desire to exclude, or discourage, literature. What we ask is that, say, six hours a week each should be devoted to mathematics, modern languages, and science, an arrangement which would still leave twenty hours for Latin and Greek. I admit the difficulties which schoolmasters have to contend with; nevertheless, when we consider what science has done and is doing for us, we cannot but consider that our present system of education is, in the words of the Duke of Devonshire's Commission, little less than a national misfortune.

In agriculture the changes which have occurred in the period since 1831 have been immense. The last half century has witnessed the introduction of the modern system of subsoil drainage founded on the experiments of Smith of Deanston. The thrashing and drilling machines were the most advanced forms of machinery in use in 1831. Since then then there have been introduced the steam-plough; the mowing-machine; the reaping-machine, which not only cuts the corn but binds it into sheaves; while the steam-engine thrashes out the grain and builds the ricks. Science has thus greatly reduced the actual cost of labour, and yet it has increased the wages of the labourer.

It was to the British Association, at Glasgow in 1841, that Baron Liebig first communicated his work "On the Application of Chemistry to Vegetable Physiology," while we have also from time to time received accounts of the persevering and important experiments which Mr. Lawes, with the assistance of Dr. Gilbert, has now carried on for more than forty years at Rothamstead, and which have given so great an impulse to agriculture by directing attention to the principles of cropping, and by leading to the more philosophical application of manures.

I feel that in quitting Section F so soon, I owe an apology to our fellow-workers in that branch of science, but I doubt not that my short-comings will be more than made up for by the address of their excellent President, Mr. Grant-Duff, whose appointment to the Governorship of Madras, while occasioning so sad a loss to his friends, will unquestionably prove a great advantage to India, and materially conduce to the progress of science in that country.

Moreover, several other subjects of much importance, which might have been referred to in connection with these latter Sections, I have already dealt with under their more purely scientific aspect.

Indeed one very marked feature in modern discovery is the manner in which distinct branches of science have thrown, and are throwing, light on one another. Thus the study of geographical distribution of living beings, to the knowledge of which our late general secretary, Mr. Sclater, has so greatly contributed, has done much to illustrate ancient geography. The existence of high northern forms in the Pyrenees and Alps points to the existence of a period of cold when Arctic species occupied the whole of habitable Europe. Wallace's line—as it has been justly named after that distinguished naturalist—points to the very ancient separation between the Malayan and Australian regions; and the study of corals has thrown light upon the nature and significance of atolls and barrier-reefs.

In studying the antiquity of man, the archæologist has to invoke the aid of the chemist, the geologist, the physicist, and the mathematician. The recent progress in astronomy is greatly due to physics and chemistry. In geology the composition of rocks is a question of chemistry; the determination of the boundaries of the different formations falls within determination of the limits of geography; while palæontology is the biology of the past.

And now I must conclude. I fear I ought to apologise to you for keeping you so long, but still more strongly do I wish to express my regret that there are almost innumerable researches of great interest and impo,tance which fall within the last fifty years (many even among those with which our Association has been connected) to which I have found it impossible to refer. Such for instance are, in biology alone, Owen's memorable report on the homologies of the vertebrate skeleton, Carpenter's laborious researches on the microscopic structure of shells, the reports on marine zoology by Allman, Forbes, Jeffreys, Spence Bate, Norman, and others; on Kent's Cavern by Pengelly, those by Duncan on corals; Woodward on crustacea; Carruthers, Williamson, and others on fossil botany, and many more. Indeed no one who has not had occasion to study the progress of science throughout its various departments can have any idea how enormous—how unprecedented—the advance has been.

Though it is difficult, indeed impossible, to measure exactly the extent of the influence exercised by this Association, no one can doubt that it has been very considerable. For my own part, I must acknowledge with gratitude how much the interest of my life has been enhanced by the stimulus of our meetings, by the lectures and memoirs to which I have had the advantage of listening, and above all, by the many friendships which I owe to this Association.

Summing up the principal results which have been attained in the last half-century we may mention (over and above the accumulation of facts) the theory of evolution, the antiquity of man, and the far greater antiquity of the world itself; the correlation of physical forces and the conservation of energy; spectrum analysis and its application to celestial physics; the higher algebra and the modern geometry; lastly, the innumerable applications of science to practical life—as, for instance, in photography, the locomotive engine, the electric telegraph, the spectroscope, and most recently the electric light and the telephone.

To science, again, we owe the idea of progress. The ancient, says Bagehot, "had no conception of progress; they did not so much as reject the idea; they did not even entertain it.' It is not,' I think, now going too far to say that the true test of the civilisation of a nation must be measured by its progress in science. It is often said, however, that great and unexpected as the recent discoveries have been, there are certain ultimate problems which must ever remain unsolved. For my part I would prefer to abstain from laying down any such limitations. When Park asked the Arabs what became of the sun at night, and whether the sun was always the same, or new each day, they replied that such a question was childish and entirely beyond the reach of human investigation. I have already mentioned that, even as lately as 1842, so high an authority as Comte treated as obviously impossible and hopeless any attempt to determine the chemical composition of the heavenly bodies. Doubtless there are questions the solution of which we do not as yet see our way even to attempt; nevertheless the experience of the past warns us not to limit the possibilities of the future.

But however this may be, though the progress made has been so rapid, and though no similar period in the world's history has been nearly so prolific of great results, yet, on the other hand, the prospects of the future were never more encouraging. We must not, indeed, shut our eyes to the possibility of failure; the temptation to military ambition; the tendency to over-interference by the state; the spirit of anarchy and socialism; these and other elements of danger may mar the fair prospects of the future. That they will succeed, however, in doing so, I cannot believe. I cannot but feel confident hope that fifty years hence, when perhaps the city of York may renew its hospitable invitation, my successor in this chair—more competent, I trust, than I have been to do justice to so grand a theme—will have to record a series of discoveries even more unexpected and more brilliant than those which I have, I fear so imperfectly, attempted to bring before you this evening, for one great lesson which science teaches is, how little we yet know, and how much we have still to learn.

CORRESPONDENCE.

FRAUDULENT ALTERATION OF CHEQUES.

To the Editor of the Chemical News.

Sir,—In the Chemical News, vol. xliv., p. 25, it is stated that Messrs. Skipper and East have obtained from Messrs. Dupré and Hehner a process to prevent the fraudulent alteration of cheques, consisting in the use of a mixture of zinc sulphate and lead carbonate.

We beg to inform you that the process described is one which has been in use by us for years past, and that the patent is, therefore, anticipated.—I am, &c.,

Perkins, Bacon, and Co.

69, Fleet Street, August 30, 1881.

CHEMICAL NOTICES FROM FOREIGN SOURCES.

Note.—All degrees of temperature are Centigrade, unless otherwise expressed.

Moniteur Scientifique, Quesneville.
July, 1881.

Industrial Society of Mulhouse.—Session of June 8.—M. Witt gave a short notice of his researches upon the diamines, which have led to the discovery of two new colouring-matters, "neutral violet" and "neutral red," now manufactured by the firm of Casella, of Frankfurt.

M. Scheurer called the attention of the Committee to a note by M. Fergusson, presented to the Academy of Sciences February 28, 1881, on the antiputrescent properties of nitrous ether. This substance may be usefully employed for the preservation of solutions of albumen.

M. Prud'homme, on behalf of M. Romann, of Barcelona, presented a note on a new method of producing upon tissues metallic sulphides, and especially that of cadmium, by means of the xanthates.

Lectures by M. Georges Ville.—This distinguished agricultural chemist has been giving a course of lectures every Sunday, at 2 p.m., at his experimental field at Vincennes. He has undertaken the cultivation of a plot of 250 hectares, the better to illustrate his system, and to show French agriculturists how to encounter American competition.

Journal für Praktische Chemie.
No. 7, 1881.

Action of Phosphorus Oxychloride upon Potassium and Sodium Salicylates, Neutral and Basic.—R. Richter.—In this preliminary communication the author treats of a keton, $(C_{12}H_8O)CO$, melting at 170°, and of an isomer, melting at 91°.

Nos. 8 and 9, 1881.

My Share in the Development of Theoretical Chemistry.—H. Kolbe.—A continuation from No. 7.

The Compounds of Certain Solid Hydroxides with Acids, Salts, and Alkalies (Conclusion).—J. M. van Bemmelen.

Trimethyl Sulphine Salts.—Prof. Crum-Brown and A. Blaikie.—From the *Transactions* of the Royal Society of Edinburgh.

Green-stones.—T. Petersen.—This paper treats of melaphyr and its varieties.

Contributions to a Knowledge of the Chemical Composition of the Zygomycetes.—N. Sieber.—The albumenoids in these moulds differ little in quantity whether grown on gelatin or on sugar. The ash is very low in specimens produced on sugar and sal-ammoniac, where cellulose forms more than the half of the dry matter.

Phloron and Xyloquinon.—E. Carstanjen.—Phloron consists of two distinct and non-isomeric quinons, toluquinon and xyloquinon. The author finds that the quinon is derived from para-xylol, and is consequently a para-xyloquinon.

Conversion of Paramido-phenol into Tri- and Tetrachlor-quinon, also into Tri-chloramido-phenol and Tri-chlor-quinon-chlorimide.—R. Schmidt and M. Andresen.—A preliminary communication.

The Compounds of the Meconic Acid Group.—H. Ost.—An account of meconic acid, of certain derivatives of comenic acid, amido-comenic acid, oxy-comenic acid, comenamid, pyromecazonic acid, oxy-pyromecazonic acid, diacetyl-pyromecazonic acid, pyromecazon, and nitro-pyromecazon.

Anthology of Modern Chemical Utterances.—H. Kolbe.—Instances of confused and unintelligible language from the writings of modern chemists.

No. 10, 1881.

Contribution to a Knowledge of the Oil of Wine. E. C. Hartwig.—The author remarks that all existing researches on the oil of wine relate to a product obtained either by the distillation of the sulphethylates, or as a by-product from the preparation of ethylic ether from alcohol and sulphuric acid on the small scale. No examination has been made of the oil of wine obtained in considerable quantity during the technical preparation of ether. This oil proves to be essentially distinct, both from the "heavy" and the "light" oil of wine as examined by previous authorities. From the former it is distinguished by the absence of sulphur, and by its permanence when boiled with water or alkalies. From the latter it is distinguished by its variable composition, being a mixture of hydrocarbons, ethers, and ketons. Among hydrocarbons "di-iso-amylene," $C_{10}H_{20}$, was obtained. An ethyl-amin-ether was recognised in the fraction boiling between 110° to 120°. Two ketons were obtained in a state of purity, an ethyl-amyl-keton and a methyl-hexyl-keton.

Crystalline Albumenoids from Various Oil-Seeds.—H. Ritthausen.—The author has obtained crystalline albumen from the press-cake of hemp seed. Under the microscope it appears in well developed forms belonging to the regular system. Similar albumens were obtained from the press-cakes of castor oil and sesame.

Behaviour of Iodine with Arsenic Sulphide at Elevated Temperatures.—R. Schneider.—On cautiously heating a mixture of 107 parts arsen-disulphide and 127 parts iodine with exclusion of air, a compound is obtained of the composition AsSI.

Remarks on Lossen's Treatise, "On the Distribution of Atoms in the Molecule."—H. Kolbe.—The author shows the incomprehensibility of many of Lossen's views.

No. 11, 1881.

My Share in the Development of Theoretical Chemistry.—H. Kolbe.—Continued from the 8th and 9th number.

Determinations of Chemical Affinity (4th treatise).—Dr. W. Ostwald.—The relative affinity, $HCl : HNO_3$, has been repeatedly determined by the experiments of J. Thomsen and the author, and found = 0·98. With increasing dilution and temperature the proportional numbers approach this value more and more. The true affinity of sulphuric acid must be placed nearly equal to that of nitric or hydrochloric acid. By the formation of acid salts sulphuric acid appears always weaker than it really is. Its true affinity is still unknown, but must at least amount to 0·9 ($HNO_3 = 1$).

THE CHEMICAL NEWS.

Vol. XLIV. No. 1137.

ADDRESS TO THE CHEMICAL SECTION OF THE BRITISH ASSOCIATION.

By Prof. A. W. WILLIAMSON, Ph.D., LL.D., F.R.S., V.P.C.S., President of the Section.

On the Growth of the Atomic Theory.

It has been thought desirable that on the occasion of this half-centenary celebration of the foundation of this great Association some notice should be presented to the members of what has been doing in the respective branches of science during the period of our activity; and I have, accordingly, traced out for your consideration a very imperfect sketch of the theories which guided chemical inquiry at the beginning of that period, and of the leading changes which have been wrought in them by fifty years' work.

There is perhaps hardly any branch of science which during the last fifty years has made such great and steady progress as chemistry. Let anyone compare recent dictionaries of the science (including the bulky supplements, which contain a record of the chief discoveries made while the body of the work was being compiled) with a treatise of chemistry fifty years old. Let him compare a published record of one year's progress of the science fifty years ago with one of modern date. Let him compare, as far as may be possible, the number of men who formerly devoted their whole time and energy to the advancement of chemistry, or who were engaged in industrial pursuits involving a knowledge of the science, with the corresponding number nowadays. Let him count up the services which chemistry had rendered to common life at the commencement of the epoch with those which it has now to show.

Everywhere he will see marvellous evidences of increasing growth. But if he be a reflecting man, he will not be satisfied with wondering at results: he will endeavour to trace them to their causes, and to discover the guiding principles which have brought them about: he will try to derive, from a knowledge of those guiding principles, a perception of the means by which such progress can best be continued and extended—how it can be most effectively directed to the benefit of his fellow-men.

It is on this aspect of the question that I propose to address you to-day.

The process of scientific investigation includes a great variety of operations, which may be considered under three headings, mental, sensual, and physical. We think, we observe, and we work with our hands. In planning a new experiment we call to mind what is known of the phenomena in question, and form an opinion as to what is likely to happen under conditions somewhat different from those which existed in previous experiments. We regulate by careful observations the necessary manual operations, so as to obtain with accuracy the desired conditions for the new experiment, and we observe attentively the changes which take place in the course of that experiment. The result of such observations is sometimes in accordance with our anticipation, but very frequently at variance with it. If it accords with our anticipation, we put on record the extension which it has given to the application of the general theory on which that anticipation was founded. But if the result is not what we expected, we carefully and critically revise the reasoning which had led us to expect a particular result, and often repeat the same experiment with greater care, or some modification of it.

Materials for a new theory are gained when logically faultless reasoning, checked by accurate observations, have led to results which could not have been foreseen by the aid of any previous theory. When a theory has thus gained a footing in science, it serves as a guide in further work. It guides us in arranging known facts. It guides us to the discovery of new facts. Sometimes it does these things for a short time only, and is then superseded by some more general theory derived from a wider and more comprehensive view of the facts.

There is, perhaps, nowhere so severe and rigorous a test of the truth of an idea as that which is afforded by its use in any accurate department of experimental science; and it is worth while, on philosophical grounds, to consider briefly the conditions of growth of the chief chemical theories which have withstood this ordeal and proved themselves to be trustworthy guides in experimental science.

Now as far as I know them, the general theories which have played the chief part in the development of chemistry are mere condensed statements of fact.

Every thoughtful man of science has doubtless indulged in speculations to find the cause of facts which are as yet unexplained; has imagined some fundamental condition or property of matter which might cause it to produce effects such as are witnessed. It is to be hoped that the time may be far distant when men of science will confine their thoughts within the range of ideas which are proved to be true. But it is most important that they should not confuse such hypothetical speculations with theories which have received experimental verification, and that while employing any theory they should not lose sight of the limits within which it has been proved to be correct, beyond which it can only be used as a hypothesis.

The foundation of the science of chemistry was laid by the discovery of chemical elements; those distinct varieties of matter which we can neither produce nor destroy. Chemical science treats of those changes of property in matter which can be represented as due to changes of combination of elementary atoms. It knows nothing of the production or destruction of those elementary atoms. Speculations respecting their ultimate form or structure will have found a place in the science as soon as such speculations have helped to arrange the facts which are known, and to discover new chemical facts.

At the commencement of our epoch chemists had classified elements according to their electro-chemical properties. Chemical analysis had established the fact that a good many compounds could be represented as consisting of elementary atoms of two kinds combined in small number. Thus carbonic oxide and carbonic acid had been found to possess respectively a composition which could be represented (adopting our present atomic symbols) by the formulæ CO and CO_2, water by the formula H_2O, marsh gas CH_4, olefiant gas CH_2. The oxides and acids of nitrogen were represented by formulæ corresponding empirically to those which we now adopt. So also ammonia and hydric chloride had their present formulæ. Sulphurous and sulphuric acid had the respective formulæ SO_2 and SO_3. Phosphorus and phosphoric acid had the formulæ P_2O_3 and P_2O_5. Baryta and the oxides of iron had the formulæ BaO, FeO, Fe_2O_3.

Such primary compounds were classified upon the same principles which served for the classification of the elements themselves, into electro-positive or basylous and electro-negative or chlorous compounds, and the smallest quantity of each of them, which consistently with an atomic representation of the results of analysis, was deemed capable of existing, was called an atom of that compound.

Very simple compounds possessed of prominent characteristics and distinct reactions had first been isolated and identified. They were found to contain their constituent elements in proportions easily recognisable as multiples of atomic weights. But such simple compounds are rare exceptions among mineral and organic materials, and if

the atomic theory could have gone no further than to guide us to an understanding of these few simple compounds, it must soon have given place to some more fundamental conception. It is moreover worthy of notice that in this its most elementary form the atomic theory was not the only conceivable interpretation of the proportions of combination between elements. Those proportions could be as consistently represented by fractions as by integral multiples. Thus, instead of representing carbonic acid as containing twice as much oxygen as is contained in carbonic oxide, we might have represented it as containing the same quantity of oxygen combined with half as much carbon, and using for the moment atomic symbols for a non-atomic theory, we might have written carbonic acid thus $\frac{C}{2}O$. Or we might represent them both by percentage numbers.

It was so simple and natural to adopt the atomic hypothesis, and to represent compounds as built up of atoms, that chemists seem to have paid little attention to any other mode of representing the proportions of combination. They assumed that the variable proportions of elements, which were observed in compounds, were due to the various numbers of elementary atoms respectively aggregated together in each compound. They perceived that the existence of elementary atoms involved the existence of compound atoms, or molecules, as we now call them, and accordingly they represented each known compound of two elements by a molecular formula as simple as possible, consistently with the view of its atomic constitution. Many of these molecules, such as those of the acids, were found to be capable of combining with others of the other class, forming salts, and those combinations were found to take place in proportions corresponding to the weights of the respective molecules, or to very simple multiples of those weights, and the secondary compounds or salts thus formed combined (if at all) in proportions corresponding to simple multiples of their molecular weights. The dualistic representation of the constitution of salts served io represent the results of their analysis consistently with the atomic theory, and a vast number of fundamental facts were collected and arranged by the aid of the dualistic theory of combination.

The actual numbers obtained by analysis of any particular compound exhibited sometimes a very near approximation to those required by an atomatic formula of its composition. Sometimes they differed considerably from those required by theory; but it was always found that the more pure in substance and the more accurate the analytical operations, the more nearly did the result agree with some atomic formula of the substance.

The compound atoms were units which had grown out of the atomic theory. Each of them was the smallest quantity of a compound, which (consistently with the results of analysis) could be represented as built dualistically of its constituent atoms.

Chemical combination was viewed as a process of juxtaposition, of simple or compound atoms, little account being taken of the disturbance of the previous arrangement of those compound atoms. It was when a constitution, similar to that attributed to salts, was imagined for other compounds not saline in their character, that the dualistic theory broke down. Thus chlorocarbonic acid was represented as a compound of carbonic acid with carbonic chloride, and was accordingly designated as carbonate of carbonic chloride, while the formula was made to contain the formulæ of those bodies. Chlorosulphuric acid and chlorochromic acid were in like manner represented as compounds of sulphuric and chromic acid respectively with imaginary hexachlorides.

Careful investigations of the reactions in which chlorocarbonic acid takes part showed, however, that in each of them it behaves as a compound containing only two atoms of chlorine. It was found that the commonest and best known carbonates and sulphates have a fundamentally similar constitution. Thus potassic carbonate may be represented as a compound in which the two atoms of chlorine in phosgene are replaced by two atoms of the radica OK; and oil of vitriol, as a compound of two atoms of hydroxyl with the same group, SO_2, which in chlorosulphuric acid is combined with two atoms of chlorine. Chlorochromic acid has not been examined to as great an extent as the above compounds, but all we know of it points clearly to its having molecular constitution similar to that of chlorosulphuric acid, viz., Cl_2CrO_2, for not only do their vapour-densities agree, but the chromates in their constitution and crystalline forms exhibit a clear analogy to the sulphates.

Moreover, the simpler molecular formulæ, which a fuller knowledge of their chemical behaviour suggested for these bodies, were found in all cases to agree with the volume belonging to the molecule of every pure substance known in the state of vapour.

A difficulty of another kind had been foreseen by the great founder of the dualistic system, and it was by the investigations in organic chemistry that it assumed serious proportions.

Carbon compounds were discovered possessing definite and specific properties, and presenting the characteristics of pure substances, but of which the results of analysis did not agree with any simple proportion between the numbers of their constituent atoms. Their empirical composition could not be decided by the aid of the so-called law of multiple proportions, for two or more atomic formulæ required percentages of the constituents differing so little from one another that analysis could not decide which was the true one.

In order to select the true molecular formulæ of such complex substances from among those which approached most nearly to the results of ultimate analysis, and to determine with certainty their empirical composition, it was necessary to find other methods for the determination of molecular weights. It was necessary to study the various properties of compounds of known composition, and of others which could be prepared in a state of purity; to determine the vapour-densities and rates of diffusion of those which could be obtained in the gaseous state without decomposition; to determine boiling-points and melting-points; to examine crystalline forms of pure compounds and of mixtures; to determine solubilities and densities of solids and of liquids; but above all it was necessary to collect fuller and more accurate knowledge of the chemical changes which take place in the mutual reaction of molecules.

A vast amount of accurate and careful work of these kinds has been done, and has been subjected to rigid and often hostile scrutiny during the various steps of its progress. We now know that compound atoms, or molecules as we call them, which can be identified by their geometrical, mechanical, and other properties, are the same as the compound atoms indicated by the most comprehensive chemical evidences of composition and reactions. The molecular constitution of matter was predicted implicitly by the atomic theory of the constitution of the elements; and, wherever the physical properties of the molecules are such as afford any basis for the determination of their relative weights, such results agree with those derived from purely chemical consideration guided by the atomic theory.

Our knowledge of molecules is as yet in its infancy. Even among the commonest elements and compounds we know the molecular weights of very few, but what we do know of them proves that the idea of compound atoms invented by chemists to explain the elementary facts of chemical action is, as far as it goes, a true representation of what exists in nature.

Many of the molecules thus proved to exist were the same as those suggested under the dualistic system; but many were proved, by the more accurate and extensive knowledge of their reactions and properties, to have a different weight from that which had been at first attributed to them, yet always consistent with the fundamental requirements of the atomic theory. Thus H_2O, CO, CO_2, CH_4,

SO_2, SO_3, CaO, FeO, Fe_2O_3, are the formulæ still used to denote the molecules of the respective compounds, though the last three ought probably to be represented by some multiple. On the other hand, the molecule of olefiant gas is now represented by the formula C_2H_4, instead of CH_2. The chloracetate is $C_2Cl_3HO_2$, instead of C_2Cl_6, $C_2O_3H_2O$. The molecule of benzoil chloride is C_7H_5OCl, instead of one corresponding to $(C_7H_5)_2O_3$, $C_7H_5Cl_3$, and chlorosulphuric acid is Cl_2SO_2, instead of $2SO_3$, SCl_6.

In proportion as chemists came to know more of the constitution of molecules, and to study chemical reactions from the point of view of the changes which they bring about in the constitution of molecules, did the idea of substitution come to be more and more used in the place of that of mere additive combination. A vast number of processes of chemical combination, which had been considered as consisting of direct combination, were found to be processes of double decomposition.

One of the most important facts which was brought to light by the careful examination of the composition of salts and organic bodies, aided by the molecular method of representing their constitution, was that hydrogen is chemically one of the metals, and that the compounds formed by the combination of water with acids are analogous to other salts of those acids; while compounds of hydrogen with elements or radicals like chlorine are salts, analogous in their constitution to other chlorides, &c.

The molecular or unitary mode of viewing the constitution of each substance affords more *true* as well as more simple records of the facts observed in chemical reactions than could be obtained in the dualistic systems. A salt such as hydric sulphate used to be considered as containing sulphuric acid and water, and represented by a formula such as SO_3, H_2O, implying the presence in it of both the substances from which it was known to be formed.

When two elements combined, their product was considered and described as containing the elementary atoms which had served to form it, and it was consistent with this habit to represent a product which had been formed by the combination of two compound molecules as containing those molecules.

But the main business of chemical investigation is to observe accurately the changes of composition which take place in the reactions of known substances, with a view of discovering the atomic changes to which they are due.

The compound formed by the combination of sulphuric acid and water differs in many physical and chemical properties from both of those bodies. Its name and its atomic formula serve to denote the aggregate of properties which are known to belong to it, whereas the dualistic formula, SO_3, H_2O, served to recall the properties of the acid and base from which it was formed, rather than those of the compound itself.

Elementary chemical reactions which according to the binary mode of viewing compounds were supposed to consist of dualistic processes, involving sometimes the assumption of forces (like predisposing affinity) of a purely metaphysical character, were now explained as consisting of atomic displacements, or interchanges of a kind well known to be of common occurrence. Thus the evolution of hydrogen by the action of zinc or aqueous hydric sulphate was supposed to be the result of a decomposition of water by the metal, such decomposition being induced by the presence of the acid (SO_3), which exerted a predisposing affinity for the zinc oxide. Our present explanation is a simple statement of the fact that, under the conditions described, zinc displaces hydrogen from its sulphate.

The recognition and study of the metallic functions of hydrogen enabled chemists to obtain far clearer and simpler views of the constitution of salts, and to observe the differences of property which are produced in them by the replacement of one element by another. It enabled us to see more and more clearly the characteristic functions of each element, by comparing the constitution and properties of salts containing it with those of the corresponding salts containing other elements.

Thus in the dualistic system we had for the three common phosphates, PO_4NA_3, PO_4Na_2H, PO_4NaH_2, molecular formulæ in which sodium was represented with twice as great an atomic weight as that which we attribute to it, and which in our atomic weights may be thus represented, viz., P_2O_5, $3Na_2O$; P_2O_5, 2Na, O; P_2O_5, Na_2O. In like manner we had such a formula as P_2O_3, $2Na_2O$ (for the phosphite PO_3Na_2H), and for the hypophosphite PO_2NaH_2 we had a formula corresponding to P_2O, Na_2O.

Determinations of water of crystallisation and of chemically combined water proved that many of the compounds assumed on the dualistic system to exist are either not obtainable or have very different properties and a different constitution from those which have been described. Thus we now know that the salts PO_4Na_2H, PO_4NaH_2, PO_3Na_2H, and PO_2NaH_2 cannot be deprived of the elements of water without undergoing a fundamental change of composition and of properties.

The atomic weights of the alkali metals and of silver were found to be half of those of the dualistic system, and an atom of one of these metals, in common double decompositions between their salts and hydrogen salts, changes place with one atom of hydrogen.

Many products of the combination of known molecules were found to be formed by processes of double decomposition, so that each molecule of such products is built up partly of atoms derived from one of the materials, partly of atoms from the other. Thus potassic hydrate is formed by the combination of a molecule of potash with one of water. Yet each molecule of the hydrate is built up of half a molecule of potash and half a molecule of water.

The study of organic compounds played an important part in the improvement of our processes of reasoning. Many of their molecules having a very complex structure were found to undergo in most of their reactions very simple changes, of the same kind as those which mineral compounds undergo. Most of the elements of each organic molecule remained combined together with functions analogous to those of hydrogen or chlorine.

The theory of radicals which had been suggested by the reactions of ammonia-salts and of cyanides was largely extended in organic chemistry.

Many families of organic compounds were discovered, in each of which the members are connected by close analogy of constitution and of properties. Each of these families forms what is called a homologous series, each term of the series being a compound of which the molecule contains one atom of carbon and two atoms of hydrogen more than the previous term.

Thus a series of compounds was proved to have reactions similar to those of common alcohol, and molecular weights ranging from 32 to 438. The lower terms of the series are distinguished from one another by differences of boiling-points approximately proportional to the number of atoms of carbon and hydrogen by which they differ from one another; whilst the higher terms undergo decomposition at the higher temperatures required for their evaporation, and are distinguished from one another by differences of melting-points, that of the alcohol, $C_{30}H_{62}O$, being about 85° C. In their constitution these alcohols were found to be analogous to the alkaline hydrates.

In like manner various other series of alcohols were discovered corresponding respectively in their constitutions to other classes of metallic hydrates. Series were also found of which the members present analogies of reaction with monobasic, bibasic, tribasic hydrogen salts respectively.

These and many other such discoveries were made under the guidance of the atomic theory, developed to the point of systematically recognising and studying the mutual reaction of molecules.

One of the most remarkable and important extensions which our knowledge of molecules has undergone consisted in the discovery that various elements in what we are accustomed to consider the free state, really consist

of molecules containing like atoms combined with one another.

Thus chemists adopt the formulæ O_2, H_2, Cl_2, P_4, J_2, As_4, to denote molecules of the respective elements, and we have for these molecular formulæ evidences of the same kinds as those which serve to establish the molecular formulæ ClH, H_2O, NH_3, &c. In all the best-known reactions in which chlorine and hydrogen are either taken up or evolved we find that those elements behave as chemical compounds of two like atoms; and, moreover, their molecules, as determined from a study of their reactions, have the same volume as that of every compound molecule proved to evaporate without decomposition.

With this knowledge of the molecular constitution of hydrogen and of chlorine gases, we come to regard the direct formation of hydric chloride as due to a process of double decomposition between two molecules, like the reaction of chlorine on an equal volume of marsh-gas.

Many other reactions, such as the evolution of hydrogen by the action of zinc on a hydrogen salt, the liberation of chlorine and nitrogen on the explosive decomposition of their compound, the direct combination of oxygen and hydrogen, we may expect to be able to resolve into mere processes of double decomposition.

The earliest determinations of combining proportions were made with salts (hydrogen salts and others) which undergo double decomposition by mutual contact, and the term equivalent was subsequently introduced to indicate the proportional weights of analogous substances found to be of equal value in their chemical effects. Tables of equivalent weights of acids consisted of numbers standing to one another in the same proportions as the weights of the respective substances found to be of equal value in neutralising a fixed quantity of a particular base; and in like manner tables of the equivalent weights of bases recorded the proportions by weight in which certain bases might replace one another in the neutralisations of a particular quantity of a given acid. Similar determinations have been tabulated of the so-called equivalent weights of elements. Under the dualistic system chemists paid little attention to the essential difference between atomic weights and equivalent weights; and some were of opinion that the facts of chemistry might be represented as consistently from the point of view of equivalence as from that of atoms, and that the idea of atoms (which they considered to be hypothetical) might be dispensed with.

In the system of atomic weights employed under that system, two atoms of hydrogen were generally represented as reacting together, and the symbol of the double atom was marked thus, $\overline{H}\overline{H}$. The alkali metals and silver were represented as having atomic weights twice as great as those which we now adopt, and equivalent to those of the magnesian metals and of oxygen. In a great number of the common reactions of these elements the atomic symbols were consistently used as equivalent symbols. But those who professed to dispense with the atomic theory used atomic symbols, even in cases where they did not represent equivalent weights. Thus nitrogen was always represented by its atomic symbol, and the composition and reactions of nitrogen compounds were always studied and represented in accordance with the atomic theory, using various multiple proportions of what they were still pleased to call equivalent weights, using molecular weights, and various other ideas which formed part of the atomic theory, and which had no known connection with the notion of fixed equivalence. If, however, it be true that all chemical compounds consist of elementary atoms, and that the explanation of chemical reactions consists in stating more and more precisely the changes of combination between the constituent atoms of the reacting molecules; equivalence could only be said to exist between a like number of atoms when they were known to have similar functions. It became necessary to study the relation of equivalence between elementary atoms, instead of studying them from the point of view of elements divisible in any proportion.

It is worth while noticing the general process by which this intellectual change was brought about; for there is a good deal yet to be done in the matter, and our future progress may be guided by experience gained in the past.

It was essentially one-sided. One consideration was brought into very prominent relief, and it threw a marvellous light on the matter. It gave us a clear view of the natural order among elements; but, like every other strong light, it fell on one side only.

The equality of vapour-volumes had been used with great advantage in conjunction with chemical reactions and other evidence as a characteristic of molecules, and the attention of chemists was greatly arrested by the consideration of four typical compounds, which upon the concurrent evidence of very extensive chemical examination and equality of vapour-volumes were known to have respectively a composition corresponding to the formulæ, ClH, OH_2, NH_3, CH_4.

It was known that the atom of oxygen in water can be replaced by chlorine, but that two atoms of chlorine are needed for the purpose. The atom of nitrogen in ammonia requires three atoms of chlorine to replace it, whilst in marsh-gas the atom of carbon is replaceable by four atoms of chlorine. Other elements were studied from the point of view of their respective resemblance to these, and arranged in classes, each of which consisted of atoms equivalent to one another. Thus chlorine, bromine, iodine, fluorine, hydrogen, potassium, sodium, lithium, silver, &c., constituted a class of atoms of equal value, and were called monads. Oxygen, sulphur, selenium, tellurium, calcium, strontium, barium, magnesium, zinc, cadmium, mercury, lead, copper, &c., were classed together as dyads, having equal value amongst themselves, but double the atomic value of the members of the first class. So nitrogen, phosphorus, arsenic, antimony, bismuth, with boron, and some other elements, were considered as forming a class of atoms each of which has three times the value of the monads. The class of tetrads contained carbon, silicon, tin, platinum, &c.

Many apparent exceptions to these atomic values were satisfactorily explained as due to the partial combination of like atoms with one another. Thus in the vast majority of hydrocarbons, such as C_2H_6, C_2H_4, C_2H_2, &c., the atoms of carbon do not appear to the tetravalent, inasmuch as each of the molecules contains less than four atoms of hydrogen to every one atom of carbon. It was well known, however, that polyvalent atoms can combine partly with one element, partly with another, and also that like atoms can combine with one another. Why then should not two tetravalent atoms like carbon combine respectively with three atoms of a monad, and also combine with one another? The compound must be a single molecule with the properties known to belong to methyle, C_2H_6. Again, if this molecule were deprived of two of its atoms of hydrogen, each of the atoms of carbon must combine further with the other atom of carbon forming H_2CCH_2; and a further step in this same direction would give us acetylene, HCCH, in which each atom of carbon is combined with the other to the extent of three-quarters of its value, and with one atom of hydrogen. An extension of this reasoning led to the discovery of long chains of atoms of carbon, each atom forming a link, and each of them (short of the ends) being combined with two other atoms of carbon, while its saturation is completed by hydrogen.

Similar partial combinations of like atoms with one another were recognised in many other classes of compounds, and there is strong reason to expect that the application of the principle will be far more widely extended in proportion as our knowledge of the silicates and other complex classes of compounds becomes somewhat definite.

This incorporation of the doctrine of equivalence into the atomic theory by the division of the elements into classes consisting respectively of equivalent atoms, was probably one of the most important general steps as yet

made in the development of the atomic theory. It was seen to correspond in so clear and striking a manner with a vast number of well known properties and reactions of compounds as to deserve and acquire the confident trust of chemists. But, as often happens in such cases, this confidence in the result carried many of them too far. It led them to assume that atomic values in all other chemical compounds must be always the same as in the compounds under consideration. They saw that they had got hold of the truth, and they thought it was the whole truth. For instance, one most distinguished chemist assumed that each elementary atom has only one value in its compounds; that the atom of nitrogen has always the value three, as in ammonia and its products of substitution, and that in sal ammoniac the atom of nitrogen is chemically combined only with three atoms of hydrogen, whilst the molecule of ammonia is in a state of molecular combination with hydric chloride. Another most distinguished chemist admitted that nitrogen and phosphorus have two atomic values, but not more than two. He held that the respective combining powers are always satisfied by the same number of atoms, no matter what the character of the uniting atoms may be.

With respect to these views it may be noticed that the assumption of combination between molecules as due to some other force than that which binds together the constituents of each molecule—in fact the assumption of molecular combination as an unknown something different from chemical combination, is open to even more grave objections than those which led us to abandon the dualistic system.

To represent a molecule of sal ammoniac as a compound containing two molecules, each one built up by the chemical combination of the constituent atoms, and the two united together by some other force called molecular, was hardly a step in advance of the view which represented it as containing two molecules united together by the same kind of force as that which holds together the atoms in each of the constituent molecules.

The other form of the theory of atomicity as an inherent property of each atom enabling it to combine with an equal number of other atoms, whatever the character of those other atoms may be, seems difficult to reconcile with such facts as the following:—An atom of nitrogen is not known to combine with more than three atoms of hydrogen alone, or of substances like hydrogen, but it forms stable compounds with five atoms (as in the ammonia salts), when four of them are basylous and one of them is chlorous. An atom of sulphur is not known to combine with more than two atoms of hydrogen alone, but it forms stable compounds with four atoms, if three of them are like hydrogen, while the fourth is chlorous. Instances like these are plentiful, and they lead us to look to the chemical characters of the atoms bound together in one molecule as a fundamental condition of the atomic value of the element which binds them together.

Theoretical limitations of natural forces are very difficult of proof, and it is well to be slow and cautious in adopting any such limitation.

A careful consideration of the facts of the case has led me not only to doubt the validity of the supposed limits of atomic value, but to doubt whether we have grounds for assigning any limits whatever to such values.

Atomic values appear to me to be in their very nature variable quantities, and I venture to think that chemistry will be greatly advanced by a full and careful study of the conditions of variation of atomic values.

Two conditions of change of atomic value are particularly worthy of notice:—

I. Temperature.

II. The chemical character of the uniting atoms.

Atomic values increase with fall of temperature, and diminish with rise of temperature. An atom which is combined with as many basylous monads as it can take up by themselves, will take up chlorous monads, or both chlorous and basylous, and reciprocally.

In illustration of the diminution of atomic values with rise of temperature, I may adduce the following well-known reactions:—Sal ammoniac containing nitrogen combined with five monads breaks up at a high temperature into ammonia and hydric chloride; and in like manner other ammonia salts decompose by heat forming ammonia or an amide, with trivalent nitrogen. The highest chlorides of phosphorus and of antimony are decomposed by heat into free chlorine and the lower chloride. Potassic fluosilicate is decomposed by heat into silicic and potassic fluorides; and carbonic acid breaks up at high temperatures into a mixture of carbonic oxide and oxygen.

Amongst illustrations of the greater atomic values which elements assume by combining with both chlorous and basylous atoms than with atoms of the one kind only, we may take the following cases:—Platinum is a metal of which the atom has been supposed to be always tetravalent, because it has not been found capable of combining with more than four atoms of chlorine. The common solution formed by aqua regia contains the compound H_2PtCl_6, a perfectly definite and crystallisable hydrogen salt. Chemists are constantly making and using the potassium and ammonium salts, &c., corresponding to it, yet they conceal from themselves the fact that the atom of platinum is directly combined with eight monads by calling the compounds double salts. The atom of silicon in the silico-fluorides such as H_2SiF_6, or K_2SiF_6, is combined with twice as many monads as it can take up of one kind; so boron, in the crystalline salt, $NaBF_4$, has a higher atomic value than in its fluoride, owing to the presence of the atom of sodium.

In like manner the atom of gold in the well-known salt $NaAuCl_4$, has a higher value than it can assume with chlorine alone.

Sulphur, of which the atom does not combine with more than two atoms of hydrogen, forms with three atoms of methyle, or ethyle, and one atom of iodine, or chlorine, &c., the well-known compounds like $JSMe_3$; and iodine, which is considered a monad, forms the crystalline and stable periodate, $OJ(OH)_5$, and the various metallic derivatives, such as—

$$OJ\begin{matrix}ONa\\(OH)_4\end{matrix} \qquad OJ\begin{matrix}(ONa)_2\\(OH)_3\end{matrix} \qquad OJ(OAg)_5$$

The crystalline compound of the perchlorate with water $(HClO_4 2H_2O)$ has probably a similar constitution. Chemical journals abound with descriptions of definite and well-characterised compounds, which have, like the above, been put aside by the atomicity theory, as mere molecular compounds. The following formulæ are taken almost at random, in illustration of the generality of atomic values far beyond those acknowledged by the theory of atomicity:—

$JPCl_6$	K_2FeF_4	K_2SnCl_6
$KAsF_6$	$2(K_2FeCl_5)$	$KHgJ_3$
K_2AsF_7	$2(K_3FeF_6)$	$K_2HgJ_4 4H_2O$
$KSbF_6$	K_2CuCl_4	$KHgCl_3$
K_2SbCl_5	K_2CuF_4	K_2HgCl_4
K_2SbF_7	$KMgCl_3$	
K_2BiCl_5	K_2MgBr_4	
K_2AgJ_3		

I have for convenience written in the middle of each of these formulæ the symbol of the atom which I assume to act as connecting element. If we consider the atomic values usually found in these elements, together with those represented by the above list, we see that their atomic values vary according to the numbers given in a line with them respectively in the following table. It has yet to be proved that the atom of platinum is tetravalent in any known compound, for there is no sufficient evidence to show that platinic chloride has a molecular weight corresponding to the formula $PtCl_4$, instead of one corresponding to Pt_2Cl_8, each atom of platinum being partly combined with the other, partly with chlorine.

Bi	3, 7
Au	3 (?), 5

Not only are there elements of which an atom is found in combination with a greater number of basylous and chlorous monads together than of either kind alone, but there are also elements which are not known to form chemical compounds with hydrogen or potassium alone, and yet which combine with either of them when also combined with chlorine, fluorine, &c. This is illustrated by the following compounds, viz., $HAuCl_4$, H_2PtCl_6, $NaBF_4$, K_2SiF_6, K_2FeF_4, K_2CuCl_4. It is also well known that there are many cases of elements of which an atom cannot combine with as many monads of one kind as of another. For instance an atom of nitrogen or of antimony is only known to be trivalent in combination with hydrogen; but each of them occurs in the form of a pentavalent compound with chlorine. Antimony forms either no compound with five atoms of bromine, or a compound more unstable than the higher chloride.

Many more such instances might easily now be given, and a vast number will doubtless be found when the investigations of chemists are directed to the search of them. I have only given these few by way of illustration of the leading conditions of change of atomic values.

In the course of their investigations of the precise interchanges of atoms which take place between molecules, chemists were frequently led to observe evidences of the order in which the constituent elements are combined; and with the more wide and accurate knowledge of reactions which is now in their possession, they have been enabled to follow up so far the study of the respective state of combination of each atom in a molecule as to arrive at simple and consistent explanations of facts which had previously eluded the grasp of science.

Our knowledge of the order of combination of atoms in a molecule and of the differences between direct and indirect combinations of particular atoms may be said to have originated chiefly in the study of the compounds of nitrogen. Thus it was found that the hydrogen in ammonia differs in many of its chemical functions from hydrogen in hydrocarbons. A base (called methylia) was discovered having a molecular composition corresponding to the empirical formula (CNH_5), and this base was found to contain two atoms of hydrogen like those of ammonia, and three atoms like those in hydrocarbons. Its constitution was accordingly represented by a formula describing it as an ammonia, in which one atom of hydrogen is replaced by the monad methyle, or, to be more explicit, as containing two atoms of hydrogen directly combined with nitrogen, and three atoms of hydrogen indirectly combined with that same atom of nitrogen through the intervening atom of carbon. Writing in juxtaposition to one another the symbols of those atoms which are directly combined, we can express the facts by the following formula, viz., H_2NCH_3.

Those marvellous varieties of matter called isomeric compounds found their natural explanation in differences of the respective arrangements of like atoms. Thus two bases were discovered having the same empirical molecular formula, C_2NH_7. One of them is made by different reactions from the other, and in its decompositions differs from the other. All these chemical differences between them are found to be due to the fact that one of them (called ethylia) contains two atoms of hydrogen directly combined with the nitrogen, and the monovalent hydrocarbon ethyle in place of the third atom of hydrogen; whilst the other (called dimethylia) contains only one atom of hydrogen combined directly with nitrogen, the carbon of the two atoms of methyle completing the saturation of the trivalent nitrogen, as expressed by the formula $HN(CH_3)_2$.

It was subsequently proved that an atom of oxygen may combine with two like or unlike monads, such monads being indirectly combined with one another through the intervening atom of oxygen. Thus five of the atoms of hydrogen in common alcohol were proved to be in direct combination with the carbon, whilst the other one is indirectly combined with it through the oxygen, as expressed by the formula $HO(C_2H_5)$.

Another compound (called methyl-oxide) was proved to have the same empirical composition, but very different properties and reactions, its constitution being explained by the formula H_3COCH_3.

Again, two compounds of distinct reactions and properties were found to have the same empirical molecular composition, C_2NH_3, and it was clearly proved that in one of them the two atoms of carbon are directly combined thus, $NCCH_3$, whilst in the other they are indirectly combined through the atom of nitrogen, $CNCH_3$.

An immense amount of admirable work has been done of late years (especially in Germany) in working out the evidences of the atomic order of complex organic bodies, and in thereby obtaining a command of their reactions.

Evidences of the same kind have been obtained of the atomic arrangement of some few of the simplest inorganic bodies, and it is to be hoped that ere long chemists will recognise the importance of examining the constitution of salts with the aid of the principles established in organic chemistry.

The foundation is already laid by our knowledge of the constitution of such compounds as—

$$HOH,\ HOK,\ HONH_4,\ HONO_2$$
$$HOPbOH,\ HOPbONO_2,\ HOCOK,\ HOSOH$$
$$O \qquad O_2$$

and there is a strong probability regarding the atomic constitution of many other water compounds, *e.g.*,—

$$SO_4H_2+H_2O=OS(OH_2)_4, SO_5H_4+H_2O=S(OH)_6.$$

Amongst the extensions of our means of examining the physical properties of matter, and thereby discovering new varieties of matter for chemical investigation, spectrum analysis has played an important part, and is no doubt destined to do far more. It has already led chemists to the discovery of several previously unknown elements, and has led to the detection of various known elements in distant masses of which we had previously no chemical knowledge.

Up to this point the growth of the atomic theory will be seen, from the general outline which I have endeavoured to trace, to have consisted mainly in the more and more full and exact identification of each elementary atom, and in the accumulation of more and more varied and accurate evidences of its functions in relation to other atoms. A step was made towards a knowledge of the general relations of atoms to one another by their preliminary classification according to their best-known values.

But a far greater step has been more recently made, one which is evidently destined to lead to most important results.

It was discovered that if we arrange the elements in the empirical order of their respective atomic weights, beginning with hydrogen and proceeding thence step by step to the heaviest atom, we have before us a natural series with periodically recurrent changes in the chemical and physical functions of its members.

Of course the series is imperfect, and exhibits gaps and

irregularities; but what view of natural order was complete in its infancy?

Some of the gaps have already been filled up by the discovery of elements possessing the anticipated properties. The generalisation affords a brilliant addition to the previous corroborations of the reality of the units of matter which chemists have discovered.

Chemists have as yet taken but little account of atomic motions; although the most perfect explanation of a chemical reaction consists of a statement of the atomic interchange which takes place between two molecules; or the change of mutual combination between the atoms in one molecule.

It has, however, been proved that the heat of combination affords a measure of its force; and we know that in giving off heat particles of matter undergo a diminution of velocity of motion. We see, accordingly, that substances capably of exerting great force by their combination are those which can undergo a great diminution of the velocity of their internal motions, and reciprocally.

The force of chemical combination is evidently a function of atomic motion.

It has been shown that the relative velocities of certain atomic interchanges afford a measure of the amount of chemical action between two substances; but a vast amount of work will doubtless be required to develop the atomic theory to the point of explaining the force of chemical action in precise terms of atomic motion.

The general terms of chemistry are mere symbols. Each of them serves to recall a group (usually a very large group) of facts established by observation. The explanation of each term is afforded by a careful study of the facts which it is used to denote; and, accordingly, a chain of evidence involving the use of chemical terms can be fully understood only by chemists accustomed to the consideration of such evidence. The general outline of it may perhaps be to some general thinkers of sufficient interest to attract them to further study of our science.

ESTIMATION OF POTASSIUM AS PLATINUM SALT.

By DAVID LINDO.

(Concluded from p. 98.)

On the Solubility of Platino-potassic Chloride.

The question as to the amount of loss sustained by washing through the solvent action of alcohol or spirit of wine on the precipitate had often occurred to me in the course of this enquiry.

The solubility of platino-potassic chloride has been very variously stated by different authors. Fresenius in his latest edition of "Quantitative Analysis" gives it as—

1 part in 12083 absolute alcohol.
" 3775 spirit of wine, 76 per cent.
" 1053 spirit of wine, 55 "

Dr. Precht (Chemical News, vol. xli., p. 11)—

1 part in 42600 absolute alcohol.
" 37300 spirit of wine, 96 per cent.
" 26400 spirit of wine, 80 "

Not having seen the original paper by Precht, I am uninformed as to the manner in which the experiments were conducted. It does not appear that any experiments have been made by Fresenius later than those adduced in support of his statements in the older editions of his work on Quantitative Analysis. On reference to these it will be found the condition of the salt—whether it was in crystals or in the pulverulent state—is not mentioned. The digestion in the menstruum was continued for six days with frequent agitation. It does not appear that shorter or onger periods of digestion were tried as a control to the results obtained in these experiments. It is probable that in the case of a substance so sparingly soluble, very prolonged contact with the solvent—at least at ordinary temperatures—will be required in order to reach the point of saturation. Be that as it may, a digestion of six days in alcohol or spirit of wine is not resorted to in analysis for the purpose of washing the precipitate: therefore, these experiments, however valuable they may be for the purpose of ascertaining the absolute solubility of the salt, will not exactly serve the needs of the present enquiry, the purpose of which is to ascertain as *nearly as possible* the loss sustained by washing the precipitate.

That we can only estimate this approximately is sufficiently obvious. The plan adopted in the experiments that follow (which of course were made while the other work was going on) was to submit the precipitates obtained in the analyses (after the latter were concluded and the results recorded) to a further washing with the fluids, the solvent action of which was to be tested. The precipitates were then dried again at 130° C., and weighed again. Before the precipitates were submitted to this treatment the weights were always verified. The pressure employed was the same as I used for filtering in the analyses, and equal to about 14 inches of mercury. The temperature of the laboratory during the experiments ranged from 26° to 30° C. The same balance was used as I employed in all my other experiments. It is a very fine Oertling, and marks 0·0001 grm. distinctly. The method of weighing has been already described. I have not placed the experiments in the order in which they were made, but grouped them together more in accordance with what they are intended to illustrate.

Every care was taken in making these experiments, yet where such small differences of weight have to be noted some allowance must be made for occasional slight observational errors. I am quite confident, however, that if the experiments to be described are repeated by others with care, the results on the whole will be found to agree with those I have recorded.

Abbreviations Employed.

S.W.—Spirit of wine 80 per cent.
Alcohol.—98 per cent strength.
D. and W.—Dried at 130° and weighed.
Pre.—Precipitate from.
Expt.—Experiment.
Passed.—Allowed the fluid to run through the precipitate under pressure of the filter-pump.

The per cent return which the precipitate selected for experiment had yielded, and its condition, whether in scales or powder, will be stated.

No. 1.—Pre. Expt. 14. Weight 0·8812. Scales. 99·89 per cent. Passed 100 c.c. S.W. D. and W. Loss, 0·0009. Passed 100 c.c. alcohol. D. and W. Further loss, 0·0001. Passed a fresh 100 c.c. alcohol. D. and W. Further loss, 0·0001.

No. 2.—Pre. Expt. 94. Weight 1·5386. Scales. 99·90 per cent. Passed 20 c.c. alcohol five times. D. and W. No loss.

No. 3.—Pre. Expt. 95. Weight 1·6624. Scales. 99·87 per cent. Passed 20 c.c. alcohol five times. D. and W. No loss.

No. 4.—Pre. Expt. 98. Weight 1·4760. Scales. 99·68 per cent. Passed 100 c.c. alcohol *five times*. D. and W. Loss, 0·0001.

No. 5.—Pre. Expt. 102. Weight 1·9260. Scales. 99·85 per cent. Passed 100 c.c. alcohol *five times*. D. and W. Loss, 0·0002.

No. 6.—Pre. Expt. 100. Weight 1·7800. Scales. 99·83 per cent. Passed 20 c.c. alcohol five times. D. and W. Loss, 0·0004.

No. 7.—Pre. Expt. 101. Weight 1·7495. Scales. 99·70 per cent. Passed 20 c.c. alcohol five times. D. and W. Loss, 0·0003.

These two last precipitates (obtained by Tatlock's method) had been digested in a very strong solution of platinic

chloride, from which they do not appear to have been quite free.

No. 8.—Pre. Expt. 44. Weight 0·9359. Powder. 99·93 per cent (?). Passed 100 c.c. S.W. D. and W. Loss, 0·0028. Passed 100 c.c. alcohol. D. and W. Further loss, 0·0002.

No. 9.—Pre. Expt. 45. Weight 0·9656. Powder. 100·08 per cent (?). Passed 100 c.c. S.W. D. and W. Loss, 0·0034. Passed 100 c.c. alcohol. D. and W. Further loss, 0·0002.

No. 10.—Pre. Expt. 57. Weight 0·9491. Powder. 99·90 per cent. Passed 20 c.c. alcohol five times. D. and W. Loss, 0·0001. Passed 20 c.c. S.W. five times. D. and W. Further loss, 0·0004.

No. 11.—Pre. Expt. 61. Weight 0·9252. Powder. 99·96 per cent. Passed 20 c.c. alcohol five times. D. and W. Loss, 0·0002. Passed 20 c.c. S.W. five times. D. and W. Further loss, 0·0008.

No. 12.—Pre. Expt. 62. Weight 0·8059. Powder. 100 per cent. Passed 20 c.c. alcohol five times. D. and W. Loss, 0·0003. Passed 20 c.c. S.W. five times. D. and W. Further loss, 0·0008.

No. 13.—Pre. Expt. 63. Weight 0·8142. Powder. 100·03 per cent. Passed 20 c.c. alcohol five times. D. and W. No loss. Passed 20 c.c. S.W. five times. D. and W. Loss, 0·0005.

No. 14.—Pre. Expt. 70. Weight, 1·0188. Powder. 99·89 per cent. Passed 20 c.c. alcohol five times. D. and W. No loss. Passed 20 c.c. S.W. five times. D. and W. Loss, 0·0005.

From these results we may conclude—

(1) That when the precipitate (whether in scales or powder) is washed with absolute or very strong alcohol there will be practically no loss, and therefore that we need not be *afraid* to wash it.

(2) That when it is in scales and washed with 80 per cent spirit of wine there will be a small loss.

(3) That when it is in powder and washed with 80 per cent spirit, the loss may be sufficient to affect the results sensibly.*

It will be noticed that the precipitates selected for the above experiments were such as, from the results of the analyses that had yielded them, might be considered pure or very nearly so. A few experiments on precipitates from analyses that had yielded high results will now be described.

No. 15.—Pre. Expt. 52. Weight 0·7966. Scales. 100·19 per cent. Passed 20 c.c. alcohol five times. D. and W. Loss, 0·0014. Passed a fresh 20 c.c. alcohol five times. D. and W. Further loss 0·0002.

First washing reduced weight to 0·7952 = 0·24301 KCl, against 0·24298 taken.

No. 16.—Pre. Expt. 53. Weight 0·8496. Scales. 100·12 per cent. Passed 20 c.c. alcohol five times. D. and W. Loss, 0·0014. Passed a fresh 20 c.c. alcohol five times. D. and W. Further loss, 0·0002.

First washing reduced weight to 0·8482 = 0·25921 KCl, against 0·25932 taken.

It is pretty evident that the impurities in these precipitates had been retained by surface adhesion, although in the *analyses* the alcohol that had been used to wash with measured 59 c.c. in Expt. 52 and 62 c.c. in Expt. 53.

No. 17.—Pre. Expt. 54. Weight 0·7797. Scales. 100·22 per cent. Passed 20 c.c. alcohol five times. D. and W. Loss, 0·0007.

No. 18.—Pre. Expt. 60. Weight 0·8149. Powder. 100·12 per cent. Passed 20 c.c. alcohol five times. D. and W. Loss, 0·0005. Passed a fresh 20 c.c. alcohol five times. D. and W. Further loss, 0·0002.

No. 19.—Pre. Expt. 81. Weight 0·6884. Powder. 100·12 per cent. Passed 20 c.c. alcohol five times. D. and W. Loss, 0·0006.

* Having abandoned the use of dilute alcohol for washing the precipitate, I have not gone into the necessary calculations for ascertaining the correction required when this fluid is employed. A larger number of experiments than the above would be required to arrive at this even approximately.

Notes.

So far, my experiments have been confined to the estimation of K when in the state of pure chloride, or in mixtures of pure chlorides of K and Na. As regards its estimation in sulphate of potassium, if sufficient HCl and platinic chloride are employed, the reaction—

$$K_2SO_4 + 2HCl + PtCl_4 = K_2PtCl_6 + H_2SO_4$$

may be expected to occur. If the reaction is complete there will be nothing to remove from the precipitate that alcohol is not capable of dissolving, and resort to aqueous fluids in washing is therefore unnecessary. If the reaction is not complete, of course we cannot obtain accurate results, however we may wash. With an aqueous fluid we should lose a portion of potassium as sulphate, and if alcohol alone were used we should be weighing a portion of K as sulphate, and calculating it as chloro-platinate.

Nitrate of potassium may be converted into KCl by repeated evaporation with HCl, but I quite agree with the Committee that it is difficult to complete the reaction. In one experiment, seven evaporations on the water-bath with excess of strong HCl proved insufficient to effect complete conversion. If NaCl and $PtCl_4$ are employed—as suggested by the Committee—to produce the reaction $2KNO_3 + 2NaCl + PtCl_4 = K_2PtCl_6 + 2NaNO_3$, nitrate of sodium has to be removed from the precipitate, and alcohol of course will not remove it.

Commercial potassium salts often contain sulphate of magnesium and sulphate of sodium. If the former is mixed with HCl and excess of $PtCl_4$, and evaporated nearly to dryness, magnesium chloro-platinate may be formed; but although this salt is largely soluble in alcohol, on adding that fluid a precipitate subsides, either immediately or after a time, being sulphate of magnesium which has partially or completely re-formed. There is little doubt but that the same thing would occur with sulphate of sodium.

Unless we can find a fluid that will dissolve out these sulphates without acting on the chloro-platinate of potassium, we must—as is generally admitted—either remove the sulphuric acid before precipitating the potassium if we wish to weigh as platinum salt, or reduce in hydrogen and weigh the platinum.

I have found that the chloro-platinate of potassium is very sparingly soluble in solutions of certain salts, remarkably so in a solution of chloride of ammonium.

My experiments as yet have been principally confined to a solution of chloride of ammonium about half saturated, made by saturating distilled water with the salt at ordinary temperature, and mixing this with an equal volume of water. If the chloro-platinate is even boiled in this solution it imparts no colour to it—or practically none—unless the boiling is continued for a long time, say one to two hours, when a faint yellow tinge is observed. Probably by this protracted boiling slight decomposition takes place.

In order to estimate roughly the solubility of the chloro-platinate in this solution, I made a saturated aqueous solution of the platinum salt first, and evaporated a weighed portion in a platinum dish to dryness on the water-bath. The residue was then moistened with alcohol, again evaporated to dryness, and weighed. It was thus found that 83 parts of this aqueous solution contained one part of the chloro-platinate. Small portions of this solution were then weighed in a beaker, and 10 c.c. of the solution of the chloride of ammonium added in each case. The mixture was then transferred to a test-tube and shaken up. It was found that when a quantity of the aqueous solution of chloro-platinate equal to about 0·001 grm. of the salt was added to 10 c.c. of NH_4Cl solution no preci-

pitate formed, even after standing several hours; but when about 0·002 grm. of chloro-platinum was added to 10 c.c. of NH_4Cl solution, a precipitate, plainly visible with a lens, formed in a few seconds.

The quantity of chloro-platinate which 10 c.c. of NH_4Cl solution of the strength employed can hold in solution may therefore be roughly stated as 0·0015 grm.

It was thought this solution of NH_4Cl might be rendered available for the purpose of washing the sulphates and nitrates out of the precipitate in the analysis of commercial potassium salts by the platinum method. With ordinary care and attention to cleanliness there would be no risk in using it.

It was intended to use about 20 c.c. of the solution in each analysis, and to pass this several times through the precipitate If the solution thus became saturated with chloro-platinate, a loss of about 0·003 grm. would occur, affecting the results sensibly.

But it is very easy to avoid this loss by saturating the NH_4Cl solution previous to using it in the analyses with the minute quantity of chloro-platinate which it is capable of dissolving. This may be effected by adding some of the chloro-platinate to the solution of NH_4Cl, and heating with frequent stirring just to boiling; or if the solution is not immediately required for use, by keeping a small quantity of the chloro-platinate in scales in the bottle containing the NH_4Cl solution, and shaking occasionally. In either case it is advisable to keep some of the platinum salt in the bottle containing the solution, and filter a portion of the latter as required for use.

The time at my disposal for trying chemical experiments being very limited, I have only been able as yet to make ten estimates by this method. The KCl was mixed with 25 per cent of sulphate of magnesium (crystals) and 10 per cent of chloride of sodium.

The precipitates in these experiments were not crushed, but they were first *thoroughly* washed with 98 per cent alcohol by running the last washings through five times. The receiver was then changed, and 20 c c, of the NH_4Cl solution prepared as above passed through five times. The alcoholic washings having been removed from the first receiver, this was again placed in position, and 25 c.c. of 80 per cent spirit of wine passed through the precipitate twice. Finished by filling the crucible once or twice with alcohol. The results are given in Table VII.

To those who have never tried it, returning the fluids so often through the precipitates may appear tedious work; in practice, however, it will be found otherwise. When the precipitate is in scales the fluids run through in a continuous stream, and to pass 25 to 30 c.c. five times scarcely occupies five minutes. The pump is kept in action all the time, and the short piece of indiarubber tubing that connects with the glass tube from the receiver is slipped off and on for the purpose of removing the filtrate and renewing connection afterwards.

The time required for all the manipulations from drenching the precipitate with alcohol after removal from the water-bath to placing it in the drying oven, is thirty or forty minutes. It is necessary to remove the excess of platinic chloride completely from the precipitate by thorough washing with alcohol before applying the NH_4Cl solution, or chloro-platinate of ammonium would be formed, and as this is very sparingly soluble in solution of NH_4Cl, it might not be completely removed by the after washing.

Table VII.

Expts.	KCl taken.	Weight of Precipitate.	KCl Obtained per cent.
104	0·46239	1·5148	100·11
105	0·40955	1·3404	100·02
106	0·42510	1·3920	100·07
107	0·41477	1·3597	100·18
108	0·45149	1·4797	100·16
109	0·48252	1·5805	100·10
110	0·44488	1·4552	99·96
111	0·43679	1·4244	99·66
112	0·43062	1·4050	99·71
113	0·41726	1·3649	99·96
	Average..		99·99

That the results might be sometimes slightly in excess of the truth was to be expected, the precipitates not having been crushed, but with the exception of the washing with spirit of wine after applying the NH_4Cl, I know of nothing in the process, if sufficient platinum is used, that could lead to minus error. The loss by passing 25 c.c. 80-per cent spirit twice through the precipitate in *scales* would be very slight. It is probable the low results obtained in Experiments Nos. 111 and 112 are due to my having been rather sparing of platinum, the solution being nearly finished.

In one experiment at least (No. 113) all the sulphuric acid went out with the alcoholic washings (which nevertheless were quite brilliant), so the washing with solution of NH_4Cl happened in this case to have been superfluous. The same may have occurred in some of the other experiments. That a portion at least of the sulphuric acid (free or in the form of sulphates) had been removed by the strong alcohol was evident, for although the filtrates were very brilliant at first, they became turbid on standing, and deposited sulphates.

Although it appears probable that this method will be found to answer, it must stand the test of a more rigorous examination before it can be pronounced thoroughly reliable. Having little time for this at present, I shall be glad to hear of the experience of others who may think it worth a trial. If the precipitates were crushed, it is probable the slight tendency to high results would cease, returning the filtrates so often would be unnecessary, and a smaller quantity of spirit of wine could be used to wash out the NH_4Cl; but the care and attention required when crushing is resorted to and solution of NH_4Cl employed are greater than those engaged in technical analyses would I fancy be willing to bestow on the process.

Solution of NH_4Cl somewhat weaker than the one I used may be found to answer, but of course it must not be so weak as to be capable of taking up more than traces of the chloro-platinate.

In the *Journal of Science* for June, 1881 (which has just reached me), I see it mentioned under the head of "Notes" that Dr. Seubert has determined the atomic weight of platinum as 194·46124. This would give the factor 0·3073 instead of 0·3056 for converting the chloro-platinate into KCl.

The consequence of employing the former intead of the latter factor is shown in the following statement:—

	Precipitate	×	Factor.	KCl per cent.
Fresenius ..	1·1170	×	0·3056	100·00
Dr. Seubert ..	1·1170	×	0·3073	100·55

If Dr. Seubert's numbers are correct, the only conclusion I can arrive at is that the determination of potassium as platinum salt, although it may perhaps be considered sufficiently accurate for technical purposes, will certainly not satisfy the requirements of scientific exactness.

The very sensible error in excess, which nearly all the analyses I have given would show if the new atomic weight for platinum were adopted, would be due either to the presence of impurities, which no amount of washing can remove, or the retention of moisture, which could only be expelled at a temperature at which the salt would suffer decomposition.

Concluding Remarks.

For those who may not have seen the paper by Gooch, describing his method, I may state—

(1.) The holes in the bottom of the crucible should be small and numerous.

(2.) The fibre of the asbestos must be silky. It is scraped to down with a penknife, boiled in HCl. Washed thoroughly with distilled water, and preserved under water for use.

(3.) To form a felting, start the pump, place the crucible in the hole in the indiarubber stopper; connect with pump; stir up the asbestos, and pour a little of the water containing it into the crucible. Do this two or three times if you require the felting thick, then run a little distilled water through to remove loose particles.

(4.) Before taking the tare of crucible and felting, ignite them gently. You need not place them under a desiccator to cool. After weighing, if you were to moisten the asbestos with water, and dry even at no higher temperature than 100° C., on weighing again you would find the weight the same.

In making a large number of potash estimates by this method, the same felting may be used several times, and with the advantage that the filtrates will be obtained very brilliant from the first if the felting has been used even once before.

The precipitate is removed carefully and as completely as possible without disturbing the felting, and the adhering particles are included in the tare for the next experiment.*

I have used feltings in this way repeatedly; there is no risk of impairing the accuracy of the results in the *slightest* degree. If reduction in hydrogen is to be effected, it is better the precipitate should be in scales. Place the Gooch's crucible with the precipitate (and with the cover I have described on) inside a Rose's crucible, turn on the hydrogen, and after a few minutes heat gently. I keep the flame of the lamp about an inch from the bottom of the Rose's crucible. After reduction, wash out the salt with hot water, using the filter pump, and ignite the platinum gently.

I employ Gooch's method in all cases where it is applicable, and find it invaluable.

In estimating mercury as sulphide, it is extremely convenient. I am certain that once having used it in the estimation of potassium as platinum salt, no one from choice will resort to a paper filter for the purpose of separating the precipitate.

Falmouth, Jamaica, B.W.I., June 22, 1881.

NOTICES OF BOOKS.

Townson and Mercer's Catalogue of Chemical Apparatus and Chemicals. Second Edition. 89, Bishopsgate Street Within.

THE present edition of Messrs. Townson and Mercer's catalogue is much extended and includes many pieces of apparatus recently brought into use. We may mention Dr. Skalweit's apparatus for testing petroleum; the appliances devised by Mr. MacIver and by Mr. Sacker for testing lubricating oils; Schwarz's apparatus for determining nitrogen; and Mr. Stephenson's apparatus for the estimation of sulphur in spent oxide.

An appendix describes and figures the exceedingly useful gas-burners, furnaces, &c., devised by Mr. Fletcher, of Warrington.

The catalogue includes not mere chemical apparatus and reagents, but the principal appliances needful for demonstration and research in the various branches of physics.

Many sets of apparatus for special purposes are here described, such as Prof. O. Graham's set for the analysis of malt, beer, &c., Prof. Tuson's selection of apparatus for the students of the Royal Veterinary College, Mr. Wanklyn's set for the use of Medical Officers of Health, the sets for the Royal College, the Pharmaceutical set as arranged by Prof. Attfield, the sets for the Oxford and Cambridge Local Examinations, &c.

* Of course, if the results are to be controlled by reduction in hydrogen, this cannot be done.

Justus von Liebig, His Merits in the Promotion of Practical Medicine. A Memorial Address, Delivered at the Annual Meeting of the Society for the Advancement of the Natural Sciences in Marburg, June 11, 1874. By the Director, Prof. Dr. F. W. BENEKE. Glasgow: James Maclehose, Publisher to the University.

THIS address has been remarkably tardy in making its appearance in our language. By whom it has been translated we are not informed. Almost at the very outset we meet with an assertion, about which we must join issue. Says Prof. Beneke, "What Newton was in the region of Natural Philosophy, Liebig was in the region of Biology." We should certainly be the last to overlook any just claims made on behalf of Liebig, but we cannot assign to him a position which, if due to any man who has yet appeared —a very doubtful question—belongs of right to Charles Darwin! The contributions of Liebig to the chemistry of physiology are of unquestionable value, but in the other great departments of biology, in morphology, embryology, and taxonomy, he played no part at all.

On p. 19 we read:—"it is still customary to give soda, particularly as carbonic acid, &c." This is, as it stands, unintelligible. For "carbonic acid," we must read "carbonate." The translator has mistaken "kohlen-saure," for kohlen-säure."

In referring to Liebig's part in the sanitary reform movement, Dr. Beneke remarks:—"This task," *i.e.*, the preservation of the fruitfulness of land, "cannot, for various reasons, be accomplished by irrigation, and thus we are brought more and more to the avowed conviction that sewage is the very reverse of being the best system for removing excrements from towns.

The pamphlet may fairly be pronounced a "clear and comprehensive epitome of the life-work of Liebig with reference to medical practice and sanitation.

Syllabus of Materia Medica, for the Use of Students, Teachers, and Practitioners, Based on the Relative Values of Articles and Preparation in the British Pharmacopœia. By ALEXANDER HARVEY, M.D., and A. D. DAVIDSON, M.D. Fifth Edition. London: H. K. Lewis.

THIS work, which is of a pocket size, is based, as the authors tells us, on a two-fold principle—first, that of an estimate of the relative values of the articles and preparations in the Pharmacopœia, and secondly, that of a selection of the more important of these. They advocate a restriction of the range at present granted to the examiner who, in Materia Medica, as well as in every other department of medical science, may at present take a perfectly encyclopædic view, and question candidates in the most unimportant things. It must be admitted that the plan adopted in the work before us, though in itself excellent, can be of little practical value until such a limitation is decreed by the proper authorities.

MISCELLANEOUS.

British Association for the Advancement of Science. —The following are the names of the Officers and Committee of Section B (Chemical Science Section) of the York Meeting of the British Association:—

President—Professor A. W. Williamson, Ph.D., F.R.S.

Vice-Presidents—F. A. Abel, C.B., F.R.S.; I. Lowthian Bell, F.R.S.; Professor J. Dewar, M.A., F.R.S.; Professor E. Frankland, D.C.L., F.R.S.; J. H. Gilbert, Ph.D., F.R.S.; J. H. Gladstone, Ph.D., F.R.S.; A. G. Vernon Harcourt, M.A., F.R.S.; Professor W. Odling, M.B., F.R.S.; Professor H. E. Roscoe, B.A., F.R.S.; Professor T. E. Thorpe, Ph.D., F.R.S.

Secretaries—Harold B. Dixon, M.A.; P. Phillips-Bedson, D.Sc.; T. Gough, B.Sc.

Committee—Capt. Abney, R.E., F.R.S.; A. H. Allen; Professor H. E. Armstrong, Ph.D., F.R.S.; R. W. Atkinson; Professor J. Attfield, Ph.D.; Professor Barker; Sir H. Bessemer, F.R.S.; P. Braham; F. D. Brown, B.Sc.; J. Y. Buchanan; W. L. Carpenter, B.A.; M. Carteighe; J. P. Cooke; R. C. Clapham; Sir J. Conroy, Bart., M.A.; Professor Corfield, M.D.; J. Fairley; A. E. Fletcher; Professor W. N. NOTES AND QUERIES.

*** Our Notes and Queries column was opened for the purpose of giving and obtaining information likely to be of use to our readers generally. We cannot undertake to let this column be the means of transmitting merely private information, or such trade notices as should legitimately come in the advertising columns.

Naphthalen.—I have read the last two articles in the Chemical News, vol. xliv., p.p. 65, 85, on the "Preparation of Pure Naphthalen." Will Mr. W. W. Staveley, or any maker, inform me through the Chemical News, at what price per ton commercial white naphthalen could be produced. Some time back I was experimenting with this article. I bought it at a wholesale chemist's, but the price was so high that I abandoned my experiments. I have since written to two supposed makers, but they answered they had ceased to make it. I particularly want to know if the article could be supplied in bulk, and at about the price per ton?—J. W. T.

TO CORRESPONDENTS.

J. Dunlop.—The old charcoal combustion furnace in use before gas furnaces were introduced would answer your purpose.

ROYAL COLLEGE OF SCIENCE,
STEPHEN'S GREEN, DUBLIN.

SCIENTIFIC AND TECHNICAL EDUCATION.
SESSION 1881-82.

This College supplies a complete Course of Instruction in Science, as applied to the Industrial Arts, especially those which may be classed broadly under the heads of CHEMICAL MANUFACTURES, MINING, and ENGINEERING.

A Diploma of Associate of the College is granted at the end of the Three Years' Course.

There are Four Royal Scholarships of the value of £50 each yearly, with free education, including Laboratory Instruction, tenable for two years. Two become vacant each year. They are given to Students who have been a year in the College.

The Fees are £2 for each Course, or £10 for all the Courses of each year, with the exception of Laboratory Practice.

Chemistry (Theoretical and Practical), Metallurgy, &c.—Professor HARTLEY, F.C.S., Dean of Faculty.
Mathematics, Mechanics, and Mechanism.—Professor HENNESSY, F.R.S., M.R.I.A.
Descriptive Geometry, Drawing, Engineering, & Surveying.—Professor PIGOT, C.E., M.R.I.A.
Experimental Physics (Theoretical and Practical).—Professor BARRETT, F.R.S.E., F.C.S.
Mining and Mineralogy.—Professor O'REILLY, C.E., M.R.I.A.
Botany.—Professor M'NAB, M.D., F.L.S.
Zoology.—Professor HADDON, M.A.
Geology.—Professor HULL, M.A., F.R.S., LL.D.
Palæontology.—Mr. BAILEY, F.G.S., M.R.I.A.

The Chemical and Physical Laboratories and Drawing School are open daily for Practical Instruction.

Fee for Chemical Laboratory, £2 per Month, or £12 for Session.
Fee for Physical Laboratory, £1 per Month, or £6 for Session.
Fee for Drawing School, £3 for Session.

The Session commences on MONDAY, October 3rd.

Programmes may be obtained on application at the College, or by letter or post-card, addressed to the Secretary, Royal College of Science, Stephen's Green, Dublin.

Professor J. P. O'REILLY, Secretary *pro tem.*

CITY AND GUILDS OF LONDON
INSTITUTE.
For the Advancement of
TECHNICAL EDUCATION.

WINTER COURSES of LECTURES, Laboratory and Workshop Instruction, at the Temporary Class Rooms of the Institute, Cowper Street, Finsbury,
COMMENCING OCTOBER 4, 1881.

TECHNICAL CHEMISTRY—H. E. ARMSTRONG, Ph.D., F.R.S., Professor.
EVENING COURSES.

Distilling (Coal Tar and Spirit)	Mondays.
Fuel and Illuminating Agents	Fridays.
Metals and Metallic Compounds	Mondays.

DAY CLASSES (Preliminary).

Lectures	Wednesdays and Fridays.
Laboratory	Tuesdays.

TECHNICAL PHYSICS—W. E. AYRTON, F.R.S., Professor.
EVENING COURSES.

Electric Lighting and Transmission of Power	Wednesdays.
Electrical Instrument Making	Mondays.
Electrical Laboratory Apparatus	Fridays.

DAY CLASSES (Preliminary).

Lectures	Tuesdays and Thursdays.
Laboratory	Thursdays.

Fees 3s. 6d., 5s., and 7s. 6d., for Lectures and Laboratory Courses together.

TRADE CLASSES (transferred from the Artisan's Institute).

Metal Plate Work and Pattern Cutting	Tuesday and Thursday Evenings.
Bricklaying	Monday Evenings.
Carpentry and Joinery	Tuesday and Friday Evenings.
Stonemasonry	Wednesday and Friday evenings.
Builders' Work, including Sanitary Engineering	Thursday Evenings.
House Decoration	Wednesday Evenings.
Modelling in Wax, Clay, &c.	Monday and Thursday Evenings.

Fees for the Session of about eight months, 6s. and 10s. 6d.

Apprentices admitted to these Trade Classes at a registration fee of 2s.

Further particulars with respect to any of these courses can be obtained on application at the Schools, or from the Director and Secretary of the Institute, Gresham College, London, E.C.
PHILIP MAGNUS,
Director and Secretary.

CITY AND GUILDS OF LONDON
INSTITUTE.
TECHNOLOGICAL EXAMINATIONS.

The next EXAMINATIONS in TECHNOLOGY will be held at the different Provincial Centres throughout the Kingdom on the evening of May 24, 1882.

Teachers desiring to form classes should apply at once to the Director and Secretary of the Institute.

List of subjects in which the examinations will be held, and general conditions of payment on results, can be obtained by application to the
Central Office, Gresham College, London, E.C.
PHILIP MAGNUS,
Director and Secretary.

THE MASON SCIENCE COLLEGE,
BIRMINGHAM.

SESSION 1881-82.

I. Department of Science and Arts.

The Session will commence on Monday, the 3rd of October, 1881.

Students under sixteen years of age will be required to pass a preliminary examination.

II. Evening Classes.

These will commence on Wednesday, the 5th of October, 1881.

The Calendar of the ensuing Session, containing full information as to the aim and objects of the College and the courses of instruction, is now ready, and may be obtained from the publishers, Messrs. Cornish Brothers, Birmingham and Manchester, price 1s.

GEO. H. MORLEY, Secretary.

Now ready, Vol. II., in 8vo., price 14s., cloth,

ANNALS OF CHEMICAL MEDICINE;
including the Application of Chemistry to Physiology, Pathology, Therapeutics, Pharmacy, Toxicology, and Hygiene. Edited by J. L. W. Thudichum, M.D.
London: LONGMANS and CO.

IRISH HILL BAUXITE (Alum Clay).

THE IRISH HILL MINING CO. are now, and always have been, the LARGEST PRODUCERS OF THIS CLAY, of Superior Quality, and supply the Manufacturers of Alum, Sulphate of Alumina, and Alum-Cake, of the United Kingdom, America, and the Continent, almost exclusively.

ANALYSIS BY JOHN PATTINSON, ESQ.

	Dried at 212° F.		
	Gertrude (extra qual.)	1st Quality.	2nd Quality.
Alumina	59·00	53·83	52·00
Peroxide of Iron	0·47	1·57	4·57
Silica	18·00	8·67	12·00
Titanic Acid		5·80	6·20
Lime, Magnesia, Potash, Soda, and Sulphuric Acid	0·23	0·83	1·14
Combined Water	22·30	29·27	24·00
	100·00	99·97	99·91

Supplies over 90 % of the Bauxite (Alum Clay) used.

Supplies over 90 % of the Bauxite (Alum Clay) used.

Our MINES, DRYING KILNS, and GRINDING MILLS are situated very close to the Shipping Ports of BELFAST and LARNE, and adjacent to Railways running alongside both Steamers and Sailing Vessels at both Ports, from either of which shipping is abundant and cheap, therefore we can guarantee Regular Delivery as Buyers require it, and are prepared to quote prices f.o.b. c.i.f., or delivered at any Port, in Bulk or Bags, Lump or Ground.

GEO. G. BLACKWELL, *Managing Director.*

Richmond Buildings, 26, Chapel St., Liverpool.

ESTABLISHED 1798.

ROBERT DAGLISH & CO.,

ENGINEERS, BOILER AND BRIDGE MAKERS, MILLWRIGHTS,

BRASS AND IRON FOUNDERS.

Manufacturers of every description of Condensing, or High-pressure Blowing, Pumping, Rolling, Winding, and Patent Steam-engines, or any required power, for Irrigating, Draining, Mining, Rolling Mills, or Water Works purposes, and Manufacturers of every description of Chemical, Colliery, Copper Ore, Gold Mining, Glass, and Rock-salt Machinery.

Black-ash Revolving Furnaces of the Most Approved Type.

Bessemer Steel-Rail Plant.

Compressing-Engines for Collieries, Iron Works, and Weldon's Patent Bleaching-Powder Process.

Caustic, Chlorate, Decomposing, Nitre Nitro-Glycerine, Iodine Potash, Sulphur, Acid, and Oxalic Pans.

Gas Producers Patent for Heating and other Purposes.

Pyrites Burners for Irish, Norwegian, and Spanish Ores of Improved Construction.

Patent Rousing Machinery for Brewers.

Retorts, Acid, Gas, Iodine, Nitric, Nitre Nitro-Glycerine and Vitriol Refining.

Steam Superheaters improved for Oil Tar, and Resin Refining.

Steam Sulphur Melter.

Stills for Oil, Resin, and Tar.

Wheels, Bevel Mitre, and Spur Moulded on the Shortest Notice by Patent Machinery.

Makers of MacTear's Patent Carbonating Furnace, Jones and Walsh's Patent Sulphate of Soda Furnace, Parnell and Simpson's Patent Causticiser, and Kynaston's Patent Alum Plan

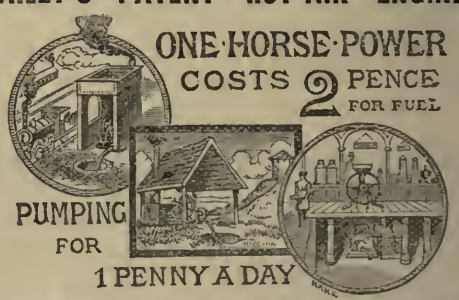
Lists sent on Application.

Photographs, Plans, and other information supplied on receipt of Order.

ST HELEN'S ENGINE, BOILER, AND BRIDGE WORKS AND FOUNDRY,

LANCASHIRE.

BAILEY'S PATENT HOT-AIR ENGINE.



Made from ¼ to 5 horse-power. 56lbs. of coke will keep a 1-horse going 12 hours. 1000 galls. of water lifted 50 feet high for a penny.

NO BOILER. NO DANGER.

Awarded Prize Medal by the chief Societies.

SOLE MAKERS—

W. H. BAILEY & Co., Albion Works, Salford, Manchester.

NICKEL AND COBALT REFINERS,

BIRMINGHAM.

Patentees and Manufacturers of Rolled Nickel Anodes for Electro-Nickel-Plating.

Malleable Nickel Sheets, Grain and Cube Nickel, German Silver, and other Nickel Alloys, Oxides of Cobalt, &c.

FOR SALE, a bargain.—3 Vats, each 4500 gallons. All perfectly clean, and equal to new vats. Almost any price would be taken, as the space they occupy is wanted.—Apply to E. Beanes and Co., Falcon Works, Hackney Wick, E.

THE CHEMICAL NEWS.

Vol. XLIV. No. 1138.

ADDRESS TO THE MATHEMATICAL AND PHYSICAL SCIENCE SECTION OF THE BRITISH ASSOCIATION.

By Sir WILLIAM THOMSON, F.R.S.,
Professor of Natural Philosophy in the University of Glasgow.
President of the Section.

On the Sources of Energy in Nature Available to Man for the Production of Mechanical Effect.

During the fifty years' life of the British Association, the Advancement of Science for which it has lived and worked so well has not been more marked in any department than in one which belongs very decidedly to the Mathematical and Physical Section—the science of Energy. The very name energy, though first used in its present sense by Dr. Thomas Young about the beginning of this century, has only come into use practically after the doctrine which defines it had, during the first half of the British Association's life, been raised from a mere formula of mathematical dynamics to the position it now holds of a principle pervading all nature and guiding the investigator in every field of science.

A little article communicated to the Royal Society of Edinburgh a short time before the commencement of the epoch of energy under the title "On the Sources Available to Man for the Production of Mechanical Effect,"* contained the following:—

"Men can obtain mechanical effect for their own purposes by working mechanically themselves, and directing other animals to work for them, or by using natural heat, the gravitation of descending solid masses, the natural motions of water and air, and the heat, or galvanic currents, or other mechanical effects produced by chemical combination, but in no other way at present known. Hence the stores from which mechanical effect may be drawn by man belong to one or other of the following classes:—

"I. The food of animals.

"II. Natural heat.

"III. Solid matter found in elevated positions.

"IV. The natural motions of water and air.

"V. Natural combustibles (as wood, coal, coal-gas, oils, marsh-gas, diamond, native sulphur, native metals, meteoric iron).

"VI. Artificial combustibles (as smelted or electrically-deposited metals, hydrogen, phosphorus).

"In the present communication, known facts in natural history and physical science, with reference to the sources from which these stores have derived their mechanical energies, are adduced to establish the following general conclusions:—

"1. *Heat radiated from the sun* (sunlight being included in this term) *is the principal source of mechanical effect available to man.*† From it is derived the whole mechanical effect obtained by means of animals working, water-wheels worked by rivers, steam-engines, galvanic engines, windmills, and the sails of ships.

"2. The motions of the earth, moon, and sun, and their mutual attractions, constitute an important source of available mechanical effect. From them all, but chiefly no doubt from the earth's motion of rotation, is derived the mechanical effect of water-wheels driven by the tides.

"3. The other known sources of mechanical effect available to man are either terrestrial—that is, belonging to the earth, and available without the influence of any external body—or meteoric—that is, belonging to bodies deposited on the earth from external space. Terrestrial sources, including mountain quarries and mines, the heat of hot springs, and the combustion of native sulphur, perhaps also the combustion of inorganic native combustibles, are actually used; but the mechanical effect obtained from them is very inconsiderable, compared with that which is obtained from sources belonging to the two classes mentioned above. Meteoric sources, including only the heat of newly-fallen meteoric bodies, and the combustion of meteoric iron, need not be reckoned among those available to man for practical purposes."

Thus we may summarise the natural sources of energy as Tides, Food, Fuel, Wind, and Rain.

Among the practical sources of energy thus exhaustively enumerated, there is only one not derived from sun-heat—that is the tides. Consider it first. I have called it *practical*, because tide-mills exist. But the places where they can work usefully are very rare, and the whole amount of work actually done by them is a drop to the ocean of work done by other motors. A tide of two metres' rise and fall, if we imagine it utilised to the utmost by means of ideal water-wheels doing with perfect economy the whole work of filling and emptying a dock basin in infinitely short times at the moments of high and low water, would give just one metre-ton per square metre of area. This work done four times in the twenty-four hours amounts to 1·1620th of the work of a horse-power. Parenthetically, in explanation, I may say that the French metrical equivalent (to which in all scientific and practical measurements we are irresistibly drawn, notwithstanding a dense barrier of insular prejudice most detrimental to the islanders),—the French metrical equivalent of James Watt's "horse-power" of 550 foot-pounds per second, or 33,000 foot-pounds per minute, or nearly two million foot-pounds per hour, is 75 metre-kilogrammes per second, or 4½ metre-tons per minute, or 270 metre-tons per hour. The French ton of 1000 kilos. used in this reckoning is 0·984 of the British ton.

Returning to the question of utilising tidal energy, we find a dock area of 162,000 square metres (which is little more than 400 metres square) required for 100 horse-power. This, considering the vast costliness of dock construction, is obviously prohibitory of every scheme for economising tidal energy by means of artificial dock-basins, however near to the ideal perfection might be the realised tide-mill, and however convenient and non-wasteful the accumulator—whether Faure's electric accumulator, or other accumulators of energy hitherto invented or to be invented—which might be used to store up the energy yielded by the tide-mill during its short harvests about the times of high and low water, and to give it out when wanted at other times of six hours. There may, however, be a dozen places possible in the world where it could be advantageous to build a sea-wall across the mouth of a natural basin or estuary, and to utilise the tidal energy of filling it and emptying it by means of sluices and water-wheels. But if *so* much could be done, it would in many cases take only a little more to keep the water out altogether, and make fertile land of the whole basin. Thus we are led up to the interesting economical question, whether is forty acres (the British *agricultural* measure for the area of 162,000 square metres) or 100 horse-power more valuable. The annual cost of 100 horse-power night and day, for 365 days of the year, obtained through steam from coals, may be about ten times the rental of forty acres at £2 or £3 per acre. But the value of land is essentially much more than its rental, and the rental of land is apt to be much more than £2 or £3 per acre in places where 100 horse-power could be taken with advantage from coal through steam. Thus the question remains unsolved, with the possibility that in one place the answer may be *one hundred horse-power*, and in another *forty acres*. But, indeed, the question is hardly worth answering, considering

* Read at the Royal Society of Edinburgh on February 2, 1852 (*Proceedings* of that date).

† A general conclusion equivalent to this was published by Sir John Herschel in 1833. See his "Astronomy," edit. 1849, § (399).

the rarity of the cases, if they exist at all, where embankments for the utilisation of tidal energy are practicable.

Turning now to sources of energy derived from sun-heat, let us take the wind first. When we look at the register of British shipping and see 40,000 vessels, of which about 10,000 are steamers and 30,000 sailing ships, and when we think how vast an absolute amount of horse-power is developed by the engines of those steamers, and how considerable a proportion it forms of the whole horse-power taken from coal annually in the whole world at the present time, and when we consider the sailing ships of other nations, which must be reckoned in the account, and throw in the little item of windmills, we find that, even in the present days of steam ascendency, old-fashioned Wind still supplies a large part of all the energy used by man. But however much we may regret the time when Hood's young lady, visiting the fens of Lincolnshire at Christmas, and writing to her dearest friend in London (both sixty years old now if they are alive), describes the delight of sitting in a bower and looking over the wintry plain, not desolate, because "windmills lend revolving animation to the scene," we cannot shut our eyes to the fact of a lamentable decadence of wind-power. Is this decadence permanent, or may we hope that it is only temporary? The subterranean coal-stores of the world are becoming exhausted surely, and not slowly, and the price of coal is upward bound—upward bound on the whole, though no doubt it will have its ups and downs in the future as it has had in the past, and as must be the case in respect to every marketable commodity. When the coal is all burned; or, long before it is all burned, when there is so little of it left and the coal-mines from which that little is to be excavated are so distant and deep and hot that its price to the consumer is greatly higher than at present, it is most probable that windmills or wind-motors in some form will again be in the ascendant, and that wind will do man's mechanical work on land at least in proportion comparable to its present doing of work at sea.

Even now it is not utterly chimerical to think of wind superseding coal in some places for a very important part of its present duty—that of giving light. Indeed, now that we have dynamos and Faure's accumulator, the little want to let the thing be done is cheap windmills. A Faure cell containing 20 kilos. of lead and minium charged and employed to excite incandescent vacuum-lamps has a light-giving capacity of 60-candle hours (I have found considerably more in experiments made by myself; but I take 60 as a safe estimate). The charging may be done uninjuriously, and with good dynamical economy, in any time from six hours to twelve or more. The drawing-off of the charge for use may be done safely, but somewhat wastefully, in two hours, and very economically in any time of from five hours to a week or more. Calms do not last often longer than three or four days at a time. Suppose, then, that a five-days' storage-capacity suffices (there may be a little steam-engine ready to set to work at any time after a four-days' calm, or the user of the light may have a few candles or oil-lamps in reserve, and be satisfied with them when the wind fails for more than five days). One of the 20-kilo. cells charged when the windmill works for five or six hours at any time, and left with its 60-candle hours' capacity to be used six hours a day for five days, gives a 2-candle light. Thus thirty-two such accumulator cells soused would give as much light as four burners of London 16-candle gas. The probable cost of dynamo and accumulator does not seem fatal to the plan, if the windmill could be had for something comparable with the prime cost of a steam-engine capable of working at the same horse-power as the windmill when in good action. But windmills as hitherto made are very costly machines; and it does not seem probable that, without inventions not yet made, wind can be economically used to give light in any considerable class of cases, or to put energy into store for work of other kinds.

Consider, lastly, rain-power. When it is to be had in places where power is wanted for mills and factories of any kind, water-power is thoroughly appreciated. From time immemorial, water-motors have been made in large variety for utilising rain-power in the various conditions in which it is presented, whether in rapidly-flowing rivers, in natural waterfalls, or stored at heights in natural lakes or artificial reservoirs. Improvements and fresh inventions of machines of this class still go on; and some of the finest principles of mathematical hydrodynamics have, in the lifetime of the British Association, and, to a considerable degree, with its assistance, been put in requisition for perfecting the theory of hydraulic mechanism and extending its practical applications.

A first question occurs: Are we necessarily limited to such natural sources of water-power as are supplied by rain falling on hill-country, or may we look to the collection of rain-water in tanks placed artificially at sufficient heights over flat country to supply motive power economically by driving water-wheels? To answer it: Suppose a height of 100 metres, which is very large for any practicable building, or for columns erected to support tanks; and suppose the annual rainfall to be three-quarters of a metre (30 inches). The annual yield of energy would be 75 metre-tons per square metre of the tank. Now one horse-power for 365 times 24 hours is 236,500 foot-tons; and therefore, dividing this by 75, we find 3153 sq. metres as the area of our supposed tank required for a continuous supply of one horse-power. The prime cost of any such structure, not to speak of the value of the land which it would cover, is utterly prohibitory of any such plan for utilising the motive power of rain. We may or may not look forward hopefully to the time when windmills will again "lend revolving animation" to a dull flat country; but we certainly need not be afraid that the scene will be marred by forests of iron columns taking the place of natural trees, and gigantic tanks overshadowing the fields and blackening the horizon.

To use rain-power economically on any considerable scale we must look to the natural drainage of hill country, and take the water where we find it either actually falling or stored up and ready to fall when a short artificial channel or pipe can be provided for it at moderate cost. The expense of aqueducts, or of underground water-pipes, to carry water to any great distance—any distance of more than a few miles or a few hundred yards—is much too great for economy when the yield to be provided for is *power*; and such works can only be undertaken when the *water itself* is what is wanted. Incidentally, in connection with the water supply of towns, some part of the energy due to the head at which it is supplied may be used for power. There are, however, but few cases (I know of none except Greenock) in which the energy to spare over and above that devoted to bringing the water to where it is wanted, and causing it to flow fast enough for convenience at every opened tap in every house or factory, is enough to make it worth while to make arrangements for letting the water-power be used without wasting the water-substance. The cases in which water-power is taken from a town supply are generally very small, such as working the bellows of an organ, or "hair-brushing by machinery," and involve simply throwing away the used water. The cost of energy thus obtained must be something enormous in proportion to the actual quantity of the energy, and it is only the smallness of the quantity that allows the convenience of having it when wanted at any moment, to be so dearly bought.

For anything of great work by rain-power, the water-wheels must be in the place where the water supply with natural fall is found. Such places are generally far from great towns, and the time is not yet come when great towns grow by natural selection beside waterfalls, for power; as they grow beside navigable rivers, for shipping. Thus hitherto the use of water-power has been confined chiefly to isolated factories which can be conveniently placed and economically worked in the neighbourhood of natural waterfalls. But the splendid suggestion made

about three years ago by Mr. Siemens in his presidential address to the Institution of Mechanical Engineers, that the power of Niagara might be utilised, by transmitting it electrically to great distances, has given quite a fresh departure for design in respect to economy of rain-power. From the time of Joule's experimental electro-magnetic engines developing 90 per cent of the energy of a Voltaic battery in the form of weights raised, and the theory of the electro-magnetic transmission of energy completed thirty years ago on the foundation afforded by the train of experimental and theoretical investigations by which he established his dynamical equivalent of heat in mechanical, electric, electro-chemical, chemical, electro-magnetic, and thermoclastic phenomena, it had been known that potential energy from any available source can be transmitted electro-magnetically by means of an electric current through a wire, and directed to raise weights at a distance, with unlimitedly perfect economy. The first large-scale practical application of electro-magnetic machines was proposed by Holmes in 1854, to produce the electric light for light-houses, and persevered in by him till he proved the availability of his machine to the satisfaction of the Trinity House and the delight of Faraday in trials at Blackwall in April, 1857, and it was applied to light the South Foreland lighthouse on December 8, 1858. This gave the impulse to invention; by which the electro-magnetic machine has been brought from the physical laboratory into the province of engineering, and has sent back to the realm of pure science a beautiful discovery—that of the fundamental principle of the dynamo, made triply and independently, and as nearly as may be simultaneously, in 1867 by Dr. Werner Siemens, Mr. S. A. Varley, and Sir Charles Wheatstone; a discovery which constitutes an electro-magnetic analogue to the fundamental electrostatic principle of Nicholson's revolving doubler, resuscitated by Mr. C. F. Varley in his instrument "for generating electricity"; patented in 1860; and by Holtz in his celebrated electric machine; and by myself in my "replenisher" for multiplying and maintaining charges in Leyden jars for heterostatic electrometers, and in the electrifier for the siphon of my recorder for submarine cables.

The dynamos of Gramme and Siemens, invented and made in the course of these fourteen years since the discovery of the fundamental principle, give now a ready means of realising economically on a large scale, for many important practical applications, the old thermo-dynamics of Joule in electro-magnetism; and, what particularly concerns us now in connection with my present subject, they make it possible to transmit electro-magnetically the work of waterfalls through long insulated conducting wires, and use it at distances of fifties or hundreds of miles from the source, with excellent economy—better economy, indeed, in respect to proportion of energy used to energy dissipated than almost anything known in ordinary mechanics and hydraulics for distances of hundreds of yards instead of hundred of miles.

In answer to questions put to me in May, 1879,* by the Parliamentary Committee on Electric Lighting, I gave a formula for calculating the amount of energy transmitted, and the amount dissipated by being converted into heat on the way, through an insulated copper conductor of any length, with any given electro-motive force applied to produce the current. Taking Niagara as example, and with the idea of bringing its energy usefully to Montreal, Boston, New York, and Philadelphia, I calculated the formula for a distance of 300 British statute miles (which is greater than the distance of any of those four cities from Niagara, and is the radius of a circle covering a large and very important part of the United States and British North America), I found almost to my surprise that, even with so great a distance to be provided for, the conditions are thoroughly practicable with good economy, all aspects of the case carefully considered. The formula itself will be the subject of a technical communication to Section A in the course of the Meeting on which we are now entering. I therefore at present restrict myself to a slight statement of results.

1. Apply dynamos driven by Niagara to produce a difference of potential of 80,000 volts between a good earth-connection and the near end of a solid copper wire of half an inch (1·27 centimetre) diameter, and 300 statute miles (483 kilometres) length.

2. Let resistance by driven dynamos doing work, or by electric lights, or, as I can now say, by a Faure battery taking in a charge, be applied to keep the remote end at a potential differing by 64,000 volts from a good earth-plate there.

3. The result will be a current of 240 webers through the wire taking energy from the Niagara end at the rate of 26,250 horse-power, losing 5250 (or 20 per cent) of this by the generation and dissipation of heat through the conductor and 21,000 horse-power (or 80 per cent of the whole) on the recipients at the far end.

4. The elevation of temperature above the surrounding atmosphere, to allow the heat generated in it to escape by radiation and be carried away by convection is only about 20° Centigrade; the wire being hung freely exposed to air like an ordinary telegraph wire supported on posts.

5. The striking distance between flat metallic surfaces with difference of potentials of 80,000 volts (or 75,000 Daniell's) is (Thomson's "Electrostatics and Magnetism," § 340) only 18 millimetres, and therefore there is no difficulty about the insulation.

6. The cost of the copper wire, reckoned at 8d. per lb., is £37,000, the interest on which at 5 per cent is £1900 a year. If 5250 horse-power at the Niagara end costs more than £1900 a year, it would be better economy to put more copper into the conductor; if less, less. I say no more on this point at present, as the economy of copper for electric conduction will be the subject of a special communication to the Section.

I shall only say, in conclusion, that one great difficulty in the way of economising the electrical transmitting power to great distances, or even to moderate distances of a few kiloms., is now overcome by Faure's splendid invention. High potential—as Siemens, I believe, first pointed out—is the essential for good dynamical economy in the electric transmission of power. But what are we to do with 80,000 volts when we have them at the civilised end of the wire? Imagine a domestic servant going to dust an electric lamp with 80,000 volts on one of its metals? Nothing above 200 volts ought on any account ever to be admitted into a house or ship or other place where safeguards against accident cannot be made absolutely and for ever trustworthy against all possibility of accident. In an electric workshop 80,000 volts is no more dangerous than a circular saw. Till I learned Faure's invention I could but think of step-down dynamos, at a main receiving station, to take energy direct from the electric main with its 80,000 volts, and supply it by secondary 200-volt dynamos or 100-volt dynamos, through proper distributing wires, to the houses and factories and shops where it is to be used for electric lighting, and sewing-machines, and lathes, and lifts, or whatever other mechanism wants driving power. Now the thing is to be done much more economically, I hope, and certainly with much greater simplicity and regularity, by keeping a Faure battery of 40,000 cells always being charged direct from the electric main, and applying a methodical system of removing sets of 50, and placing them on the town-supply circuits, while other sets of 50 are being regularly introduced into the great battery that is being charged, so as to keep its number always within 50 of the proper number, which would be about 40,000 if the potential at the emitting end of the main is 80,000 volts.

Tin Mining at Billiton.—M. Ferrier.—The yield of tin at Billiton is now decidedly greater than in the neighbouring Island of Banca.—*Revue Universelle des Mines.*

ON THE NEW METAL ACTINIUM.

By Dr. T. L. PHIPSON, F.C.S., &c.

SINCE the publication of my two notes in the CHEMICAL NEWS, vol. xliii., p. 283, and vol. xliv., p. 73, I have made a great number of experiments with the view of isolating the new substance to which the white zinc pigment owes its remarkable property of darkening in the sunlight, returning to its white state in the dark, and not being affected in this manner under a sheet of glass.

These experiments have at last proved successful, and a very short note to that effect was communicated, about a fortnight ago, to the Académie des Sciences, and another to the British Association on Monday, September 5. I will now describe the process by which I have isolated the oxide and the sulphide of the new metal in a state of tolerable purity. Perhaps this process may be improved hereafter, but it is not very complicated, though it has required an enormous number of experiments to arrive at it. First, one word as to the manner in which the pigment found in commerce is prepared. Ordinary zinc scrap is dissolved in sulphuric acid and a considerable excess of zinc is left in the solution in order to keep out iron, lead, arsenic, and other metals. The liquid is drawn off and then precipitated by a solution of sulphide of barium; the precipitate is dried, calcined, raked whilst hot into cold water, dried again, ground, &c. It then consists of sulphide of zinc, oxide of zinc, and sulphate of baryta, with *minute* quantities of iron, lead, arsenic, manganese, &c.

The manner in which I have obtained the oxide and sulphide of actinium from this pigment is as follows, and the process will doubtless serve for the treatment of other substances in which the presence of the new metal may be detected :—

About 15 grms. of the finely pulverised pigment are left for 24 hours in dilute acetic acid (strongest acetic acid and water equal parts) and the mixture well stirred or shaken occasionally. This takes out most of the iron, manganese, magnesia, lime, and *oxide* of zinc. The residue, after being washed, is treated exactly in the same manner with dilute hydrochloric acid (acid 8 parts, water 92 parts); with the object of completing the action of the acetic acid. The residue, well washed, is then heated with strong hydrochloric acid, to which a little nitric acid is added from time to time. The solution of the chlorides thus obtained is filtered to separate free sulphur and the insoluble sulphate of baryta, any remaining sulphur in suspension after filtration being oxidised by a few crystals of chlorate of potash. To this solution of chlorides, somewhat diluted, a considerable excess of caustic soda is added and the solution heated. The zinc oxide goes into solution and the white oxide of actinium remains; the latter is received upon a filter, washed, dissolved in hydrochloric acid, and the solution again treated with excess of caustic soda (these operations may be repeated two or three times, in order to eliminate the zinc oxide as completely as possible). Finally, the oxide of actinium, still impure, is washed on a filter and dissolved in a considerable excess of hydrochloric acid. The solution is neutralised by ammonia, and then the latter is added in excess. All but a little iron oxide remains dissolved (if not, dissolve again in HCl and add ammonia in excess, which, this time, will only precipitate the iron). The iron oxide is separated by the filter, and to the filtrate sulphide of ammonium is added, which throws down the sulphide of actinium as a bulky pale canary-yellow precipitate, the colour of which is best seen when it is received on a filter.

Oxide of Actinium.—The hydrate as precipitated by soda or ammonia forms a bulky white precipitate more gelatinous than oxide of zinc; unlike the latter it is only very slightly soluble in caustic soda, even when the liquid is heated; it is not precipitated by ammonia from solutions containing ammoniacal salts. It is a permanent white, with a slight tinge of salmon colour when seen in bulk, and it does not change colour when exposed to the air, as oxide of manganese does, neither does it appear to be affected by the direct rays of the sun. It is readily soluble in acids. The anhydrous oxide is not volatile nor decomposed by heat. It has a pale fawn-coloured tint.

Sulphide of Actinium.—The hydrate as precipitated from its neutral or alkaline solutions by sulphide of ammonium is a bulky pale canary-yellow precipitate, insoluble in excess of sulphide of ammonium, scarcely at all soluble in acetic acid, readily soluble in mineral acids even when they are diluted. When exposed to the direct rays of the sun it darkens and becomes quite black in about twenty minutes, except in those places where it is protected by a piece of ordinary window glass.

The quantity of actinium sulphide obtained from the white pigment amounts to no less than about 4 per cent. This yield is enormous. The presence of this new element in zinc will account, probably, for the discrepancies noticed in the *equivalent* of this metal as determined by various observers. The new element differs very essentially from manganese, zinc, and cadmium, but has, perhaps, some points of similarity with lanthanum. It exists, evidently, in considerable quantities in, at least, some kinds of commercial zinc. As soon as I shall have written the next number of my "Journal of Medicine," I intend to pursue these investigations.

ON THE NATURE OF CERTAIN VOLATILE PRODUCTS CONTAINED IN CRUDE COAL-TAR BENZENES.

By WATSON SMITH, F.C.S., F.I.C.,
Demonstrator and Assistant Lecturer on Chemistry in the Owens College.

VINCENT and DELACHANAL (*Comptes Rendus*, lxxxvi., 340), on rectifying crude benzene, obtained in the usual way, from the "light oils" of certain Paris coal-tars, received over a certain quantity of products boiling below 80° C. On standing, a separation of the portion boiling below 80°, into two layers, took place, a lower one much heavier than water, composed chiefly of carbon bisulphide, and an upper layer lighter than water. Submitting the upper layer to distillation, carbon bisulphide was received over below 75°; the portion distilling between 75° and 83°, on treatment with a lye of potash, or soda, or with lime, and distilling in a retort with inverted condenser, disengaged torrents of ammonia, and an acetate was formed and remained in the alkaline liquid. When the disengagement of ammonia had ceased, there remained in the apparatus with the excess of alkaline lye and the acetate, a liquid product, which, when distilled and dried over quicklime, presented all the properties of anhydrous ethyl-alcohol. The decomposition with alkalies yielding ammonia and an acetate indicated the presence of aceto-nitrile, and this was separated from the alcohol as follows :—By fractional distillation the products were classified as much as possible, and afterwards the largest possible quantity of previously fused and powdered calcium chloride was dissolved in the boiling mixture in order to absorb the alcohol, which it does on cooling, forming a kind of unstable compound. Repeated distillations and treatments with calcium chloride at length gave an aceto-nitrile, containing but traces of alcohol, which were finally eliminated by a distillation from a small quantity of phosphorus pentoxide, followed by a rectification. It may be mentioned that though alcohol boils at 78·4° and aceto-nitrile at 81·6°, yet mixtures of equal parts of these two bodies boil at a much lower temperature, viz., 72·7°. The lower layer of liquid of the crude products consisted of carbon bisulphide mixed with very small quantities of hydrocarbons, apparently containing amylen.

Otto Witt (*Berichte der Deutschen Chemischen Gesellschaft*, 1877, page 2227) likewise found ethyl-alcohol

in the benzenes from certain Paris coal-tars. The quality tested was the so-called 90 per cent aniline-benzene. Witt obtained by a fractional distillation 5 to 6 per cent of a product distilling over between 60° and 70°. On renewed fractionation a turbid product was obtained, gradually separating into two layers, the lower one consisting of carbon bisulphide and the upper one of ethyl-alcohol. The amount of alcohol according to Witt was about 0·2 per cent on the benzene operated on. Witt, moreover, asserts that ethyl-alcohol continually accompanies benzene obtained from coal-tar.

My own experiments were made with a sample of benzene from a London tar kindly furnished me by my friend Mr. Chas. Lowe, of Reddish and Manchester. The benzene received was from the so-called "first runnings" of the still. Mr. Lowe informed me that several London tar distillers had been much troubled by complaints from their customers that the "aniline-benzenes" sold to them contained certain low-boiling substances, whose presence had the effect of reducing the boiling-point of the mixture, and of course also themselves contributing to make up the bulk of the benzenes, appeared to confer a fictitious value upon the article. In some cases it was even insinuated that petroleum spirit had been purposely introduced. The distillers appeared quite unable to account for the anomaly.

The specific gravity of the benzene was first determined, and found to be 0·911 at 15°. This being considerably above the correct specific gravity of benzene, viz., 0·880 at 15°, a portion was now distilled, and the specific gravity of all coming over below 80° was determined, and also that of all boiling between 80° and 90°. The numbers obtained were, respectively, 0·954 and 0·887 at 15°. The portion boiling below 80° was again distilled, and all coming over below 74° taken apart. This was found to smell disagreeably, and to sink in water, forming transparent, strongly refractive, oily drops. The portion sinking in water began to distil at 45°. I never observed the least tendency of any of the products I obtained to separate into two layers, as in the case of the benzenes operated upon by Vincent and Delachanal and by Otto Witt; also, all fractions obtained between 50° and 80°, on further fractionation, always split up into portions boiling at or below 50°, or at and above 80°. After some seven weeks of continual fractional distillation I succeeded in splitting up all my products into three main portions—

1. Boiling from 40° to 53°
2. ,, ,, 81° to 82°
3. ,, above 82°

It did not now seem probable that either alcohol or aceto-nitrile were present appreciably. In course of the fractionating, a fraction boiling from 65° to 80° was obtained. This was sealed up in a glass tube with a lye of caustic soda. A portion of that placed above as No. 2, and boiling from 81° to 82° was similarly treated. The two tubes were heated to 100° for two days, but on opening not the least odour of ammonia was perceptible.

All efforts to detect alcohol in this benzene resulted only in evidence of minute traces. Vincent and Delachanal's method of treatment with powdered calcium chloride entirely failed to abstract any, and distillation of the No. 2 portion with very small fragments of sodium was then resorted to, with the object of fixing traces of alcohol. The residue obtained was carefully dried, but by the action of water and final testing, only traces of alcohol could be found.

The portion No. 1, boiling at from 40° to 53° and sinking in water, having also the odour of ordinary carbon bisulphide was now treated gradually with bromine. The first additions were at once decolourised. So much bromine was now added that a permanent brown colour remained in the solution. At first the action was totally unaccompanied by liberation of HBr; when a slight excess of bromine was, however, added, some fumes of HBr appeared, indicating that also a small quantity of substitution-compounds is formed. On leaving the brominated mixture in a flask loosely corked, the neck was after twenty-four hours found covered with fine acicular crystals, and a few drops of a heavy oily bromine compound had settled down to the bottom of the vessel. The mixture was now distilled, when the carbon bisulphide first came over, together with the heavy brown oily body, which had a most disagreeable and persistent odour, and on separating from the carbon bisulphide it soon solidified to a crystalline mass. Its quantity was very small. It was possibly the bromine compound of a polymeric amylen. Small quantities of products now distilled over from 80° to 140°, but the most considerable fraction was that passing over between 160° and 180°, and on further fractionation yielding a product boiling constantly from 175° to 178°, and possessing the odour of bibrom-amylen. Odour and boiling-point agreeing with those of α- and β-bibrom-amylens, a vapour-density determination by Victor Meyer's method was now made by Mr. Wilhelm Bott, with the following results (a naphthalen bath was used):—

S = 0·12 grm.; t = 17°; w = 14·42 c.c.; B = 758·5 m.m.; V = 13·1 c.c.

Substituting the numbers given in Meyer's formula—

$$d = \frac{S(1+0{\cdot}003665\,t)\,587780}{(B-w)V} = \frac{0{\cdot}12\,(1+0{\cdot}003665\times 17)\,587780}{(758{\cdot}5-14{\cdot}42)\,13{\cdot}1} = 7{\cdot}68$$

V.-d. Found.

V.-d. calc. for $C_5H_{10}Br_2$ = 7·86

The portion which boiled constantly at 81° to 82° is pure benzene. It solidified easily and completely on cooling to 0° C., and was proved to be free from alcohol and aceto-nitrile. The proportion of the carbon bisulphide I found to be present in the crude benzene operated on is 5·92 *per cent by volume*, *i.e.*, from 4220 c.c. of the benzene I obtained 250 c.c. of pure carbon bisulphide. It would seem most probable that the carbon bisulphide is to be traced to the action of a very high temperature in the gas retorts upon coals containing a considerable amount of sulphur. It would appear very possible that at an extremely high temperaturature the tendency of sulphur to form carbon bisulphide in contact with intensely red-hot carbon (coke) would be greater than to form the ordinary sulphur compounds met with in gas-lye products, many of which are probably less stable at extremely elevated temperatures.

With regard to the origin of ethyl-alcohol in coal-tar benzenes, I do not feel able to accept the work of Vincent and Delachanal or of Otto Witt as any proof that the ethyl-alcohol they extracted was actually present in the coal-tars from which the benzene was distilled, until their experiments are repeated with like results, on the crude first portions of the light oils coming direct from the tar-stills. My reason is this. The benzenes they operated upon, as I understand, were rectified products, *i.e.*, the products obtained by treatment of the first light oils with about 3 per cent of concentrated sulphuric acid (volume), followed by agitation with alkaline lyes, and subsequent distillation. Now, with the olefines shown to be present it is almost certain that olefiant gas would also exist in the coal-tar, dissolved in the oils composing the fluid portion thereof. On distilling the tar the olefiant gas would pass over with the first portions of the light oils, and on the condensation of the latter doubtless re-dissolve to a certain extent in these lighter oils. On subsequent treatment with sulphuric acid, ethyl-sulphuric acid would be formed, and the after-treatment with alkali, followed by distillation, would yield a small quantity of ethyl alcohol passing over thus with the rectified benzene. The fact that notwithstanding this treatment with sulphuric acid and alkali, amylene should be found in the rectified benzene is easily explained. The α- and β-amylenes, $CH_3-CH_2-CH_2-CH=CH_2$ and $CH_3-CH_2-CH=CH-CH_3$, which (judging from the boiling-point of the possible mixure of the bibromo-compounds obtained) are probably the

ones contained in the benzene I examined, are neither of them attacked by sulphuric acid in the cold. *a*-iso-amylene—

$$\begin{matrix} CH_3 \\ CH_3 \end{matrix}\!\!>\!CH-CH=CH_2,$$

is truly not affected by cold sulphuric acid, but its boiling-point is 21°, and from this fact, and remembering that the bisulphide of carbon mixture did not begin to boil till 40°, it is not likely to be present.

LONDON WATER SUPPLY.

REPORT ON THE COMPOSITION AND QUALITY OF DAILY SAMPLES OF THE WATER SUPPLIED TO LONDON, FOR THE MONTH ENDING AUGUST 31ST, 1881.

By WILLIAM CROOKES, F.R.S.,
WILLIAM ODLING, M.B., F.R.S., F.R.C.P.,
Professor of Chemistry at the University of Oxford;
and C. MEYMOTT TIDY, M.B., F.C.S.,
Professor of Chemistry and of Forensic Medicine at the London Hospital; Medical Officer of Health for Islington.

To the RIGHT HONOURABLE THE PRESIDENT OF THE LOCAL GOVERNMENT BOARD.

September 2nd, 1881.

SIR,—We beg to lay before you the results of our daily examinations of the water delivered, for the month ending the 31st of August, by the seven London water companies taking their supply from the Thames and the Lea. The samples are taken by a man in our service at places and times which we ourselves appoint.

In 6 only of the 182 samples taken during the month were we able to detect by examining the water in large bulk with the naked eye the minutest trace of matter in suspension.

In Table I. we have recorded the analyses in detail of samples, one taken daily from August 2nd to August 31st, inclusive.

The purity of the water in respect of organic matter has been determined by the Oxygen and the Combustion processes, and the results of our analyses by these methods are stated in columns XIV. to XVIII.

We have recorded in Table II. the tint of the 182 samples of water as determined by the colour-meter we have described in a previous report. Practically the waters differ very little in their appearance (even when examined in large bulk) from distilled water. Despite the heavy rain-fall of the month, on four or five days only was the pure blue colour of the water in any degree interfered with.

Of the 26 samples supplied by the New River Company, the whole, excepting one which was "very slightly turbid," were found to be well filtered, clear, and bright.

Of the 26 samples from the mains of the East London Company, all were found to be well filtered, clear, and bright.

Of the 26 samples from the mains of the Chelsea Water Company, all were found to be well filtered, clear, and bright.

Of the 26 samples from the mains of the West Middlesex Company, the whole, excepting one sample which was "very slightly turbid," were found to be well filtered, clear, and bright.

Of the 26 samples from the mains of the Lambeth Water Company, the whole excepting two which were "very slightly turbid," were found to be well filtered, clear, and bright.

Of the 26 samples from the mains of the Grand Junction Company, the whole excepting one which was "very slightly turbid," were found to be well filtered, clear, and bright.

Of the 26 samples from the mains of the Southwark and Vauxhall Company, one was noted as "very slightly turbid." The rest were well filtered, clear, and bright.

In Table III. we have recorded the oxygen required to oxidise the organic matter, and the quantities of free oxygen present in the whole of the samples collected.

Our daily examinations of the water delivered to London during the past month satisfy us of its excellent quality, and of its suitability in every way for the supply of the Metropolis.

Further, our results, which are in accordance with those of all chemists who have examined and reported on the subject, show that the water of the Thames in its flow of some hundred and thirty miles as a definite stream, does not acquire any increased proportion of organic matter,—the amounts of organic carbon and of organic nitrogen existing in the water supplied by the companies not exceeding the amounts existing in the river water at Lechlade, where the main stream of the Thames is formed.

We remain, Sir,
Your obedient Servants,
WILLIAM CROOKES,
WILLIAM ODLING,
C. MEYMOTT TIDY.

ANALYSIS OF KINGSTEAD CHALYBEATE SPRING.

By WILLIAM JOHNSTONE, F.I.C., &c.,
Public Analyst for the Borough of King's Lynn.

THE village of Kingstead is situated about one mile and a half S.E. of Hunstanton, St. Edmunds, a rising and fashionable seaside resort. The most valuable feature of Kingstead, however, is the Chalybeate Spring, which is now being so extensively recommended by the medical faculty. It is situated in Mr. Dodman's farm-yard at the Kingstead Downs, within a delightful walk a short drive from Hunstanton. The following are the direct results obtained from an analysis of the water collected on October 14, 1880, in 1000 parts:—

Ferrous oxide	0·00739
Silica	0·01492
Calcium oxide	0·10007
Magnesium oxide	0·00980
Sulphuric anhydride	0·00912
Chlorine	0·01978
Bromine	0·00043
Phosphoric anhydride	0·00192
Potassium	0·00053
Sodium	0·01241
Carbonic dioxide (combined)	0·14146

Besides the above, it contained traces of free and albumenoid ammonia, crenic and apocrenic acids, with spectroscopic traces of lithium and strontium. The following table shows the name and quantity of the various elements in combination in 1000 parts:—

Specific gravity	1·1465
Temperature of air	52° F.
„ „ water	53° F.
Calcium sulphate	0·01550
„ phosphate	0·00419
„ carbonate	0·22882
Magnesium bromide	0·00144
„ chloride	0·00053
„ carbonate	0·02719
Potassium chloride	0·00056
Sodium chloride	0·03157
Ferrous carbonate	0·01190
Silica	0·01942
	0·34113

Natural gases dissolved in the water:—

Carbonic acid	24·422 c.c.
Nitrogen	32·806 ,,
Oxygen..	5·236 ,,
Total.. ..	62·464 ,,

The following table gives the several constituents expressed in grains per imperial gallon, so as to meet the requirements of the medical adviser:—

Calcium sulphate	1·0850
,, phosphate	0·2933
,, carbonate	16·0174
Magnesium bromide	0·1008
,, chloride	0·0371
,, carbonate	1·9033
Potassium chloride..	0·0392
Sodium chloride	2·2099
Ferrous carbonate	0·8330
Silica	1·3594
	23·8784
Total by direct estimation	23·5200

Natural gases dissolved in the water:—

Carbonic acid	6·507 cub. ins.
Nitrogen	8·776 ,, ,,
Oxygen..	1·400 ,, ,,
Total	16·613 ,, ,,

A NEW DEMONSTRATION OF THE CARBONIC ACID OF THE BREATH.

By C. F. CROSS.

SOME time since I made the observation that the carbonic acid of the breath determines the liberation of iodine from a mixture of potassium iodide and iodate, and that the presence of starch renders the decomposition a very effective lecture-experiment, in demonstration of the presence of an active acid body in respired air. A friend to whom I lately communicated this result, threw doubt upon my interpretation, and while admitting the occurrence of the decomposition under the condition of respiring vigorously into the solution, preferred to attribute it to the action of the air or of acid vapours accidentally present. I therefore repeated the experiment with special precautions, viz., washing the respired gases, and performing parallel experiments, in which, for the breath I substituted a rapid current of air, and lastly raising the latter to a temperature of 40° C. The result was to prove conclusively my original statement that the decomposition is brought about by a constituent of the respired air, and therefore by its carbonic acid. In performing this experiment it is only necessary to secure the neutrality of the solution; this being done the development of a full purple colour occupies from two to three minutes.

It is evident that this demonstration of the presence of *some* acid body precedes the lime-water test in the logical development of the complete proof of the presence of *carbonic* acid.

COPYING INK FOR READILY TRANSCRIBING LETTERS WITHOUT A PRESS.

A PAPER on this subject by Professor Attfield, F.R.S., &c., was read at the annual Pharmaceutical Conference at York, on Tuesday last. The author stated that for the past thirteen years all letters, reports, &c., that he had written had been transcribed into an ordinary thin-paper copying-book with no more effort than was employed in using a piece of blotting-paper. It had only been necessary to place the page of writing, note size, letter size, or even foolscap, in the letter-book, and use a leaf of the letter-book just as one would use a leaf of blotting-paper. The superfluous ink that would go into blotting-paper went on to the leaf of the letter-book, and, showing through the thin paper as usual, gave, on the other side of the leaf, a perfect transcript of the letter. Any excess of ink on the page either of the letter or of the copying paper was removed by placing a sheet of blotting-paper between them and running one's hand firmly over the whole in the ordinary manner.

This ready transcription was accomplished, as would be anticipated, by using ink which dried slowly. Indeed, obviously, the ink must dry sufficiently slowly for the characters at the top of a page of writing to remain wet when the last line was written, while it must dry sufficiently fast to preclude any chance of the copied page being smeared while subsequent pages were being covered. The drying must also be sufficiently rapid to prevent the characters "setting off," as printers term it, from one page on to another after folding.

The author then alluded to some difficulties attending the employment of the ink which had prevented its becoming an article of wholesale trade, but, he said, any chemist and druggist could make it and sell it, giving directions for use to customers. He himself had used it from year's end to year's end without any trouble whatever. It would be particularly useful to professional men and private persons.

The principle of the method of preparation consisted in dissolving a moderately powerful hygroscopic substance in any ordinary ink. After experimenting on all such substances known to him, he gave the preference to glycerin. Reduce, by evaporation, ten volumes of ink to six; then add four volumes of glycerin. Or manufacture some ink of nearly double strength and add to any quantity of it nearly an equal volume of glycerin.

NOTICES OF BOOKS.

A Dictionary of Chemistry and the Allied Branches of Other Sciences. By HENRY WATTS, F.R.S., &c. Third Supplement. Part II. London: Longmans, Green, and Co.

ONLY persons who, like ourselves, find it necessary to keep a constant watch on the progress of chemical science, can form any adequate idea of the more than Herculean labour which Mr. Watts has undertaken. The continual stream of discoveries—some of them of a very high order—necessitates not merely additions to, but modifications of, our previous knowledge in almost every department of chemistry. That the author suceeds in giving so full, fair, and accurate a survey of all this wealth of research, redounds highly to his credit, both for industry and discrimination.

Among the most important articles, most of which are, of course, merely supplemental to what has been written on the same subjects in former volumes, we may mention those on meteorites, naphthalen, phenol, phthaleines, nutrition and respiration of plants, resorcinol, &c. The treatise on thermodynamics almost deserves the rank of a monograph, and along with the section on thermochemistry (under heat) will be of signal utility both to chemists and physicists.

The behaviour of lead with water and the saline solution has been made the subject of many recent investigations, which are here carefully summed up.

The article Light is copious and includes many interesting results in circular polarisation. Under "Refraction and Dispersion," we find an anomaly in nomenclature which we should scarcely have expected. The author uses

"fuchsine" as a trivial synonym for the tinctorial salts of rosaniline. We submit that this word is not English at all. It is incapable of being pronounced by any Englishman unless he is acquainted with the German language, and like the now obsolete terms "azaleine," "roseine," &c., it is ambiguous. We find the same word several times repeated in the article on rosaniline, and in that on saffranine.

The enumeration of meteoric stones which have been found and analysed lately, and many of which have been actually observed falling, is very full.

In the valuable notice on isomerism, which is from the pen of Dr. H. E. Armstrong, one of the ablest and most successful of British chemists, the question is raised whether any two compounds, differing in physical characters, are precisely alike in their so-called chemical properties. "The two tartaric acids, which probably resemble each other more closely than any other two compounds with which we are aquainted, undergo fermentation, it is said, with different degrees of readiness, the dextrorotatory acid disappearing first."

Reference is made to the synthetic preparation of glycerin. The process scarcely admits of industrial application, but if capable of sufficient simplification, it might become very important, now the ordinary source of glycerin—the manufacture of stearic acid—is declining in consequence of the growing disuse of candles.

We find some interesting facts on the so-called fish-guanos prepared in Norway and elsewhere from the refuse of the fisheries. Fish-guanos not free from fat are very slow in putrefying, and, consequently, we may presume, in giving up their valuable constituents to the soil. Treatment with sulphuric acid was also not found advantageous, as the acid even when added to the extent of 30 per cent, was chiefly taken up by the organic matter, and only about 3·60 per cent of phophoric acid, out of a total of 13·89 per cent, was rendered soluble. Some authorities consider it most advantageous to feed cattle with the fish-guano and to use their excrements as manure. What might be the effect of such a diet upon the flesh, milk, &c., of the cattle, does not seem to have been examined.

Concerning the value of the volume before us, comment is scarcely requisite. It is an integral part of a work of reference which no chemist can afford to dispense with.

As far as we can learn, a very general wish has sprung up in chemical circles for a new edition of the whole of "Watts's Dictionary," in which the supplements should be incorporated with the original volumes, and all more recent matter should be introduced under a new arrangement. Of the value of such an edition to chemists there can be but one opinion, and we have no doubt that it would be prized accordingly. Considering the number of persons now engaged in chemical studies, the publishers ought to receive ample support in an undertaking which may well be pronounced of national importance.

Journal and Proceedings of the Royal Society of New South Wales, 1880. Vol. XIV. Edited by A. LIVERSIDGE. Sydney: Thomas Richards. London: Trübner and Co.

THE Royal Society of New South Wales has scarcely been as active as might be wished. Of its sections, those for astronomy, meteorology, physics, mathematics, and mechanics; for chemistry and mineralogy; for geology and palæontology; for biology, and for geography and ethnology, did not meet at all during the past year.

The Vice-President, Mr. G. Moore, F.L.S., in his able anniversary address, regrets that so few papers were read at the general meetings.

Several interesting papers on chemical subjects have, however, been communicated to the Society. Mr. E. H. Rennie has read a paper on the acids of the native currant (*Leptomeria acida*), which appear to be the malic, with probably a small quantity of citric, acid.

Prof. Liversidge has made a careful examination of the alkaloid from piturie. The sample operated upon, was the product of a Solanaceous plant, *Duboisia Hopwoodi*, now named *D. pituri*. The author assigns to the alkaloid the formula $C_{12}H_{16}N_2$. It is distinguished from coneine by its aqueous solution not turning turbid on heating nor on the addition of chlorine-water. It differs from aniline by not being coloured by chloride of lime; it differs from picoline in specific gravity, from pyridine by its reaction with copper sulphate, and is distinguished from nicotine by its behaviour with platinic chloride, gold chloride, iodine, and mercuric chloride.

Prof. Liversidge also communicates the analysis of water from a hot spring in New Britain; and of water from a hot spring at Savu Savu, Fiji Islands.

Other papers by the same author are "On Some New South Wales Minerals" and "Notes on Some Minerals from New Caledonia."

Mr. W. A. Dixon, F.C.S., of the Sydney Technical College, communicates a paper on "Salt-bush and Native Fodder Plants of New South Wales." In all of them, except the "old man" and the "cotton-bush," the total digestible matter falls below that of European fodders.

Mr. Dixon also read a paper on the "Inorganic Constituents of the Coals of New South Wales."

From a paper on the "Causation and Prevention of Insanity," read before the Medical Section by F. Norton Manning, M.D., we quote this significant passage:—"I know no stronger evidence as to the evil done by over work at schools and competitive examinations than that of Dr. Andrew Clarke, who states that he has discovered temporary albuminuria in 10 per cent of the candidates sent to him for examination as to physical health after passing the Civil Service examination for India."

From certain passages in this Journal, we fear that the Australians labour under a delusion, from which the mother-country and America are just recovering, *i. e.*, the notion that they have no time for science. National prosperity, in these days, is not to be compassed by rule-of-thumb.

CORRESPONDENCE.

PREPARATION OF PURE NAPHTHALEN.

To the Editor of the Chemical News.

SIR,—Mr. Staveley, in the CHEMICAL NEWS, vol. xliv., p. 85, makes some remarks upon my communication on the above subject, to which I beg to reply briefly.

Divested of its courteous garb, his objection comes to this, that my communication was unnecessary, inasmuch as it is the easiest thing in the world to make perfectly pure naphthalen, and everybody concerned knows all about it. To this I oppose the following *fact*:—Last autumn I made a tour in England, Germany, and France, for the sole purpose of collecting information about the newest plant and processes for tar distilling, in connection with my forthcoming treatise on this subject. I found that several large tar distillers did *not* know how to make permanently white naphthalen, and frankly confessed as much. Others certainly professed to know it, but treated it as a great *secret*. Those who really manufacture naphthalen remaining permanently white in cakes (not merely in flakes!), wrapped themselves up in complete mystery. Hence, when I found I could fill up that gap from my own experiments, I believed that I could render a slight service to technical chemistry by publishing my process, and to that opinion I adhere still, *pace* Mr. Staveley. It is all very well to say now in a general way that the use of MnO_2, and other oxidising agents for the purpose of purifying tar products is known to most tar works chemists, at least in the laboratory; the fact is that before my pub-

lication, MnO_2, &c., was nowhere stated to effect a permanent decolourisation of naphthalen, that I found this out for myself by reasoning and experiment, and that a large tar distiller, to whom I communicated my process, and who found it to answer *on the large scale*, recognised it to be a novelty worthy of remuneration. This also disposes of the objection that it is unfair to compare my samples with those prepared at the works. Neither was it incumbent upon me to say anything about hydraulic pressure in my short note; *that* would have been unnecessary, as everybody knows all about it.

As far as the cause of the pink discolouration is concerned, Mr. Staveley too generously credits me with having originated the supposition that aurin may be formed by the oxidation of a mixture of phenol and cresol. This reaction is known to everybody who has studied the chemistry of the coal-tar colours; it is precisely analogous to the formation of rosaniline from aniline and toluidine. Zulkowsky has actually prepared aurin by that very reaction (*Berlin Berichte*, x., 1201; abstracted *Journ. Chem. Soc.*, 1877, ii., 888), and it has been carried out at Cologne on a manufacturing scale (*Wagner's Jahresberichte*, 1878, p. 1066). I hope Mr. Staveley is satisfied on this point now.

Unfortunately the "interesting observation" made by Mr. Staveley, that lime hastens the development of a pink colour in the presence of air, is not quite new. Runge made it half a century ago, and was thereby led to the discovery of rosolic acid, and every other chemist who has worked on this subject has noticed it likewise. Only the explanation given by Mr. Staveley is novel, but not equally convincing to my mind; for, if not the O but the CO_2 of the air causes the formation of the colouring-matters, the presence of lime, which absorbs the CO_2, ought to prevent, instead of assisting, that reaction.

It is not very encouraging to those who are desirous of spreading a knowledge of technical chemistry, if they have to waste their time and the space of scientific periodicals in defending themselves for taking that liberty.—I am, &c.,

G. Lunge.

Zürich, August 22, 1881.

CHEMICAL NOTICES FROM FOREIGN SOURCES.

Note.—All degrees of temperature are Centigrade, unless otherwise expressed.

Comptes Rendus Hebdomadaires des Séances, de l'Académie des Sciences. No. 3, July 18, 1881.

Researches on Glycolic Ether and the Oxides of Ethylen.—M. Berthelot.—A thermo-chemical paper; the author has determined the evaporation-heat of glycolic ether as +6·1 cals.; its solution-heat at 13° in 160 parts of water at +1·5 cals.; its formation-heat from its elements (C_4, diamond, $+H_4+O_2$) +17·7 cals. The heat developed by the transformation of ethylen into glycolic ether is +33 cals.

Distribution of Energy in the Normal Spectrum.—M. Lengley.—According to the author's investigations made with a novel instrument the energy is feeble in the ultra-violet, whilst the rapid increase towards the blue contrasts with the slow decrease towards the red. At the very place of the maximum ordinarily placed in this region there is in reality merely a point of inflection. The so-called curve of light coincides almost exactly with that of heat, instead of being totally distinct as hitherto believed. Hence the luminous effects of solar energy upon the retina are approximately proportional to those of heat upon the thermometer.

Hydrosulphurous Acid.—M. Schützenberger.—A reply to the communication of M. Bernthsen (*Comptes Rendus*, July 11, 1881). The author contends that the results of M. Bernthsen prove nothing against his formula.

A Method of Amplifying the Displacements of the Plane of Polarisation of Light.—H. Becquerel.—Not suitable for abstraction.

Speed of the Propagation of Ignition in Explosive Gaseous Mixtures.—MM. Mallard and Le Chatellier.—With mixtures of hydrogen and air the maximum speed is produced with a mixture containing about 10 per cent more hydrogen than the theoretical detonating mixture. When gases are heated their speed of propagation increases. The diameter of the tube has no notable influence upon the speed, except it is very small.

Splitting up and Enlargement of the Bands of the Rainbow.—C. Ritter.—If the drops of water are at a less distance than 1·50 metres, we ought, when looking at them with both eyes, to perceive two distinct bows or rings; these bows will have their maximum interval on their horizontal diameter, and the interval, in the form of a crescent which separates the inner violet of the one from the outer red of the other, will decrease progressively to the upper and lower points of intersection of the two rings. At the distance of 1·50 metres the two bows are in contact, violet against red, on the horizontal line. Beyond 1·50 metres the bows cross each other on their whole circumference, but without ever producing complete superposition.

Action of Sulphur upon Certain Metallic Solutions.—MM. E. Filhol and Senderens.—If finely divided sulphur is mixed with a solution of lead sulphate and the mixture boiled, lead sulphide is deposited, and the sulphuric acid is set at liberty. The authors show that this result is to be foreseen according to the principles laid down in the *Traité de Mécanique Chimique* of M. Berthelot. Silver carbonate, oxalate, nitrate, and acetate are also decomposed in the same manner. Silver chloride has not been decomposed. Lead sulphate is decomposed very slowly, and the supernatant liquid is not acid. Copper sulphate, nitrate, and chloride have not been appreciably decomposed.

Separation and Determination of Alumina and the Ferric and Chromic Oxides.—A. Carnot.—Inserted in full.

The Magnesia Industry.—T. Schlœsing.—The author speaks in the first place of two distinct systems of dealing with fœcal matter: water-carriage in sewers and the separate collection of the excrements, and their conversion into portable manures. For this purpose the author recommends an addition of phosphoric acid and magnesia, so as to form in combination with the ammonia of the urine, &c., an ammonium-magnesian phosphate. A plentiful supply of magnesia at a cheap rate is necessary. He shows the impracticability of obtaining magnesia on a commercial scale by precipitating its saline solutions with the milk of lime. He then refers to a process which he will describe on a future occasion.

Experiments with Phenol, Ammonium, Phenate, &c., on Patients Suffering from Yellow Fever.—M. de Lacaille.—The author, a physician practising at Rio de Janeiro, has used phenol successfully in yellow fever. In one of the cases the "black vomit" had already set in.

Revue Universelle des Mines, de la Metallurgie, &c., Tome 9, No. 2, March and April, 1881.

Researches on the Chemical Stability of Explosives.—P. von Hess.—Not adapted for abstraction.

Note on the Beds and the Working of Guano in the South of Peru.—E. G. Detienne.—The author remarks that the meridian circle of elevation passes by the Gallapagos Islands, Huancavelica, Monte Video, Sumatra, Japan, and the Aleutians. On this track mercury is everywhere associated with thermal waters, and sometime

gushes up alone. He considers that the production of guano has ceased long ago. The birds by which it was deposited have ceased to exist, and on this coast only nitrate of soda offers the prospect of prolonged working on a large scale.

The Mineral Wealth of Maxos, Paros, and the Cyclades.—M. Rosseel.—The products of these islands are emery, marble, argentiferous galena, calamine, sulphur, the yearly yield of which is about 1200 tons, mill stones and manganiferous hæmatite.

New Process for the Volumetric Determination of Potassium.—L. L. de Koninck.—The potassium is thrown down, with the ordinary precautions, by platinum chloride; the K_2PtCl_6 is collected on a filter, washed in alcohol, and immediately dissolved in boiling water. The solution is reduced hot by magnesium. All the chlorine of the chloro-platinate is obtained in the form of a soluble chloride, and a black precipitate of reduced platinum. At the same time the magnesium decomposes the water, yielding hydrated magnesia with an escape of hydrogen. When the reduction is complete the mixture is filtered, and in the neutral solution the chlorine is determined in the usual manner with a standard solution of silver nitrate, using potassium chromate as indicator.

Journal für Praktische Chemie.
No. 11, 1881.

The Compounds of the Mono- and Bi-basic Fatty Acids with Phenols (Second and Third Treatises).—M. Nencki and N. Sieber.—The authors describe the preparation and properties of two colouring-matters, acet-fluoresceine and resaceteine, the former of which is characterised by a fine green fluorescence.

Anthology of Modern Chemical Utterances.—H. Kolbe.—Continued from No. 9, and deserving careful attention.

Two Spurious Inaugural Dissertations.—Detected and made known by H. Kolbe and E. von Meyer.—The two dissertations are *verbatim* piracies. The offenders are not known in England, and the publication of their names would therefore be useless.

Les Mondes, Revue Hebdomadaire des Sciences.
No. 1, May 5, 1881.

Action of Ammonia upon Isatin.—Dr. E. von Sommaruga.—Isatin contains at least one hydroxyl group. Diamide, a derivative of isatin, gives rise to ammonia under the action of alkalies, even if dilute, which causes us to suppose the presence of a group of amide in the diamide, and of a hydroxyl group in the isatin.

New Hydrocarbon.—J. Kachler and F. V. Spiher.—This compound is hydrocamphen. It is obtained by the substitution of hydrogen for chlorine in the compounds $C_{10}H_{17}Cl$.

Oxidation of Quinine.—Quinine, in place of cinchonic acid, yields a new nitrogenous compound, quinic acid, of a light yellow colour, slightly soluble in water, even at 100°. Its salts crystallise readily, and are characterised by an odour like that of coumarine, which they give off if heated.

No. 2, May 2, 1881.

This issue contains no chemical matter save what is extracted from other journals.

MISCELLANEOUS.

Hot-air Engines.—At the Royal Manchester and Liverpool Agricultural Society's show, held at Blackburn, September 1, 2, and 3, Messrs. W. H. Bailey and Co., of the Albion Works, Salford, exhibited their slow-combustion hot-air engine, for which they obtained the first class silver medal for its excellence and superiority.

British Association for the Advancement of Science.—The Jubilee Meeting at York, both as regards the number of members and associates attending and the importance of the papers read, has admittedly been a great success. In 1879 at Sheffield the total was 1404, and at Swansea last year 915, but this year the number has risen to 2533, which includes 22 foreign members, 510 ladies, and 1173 associates. The following is the synopsis of grants of money appropriated to scientific purposes by the general committee:—The Council, Exploration of Mountain District of Eastern Equatorial Africa, £100. Mathematics and Physics—Mr. G. H. Darwin, Lunar Disturbance of Gravity, £15; Dr. A. Schuster, Meteoric Dust, £20; Professor Sylvester, Fundamental Invariants (partly renewed), £30; Mr. R. H. Scott, Synoptic Charts of the Indian Ocean, £50; Professor G. C. Foster, Standards for use in Electrical Measurements (partly renewed), £100. Chemistry—Professor Dewar, Present state of Knowledge of Spectrum Analysis, £5; Professor Balfour Stewart, Calibration of Mercurial Thermometers, £20; Professor Roscoe, Wave-lengths Tables of Spectra of Elements, £50; Dr. Hugo Müller, Chemical Nomenclature, £10; Professor Odling, Photographing the Ultra-Violet Spark Spectra, £25. Geology—Dr. J. Evans, Record of the Progress of Geology, £100; Professor Ramsay, Earthquake Phenomena of Japan, £25; Dr. H. C. Sorby, Conditions of Conversion of Sedimentary Materials into Metamorphic Rocks, £10; Professor W. C. Williamson, Fossil Plants of Halifax, £15; Professor A. C. Ramsay, Geological Map of Europe, £25; Professor E. Hull, Circulation of Underground Waters, £15; Professor W. C. Williamson, Tertiary Flora associated with the Basalts of the North of Ireland, £20; Dr. Sorby, British Fossil Polyzoa, £10; Professor Leith-Adams, Carboniferous Limestone Caves in South Ireland, £10; Professor Green, Exploration of Reygill Fissure, £20. Biology—Mr. F. M. Balfour, Table at the Zoological Station at Naples, £80; Dr. Burdon Sanderson, Albumenoid Substances of Serum, £10; Dr. Pye-Smith, Influence of Bodily Exercise on the Elimination of Nitrogen, £50; Dr. M. Foster, Zoological Station in Scotland, £40; Mr. J. Cordeaux, Migration of Birds, £15; Lieut.-Colonel Godwin-Austen, Natural History of Socotra, £100; Mr. Thiselton-Dyer, Natural History of Timor Laut, £100; Mr. Stainton, Record of Zoological Literature, £100; Professor Flowers, Photographs of Typical Races, £10. Statistics—W. F. Galton, Anthropometry, £50—£1280. The meeting in 1882 will be held at Southampton under the presidency of Dr. C. W. Siemens, and Oxford has been selected for the Association's meeting in 1883.

NOTES AND QUERIES.

*** Our Notes and Queries column was opened for the purpose of giving and obtaining information likely to be of use to our readers generally. We cannot undertake to let this column be the means of transmitting merely private information, or such trade notices as should legitimately come in the advertising columns.

White Naphthalen.—J. W. T. can procure commercial "white naphthalen," in any quantity, at a price of about £10 per ton, and a sample can be had if he will forward his address.—B.

TO CORRESPONDENTS.

Sutton.—No process is known which will suit your requirements.

NOTICE.

The STUDENTS' NUMBER of the Chemical News, will be published on Friday, September 23rd. Gentlemen holding official positions in the Universities, Colleges, Medical Schools, &c., of the United Kingdom, where Chemistry and Physical Science form a part of the education, who have not yet forwarded the necessary information to our Office for publication in that Number, will confer a favour by sending it with the least possible delay.

THE CHEMICAL NEWS.

VOL. XLIV. No. 1139.

ADDRESS TO STUDENTS.

Now our colleges and scientific schools are resuming their duties, we feel called upon again to make a few remarks for the special consideration of the student. We would above all ask him what is his especial object in seeking an acquaintance with chemical science? He may regard it as a subject of which in these days no man of culture can well afford to be entirely ignorant, and with this view he may seek to gain a clear and accurate, though of course summary, knowledge of its leading facts, of the thories in which they are embodied, and of their practical applications. Such a knowledge of principles he will find of great value in almost every capacity or station of life, and we bid him therefore go on and prosper.

A second student may carry the same idea somewhat further. Wishing to acquire a thorough mental training, he may devote a portion of his time to chemistry, not so much for the especial value of the facts or the laws which it teaches as for the discipline it conveys. We know that the advocates of an exclusively classical and mathematical education admitted that the value of their favourite studies lay less in *doctrine* than in *method*. But chemistry, if rightly studied, gives a kind of mental training which classics and mathematics cannot impart. It teaches the art of minute and accurate observation; it fixes the mind upon facts rather than upon words; it instructs us in the experimental examination of Nature. To all who view chemical science in this light, as one of the most important agents in intellectual culture, we would address a word of encouragement. If they persevere they will assuredly never regret the hours they have spent in the laboratory. It must be distinctly understood, however, that we refer here to actual work. No book studies, no paper training, will convey the arts of observing and experimenting.

We come now to the noblest type of the student. There are men, unhappily too few, endowed with exceptional mental powers, and with a natural love for science quite irrespective of any outward results in the shape of emoluments or honours. If such persons are willing to devote their lives to discovery, and possessing a competence are not liable to have their time wasted by the exigencies of a profession or business, they may find in the pursuit of chemistry a field for their talents, not merely fruitful but inexhaustible. It is not merely for the honour but for the actual benefit of this country, and of the whole human race, that we wish this class of students to be multiplied. To all who combine the various qualifications needful, we would say: give your lives to research!

We come now to students who enter the laboratory with a professional or practical intention, having an eye mainly to the actual or possible applications of chemical science. Of such there are two distinct classes. There are many who look forward to employment in some of the many arts and manufactures which are more or less exclusively based upon chemical principles, such as metallurgy, glass-making, dyeing, tissue-printing, colour-making, bleaching, the manufacture of alkali, &c. For all such a scientific knowledge of chemistry is essential as a foundation. The day is over when a bundle of receipts and the possession of a few trade secrets could make either a master, a manager, or a foreman equal to the duties required of him. Before we can rationally teach applications we must lay down principles. Otherwise our knowledge will be mere empiricism, very good, doubtless, under some particular set of circumstances, but utterly useless the moment any new and unexpected contingency arises.

But there is another class of students who start with a practical aim whom we must bid pause and reflect. We refer to those who, without being prospectively connected with any of the chemical industries, would follow chemistry as a profession, and become "analytical and consulting chemists." We would warn such students that this profession is over-crowded and ill-remunerated, and that to its most distinguished and successful members it brings nothing like the rewards which fall to the lot of the lawyer, the engineer, or even of the medical practitioner. We would therefore bid all students of this class to consider whether they possess the necessary qualifications, bodily as well as mental, and whether they have the means for their support during the years which must pass before they can acquire a connection. In any case we would advise such, after the completion of their college course to seek a practical acquaintance with some of the chemical arts. Some eminent authorities, indeed, would invert the arrangement, and advise a young man to work for two or three years—*e.g.*, in the dye-house—before beginning his college training.

There is, last in rank and value, but certainly not least in numbers, s class of students who care nothing for chemistry as a mental discipline—who would not if they could, and could not if they would, devote themselves to research, and who have just as little sympathy or connection with the chemical arts. The object of these worthies is to pass some examination. Chemistry is one of the subjects to be "got up," and is of course regarded as a necessary evil, or in the language of the class in question, as an "awful bore." What can we say to such? We can give them neither advice nor encouragement, and can only regret the institutions which render them possible.

UNIVERSITIES AND COLLEGES.

UNIVERSITY OF LONDON.

CANDIDATES for any Degree granted by this University are required to have passed the Matriculation Examination, to which no candidate is admitted unless he has produced a certificate showing that he has completed his sixteenth year.

The Fee for this examination is £2.

The Examination will be held on Monday, January 9th, 1882. It is conducted by means of Printed Papers; but the Examiners are not precluded from putting, for the purpose of ascertaining the competence of the Candidates to pass, *viva voce* questions to any Candidate in the subjects in which they are appointed to examine.

Candidates are not approved by the Examiners unless they have shown a competent knowledge in each of the

following subjects:—Latin. Any two of the following Languages:—Greek, French, German, and either Sanskrit or Arabic. The English Language, English History, and Modern Geography. Mathematics. Natural Philosophy. Chemistry.

The Papers in Latin and Greek will contain passages to be translated into English, with questions in Grammar and History and Geography arising out of the subjects of the books selected. Short and easy passages will also be set for translation from other books not so selected. A separate paper will be set containing questions in Latin Grammar, with simple and easy sentences of English to be translated into Latin.

Candidates may substitute German for Greek.

The papers in French and German will contain passages for translation into English, and questions in Grammar, limited to the Accidence. The paper in Sanskrit or Arabic will contain passages for translation into English, and questions in Grammar.

The examination in the English Language, English History, and Modern Geography includes Orthography; Writing from Dictation; the Grammatical Structure of the Language. History of England to the end of the Seventeenth Century, with questions in modern Geography.

That in Mathematics includes the ordinary Rules of Arithmetic; Vulgar and Decimal Fractions; Extraction of the Square Root. Addition, Subtraction, Multiplication, and Division of Algebraical Quantities; Proportion; Arithmetical and Geometrical Progression; Simple Equations. The First Four Books of Euclid, or the subjects thereof.

The Questions in Natural Philosophy are of a strictly elementary character; they include Mechanics, Hydrostatics, Hydraulics, Pneumatics, Optics, and Heat.

The Examination in Chemistry is—Chemistry of the Non-metallic Elements; including their compounds—their chief physical and chemical characters—their preparation—and their characteristic tests.

A Pass Certificate, signed by the Registrar, will be delivered to each Candidate who applies for it, after the Report of the Examiners has been approved by the Senate.

If in the opinion of the Examiners any Candidates in the Honours Division of not more than Twenty years of age at the commencement of the Examination possess sufficient merit, the first among such Candidates will receive an Exhibition of thirty pounds per annum for the next two years; the second among such Candidates will receive an Exhibition of twenty pounds per annum for the next two years; and the third will receive an Exhibition of fifteen pounds per annum for the next two years; such exhibitions are payable in quarterly instalments, provided that on receiving each instalment the Exhibitioner declares his intention of presenting himself either at the two Examinations for B.A., or at the two Examinations for B.Sc., or at the First LL.B. Examination, or at the Preliminary Scientific and First M.B. Examinations, within three academical years* from the time of his passing the Matriculation Examination.

Under the same circumstances, the fourth among such Candidates will receive a prize to the value of ten pounds in books, philosophical instruments, or money; and the fifth and sixth will each receive a prize to the value of five pounds in books, philosophical instruments, or money.

Any Candidate who may obtain a place in the Honours Division at the Matriculation Examination in January is admissible to the First B.A. or to the First B.Sc. Examination in the following July.

First B.Sc. Examination.

The First B.Sc. Examination will be held in July, 1882.

No Candidate (with the exception of such as have obtained Honours at the Matriculation Examination in the preceding January) is admitted to this Examination within one academical year of the time of his passing the Matriculation Examination.

The Fee for this Examination is £5.

The Examination embraces the following subjects:—Pure and Mixed Mathematics, Inorganic Chemistry, Experimental Physics, and General Biology.

Examination for Honours.

Any Candidate who has passed the First B.Sc. Examination in all its subjects may be examined at the Honours Examination next following the First B.Sc. Examination at which he has passed for Honours in (1) Mathematics, (2) Experimental Physics, (3) Chemistry, (4) Botany, and (5) Zoology; unless he has previously obtained the Exhibition in Pure and Mixed Mathematics at the First B.A. Examination, in which case he will not be admissible to the Examination for Honours in that subject; or unless he has previously obtained an Exhibition at the Preliminary Scientific (M.B.) Examination in either of the subjects which are common to it with the first B.Sc. Examination, in which case he will not be admissible to the Examination for Honours in that subject.

Candidates for Honours in Chemistry will be examined in Inorganic Chemistry, treated more fully than in the Pass Examination. In addition, they will be examined practically in Simple Qualitative Analysis. This Examination, which will consist of six hours' examination by printed papers and of six hours' practical work, will take place on Thursday and Friday (with Saturday if necessary) in the same week with the Examination for Honours in Mathematics, commencing on each day at 10 a.m.

In the Examination for Honours, the Candidate, not being more than 22 years of age at the commencement of the Pass Examination, who most distinguishes himself in Mathematics, will receive an Exhibition of £40 per annum for the next two years.

Second B.Sc. Examination.

The Second B.Sc. Examination will be held in October, 1882.

Candidates for this Examination are required to have passed the First B.Sc. Examination at least one academical year previously.

The Fee for this Examination is £5.

The regulations are framed with the view of allowing the candidate to select *any three* of the following nine subjects:—

1. Pure Mathematics.
2. Mixed Mathematics.
3. Experimental Physics.
4. Chemistry.
5. Botany, including Vegetable Physiology.
6. Zoology.
7. Animal Physiology.
8. Physical Geography and Geology.
9. Mental and Moral Science.

Examination for Honours.

Any Candidate who has passed the Second B.Sc. Examination, and has not previously passed the Second B.A. Examination, may be examined at the Honours Examination next following the Second B.Sc. Examination at which he has passed, for Honours in (1) Mathematics, (2) Mental and Moral Science, (3) Experimental Physics, (4) Chemistry, (5) Botany, (6) Zoology, (7) Physiology, (8) Physical Geography and Geology; provided that he shall have gone through the Pass Examination in the

* By the term "Academical Year" is ordinarily meant the period intervening between any Examination and an Examination of a higher grade in the following year; which period may be either more or less than a Calendar year. Thus the interval between the *First* Examinations in Arts, Science, and Medicine, and the *Second* Examinations of the next year in those Faculties respectively, is about sixteen months, whilst the interval between the Second B.A. Examination and the M.A. Examination of the nex tyear, or between the Second B.Sc. Examination and the D.Sc. Examination of the next year, is less than eight months. Nevertheless, each of these intervals is counted as an "Academical Year."

corresponding subject or subjects immediately before. And any Bachelor of Arts who has passed the Second B.Sc. Examination may under the same conditions be examined for Honours in one or more of the above mentioned subjects, unless he have previously obtained a Scholarship at the Second B.A. Examination in either of the first two of those subjects, in which case he shall not be admissible to the Examination for Honours in that subject.

The examination for Honours in Chemistry will take place on Monday and Tuesday in the week following the Examination for Honours in Mathematics; on Monday by printed papers (chiefly on Organic Chemistry), and on Tuesday by practical exercises in Simple Qualitative and Quantitative Analysis.

The candidate, being not more than 23 years of age, who most distinguishes himself in Chemistry, will receive £50 per annum for the next two years, with the style of University Scholar.

Doctor of Science.

The examination for the Degree of Doctor of Science takes place annually within the first twenty-one days of June, and the examination in each branch occupies four days.

No candidate is admitted to the examination for the Degree of D.Sc. until after the expiration of two Academical Years from the time of his obtaining the Degree of B.Sc. in this University, unless he shall have passed the Second B.Sc. Examination in the First Division at least two Academical years subsequently to having passed the first B.Sc. Examination, in which case he shall be admitted to the examination for the Degree of Doctor of Science at the expiration of *one* Academical Year from the time of obtaining his B.Sc. Degree.

The Fee for this Examination is £10.

Every candidate for the degree of D.Sc is examined in some one or more of the various branches of Physical, Biological, Geological and Palæontological, or Mental Science, to be selected by himself; and no candidate is approved by the examiners unless he has shown a thorough practical knowledge of the principal subject and a general acquaintance with the subsidiary subject or subjects, specified as belonging to the branch so selected. He is expected to be so fully conversant with the principal subject he may select as to be able to go through any examinational test (whether theoretical or practical) of his acquirements in it that can be fairly applied. Candidates, when giving notice, must specify the branch or branches in which they desire to be examined.

Branch IV. of Physical Science. Inorganic Chemistry.

Principal Subject—Inorganic Chemistry.

Subsidiary Subjects—Either Organic Chemistry; or Mineralogy, Crystallography, and Chemical Technology in its relations to Inorganic Chemistry.

Branch V., Organic Chemistry.

Principal Subject—Organic Chemistry.

Subsidiary Subjects—Either Inorganic Chemistry; or Chemical Technology in its relations to Organic Chemistry, and the Chemistry of Animal and Vegetable Life.

Preliminary Scientific (M.B.) Examination.

This examination will be held in July, 1882.

No Candidate is admitted to this examination until he has completed his seventeenth year, and has either passed the Matriculation Examination* or taken a Degree in Arts in one of the Universities of Sydney, Melbourne, Calcutta, or Madras (provided that Latin was one of the subjects in which he passed). The fee for this examination is five pounds.

Candidates for the degree of M.B. are strongly recommended by the Senate to pass the Preliminary Scientific Examination before commencing their regular medical studies; and to devote a preliminary year to preparation for it according to the following programme:—Winter Session: Experimental Physics; Chemistry (especially Inorganic); Zoology. Summer Session: Practical Chemistry (Inorganic); Botany.

Any candidate who has passed the Preliminary Scientific (M.B.) Examination, may be examined at the Honours Examination next following the Preliminary Scientific Examination at which he has passed, unless he has previously obtained an Exhibition in any one of the subjects at the First B.Sc. Examination, in which case he is not admissible to the Examination for Honours in that subject.

Candidates for Honours in Chemistry are examined in Inorganic Chemistry, treated more fully than in the Pass Examination. In addition they are examined practically in Simple Qualitative Analysis.

Examination in Subjects relating to Public Health.

A Special Examination will be held in December in subjects relating to public health.

No candidate is admitted to this Examination unless he has passed the Second Examination for the Degree of Bachelor of Medicine in this University at least one year previously; nor unless he shall have given notice of his intention to the Registrar at least two calendar months before the commencement of the Examination.

The Fee for this Examination is £5.

Candidates are examined in the following subjects:—

Chemistry and Microscopy, in relation to the examination of Air, Water, and Food.

Meteorology and Geology, as far as they bear on the duties of Health Officers, viz.:—General knowledge of Meteorological Conditions; Reading and Correction of Instruments. General knowledge of Rocks; their Conformation and Chemical Composition, and their relation to underground Water, and to drainage and sources of Water-supply.

Physics and Sanitary Apparatus.—The laws of Heat Mechanics, Pneumatics, Hydrostatics, and Hydraulics, in relation (or sanitary purposes) to the construction of Dwellings, and to the principles of Warming, Ventilation, Drainage, and Water-supply, and to forms of apparatus for these and other sanitary uses. And the reading of Plans, Sections, Scales, &c., in regard to sanitary constructions and appliances.

Vital Statistics, in reference to the methods employed for determining the Health of a Community; Birth-rate; Death-rate; Disease-rate; Life-Tables; Duration of and Expectancy of Life. Present amount of Mortality, and its causes, in different Communities. Practical statistics of Armies, Navies, Civil Professions, Asylums, Hospitals, Dispensaries, Lying-in Establishments, Prisons, In-door and Out-door Paupers, Friendly Societies, Sick-Clubs, Medical and Surgical Practice, Towns.

Hygiene, including the Causation and Prevention of Disease.

Sanitary Law, as far as it relates to the duties of Officer of Health. A knowledge of the powers given under the various Sanitary Acts, as defined in the Instructions issued by the Local Government Board, and of the methods of procedure in special cases.

The Examination, which is both written and practical, extends over four days.

Gilchrist Scholarships.

1. A Scholarship of the value of Fifty Pounds per annum, and tenable for three years, is annually awarded to the Candidate from the Royal Medical College, Epsom, who at the June Matriculation Examination stands highest

* Candidates who pass in all the subjects of the Preliminary Scientific (M.B.) Examination, and also pass *at the same time* in the Pure Mathematics of the First B Sc. Examination, or who have previously passed the First B.A. Examination, are admissible to the Second B Sc. Examination.—One Fee of £5, paid on entering for the Preliminary Scientific Examination, admits a Candidate to the First B.Sc. Mathematics also, *if taken at the same time.*

among the Candidates approved by the Head Master of that Institution, and who passes either in the Honours List or in the First Division; on condition of his prosecuting his studies during the tenure of his Scholarship with a view to Graduation in one of the Faculties of the University of London.—Particulars may be obtained on application to the Secretary of the Royal Medical College, 37, Soho Square, W.

2. A similar amount is annually offered to Candidates intending to pursue, at Owens College, Manchester, their studies for Graduation in one of the Faculties of the University of London; a single Scholarship of Fifty Pounds per annum for three years being awarded to the highest of those Candidates at the June Matriculation Examination who shall have been previously approved by the Principal of Owens College, provided that he pass in the Honours Division; or, in case no Candidate should so pass, two Scholarships, each of Twenty-five Pounds per annum, being awarded to the two Candidates as aforesaid who shall stand highest in the First Division.—Particulars may be obtained on application to the Principal of Owens College, Manchester.

Particulars of the Colonial and Indian Scholarships may be obtained on application to the Secretary of the Gilchrist Educational Trust, 4, Broad Sanctuary, Westminster, S.W.

SCIENCE AND ART DEPARTMENT OF THE COMMITTEE OF COUNCIL ON EDUCATION, SOUTH KENSINGTON.

A sum of money is voted annually by Parliament for scientific instruction in the United Kingdom. The object of the grant is to promote instruction in Science, especially among the industrial classes, by affording a limited and partial aid or stimulus towards the founding and maintenance of Science schools.

In order to place a science school in connection with the Science and Art Department, an approved committee, consisting of at least five well known and responsible persons, must be formed.

The following are the sciences towards instruction in which aid is given by the Science and Art Department:—Practical, Plane, and Solid Geometry; Machine Construction and Drawing; Building Construction; Naval Architecture and Drawing; Pure Mathematics; Theoretical Mechanics; Applied Mechanics; Sound, Light, and Heat; Magnetism and Electricity; Inorganic Chemistry; Organic Chemistry; Geology; Mineralogy; Animal Physiology; Elementary Botany; Biology, including Animal and Vegetable Morphology and Physiology; Principles of Mining; Metallurgy; Navigation; Nautical Astronomy; Steam; Physiography; Principles of Agriculture.

The aid is given in the form of—1. Public examinations in which Queen's Prizes are awarded, held at all places, complying with certain conditions; 2. Payments on the results of examination and on attendance; 3. Scholarships and Exhibitions; 4. Building grants; 5. Grants towards the purchase of apparatus, &c.; 6. Supplementary grants in certain subjects, and special aid to teachers and students.

The examinations are held about the month of May under the superintendence of the local committees and local officers. The examination papers are prepared by the professional examiners in London, and the examination in each subject is held simultaneously over the whole kingdom.

A packet of examination papers is sent to a specially appointed custodian, and the superintendents of the examination open it in the presence of the candidates. The superintendents are responsible that no unfair means of any description are used in working the papers, and that the rules of the Department are strictly complied with.

The subjects are divided into three stages, and a separate set of questions is set in each. In each stage—Elementary, Advanced, and Honours—there are two grades of success, 1st and 2nd Class. The Elementary and Advanced stages are for the ordinary Science Schools. The Honours examination is of a very advanced character.

Any person however taught may sit at any one of these examinations.

Queen's prizes, consisting of books or instruments, are given to all candidates who are successful in obtaining a first class in either the elementary or the advanced stage, and Bronze Medals to those who obtain a first class in Honours.

Payments are made on the results of the May examination on account of the instruction of students of the industrial classes, or of their children. The payments are—£2 for a first class, and £1 for a second class, in the elementary and in the advanced stage, and £2 and £4 for a second or first class respectively in honours. Extra payments are made for attendance in Organised Science Schools. Special payments are also made for practical Chemistry. The teacher must have given at least 28 lessons to the class and each student must have received 20 lessons at least.

There are also two forms of scholarship in connection with elementary schools.

a. In the Elementary School Scholarship £5 are granted to the managers of any elementary school for the support of a deserving pupil selected by competition, if they undertake to support him for a year and subscribe £5 for that purpose. The payment of £5 by the Science and Art Department is conditional on the scholar passing in some branch of science at the next May examination.

b. In the Science and Art Scholarship, which is of a more advanced character, a similar contribution of £5 is required on the part of the locality, and a grant of £10 is made by the Department towards the maintenance, for one year, of the most successful pupil or pupils in elementary schools who have passed certain examinations in science and in drawing.

In the first case the scholar must be from twelve to sixteen, and in the latter from twelve to seventeen years of age. One scholarship is allowed per 100 pupils in the school. Thus a school with 50 pupils may have one scholarship, a school with 150 pupils two scholarships.

There are also two forms of Exhibitions. These are:—

a. Local Exhibitions to enable students to complete their education at some college or school where scientific instruction of an advanced character may be obtained. Grants of £25 per annum, for one, two, or three years are made for this purpose when the locality raises a like sum by voluntary subscriptions. And if the student attend a State School, such as the Royal School of Mines in London, the Royal College of Chemistry in London, or Royal College of Science in Ireland, the fees are remitted. The exhibition must be awarded in competition.

b. Royal Exhibitions of the value of £50 per annum tenable for three years, to the Royal School of Mines, London, and the Royal College of Science, Dublin, are given in competition at the May examinations. Six are awarded each year—three to each institution. The exhibitions entitle the holder to free admissions to all the Lectures, and to the Chemical and Metallurgical Laboratories at those two institutions.

The competition for the Whitworth Scholarships, tenable for three years, is also in part determined by the results of the May examinations.

A grant in aid of a new building, or for the adaptation of an existing building, for a School of Science may be made at a rate not exceeding 2s. 6d. per square foot of internal area, up to a maximum of £500 for any one school, provided that certain conditions are complied with and that the school be built under the Public Libraries and Museums Act, or be built in connection with a School of Art, aided by a Department building grant.

A grant towards the purchase of fittings, apparatus, diagrams, &c., of 50 per cent of the cost of them is made to Science Schools.

Special extra grants in the form of capitation payments are made in fully organised Science Schools.

UNIVERSITY OF OXFORD.

Waynflete Professor of Chemistry.—W. Odling, M.A., F.R.S.

Professor of Mineralogy.—N. S. Maskelyne, M.A., F.R.S.

Every Student must reside in one or other of the Colleges or Halls, or in licensed lodgings, for a period of three years, passing at least two examinations in Arts, and one in either Mathematics, Natural Science, Law, Modern History, or Theology, when, if he obtain a first, second, or third class, he can take his B.A. Degree; if he do not gain such honour he has to pass a third examination in *Literis Humanioribus*.

The fee for students working in the Laboratory for three days in the week during the Term is £3; for students working every day, £5.

Scholarships of about the value of £75 are obtainable at Christ Church, Magdalen, and other colleges, by competitive examination in Natural Science.

More detailed information may be obtained from the University Calendar; from the professors; from E. Chapman, Esq., M.A., Frewin Hall; and from the Sub-Librarian in the Radcliffe Library or the Museum.

UNIVERSITY OF CAMBRIDGE.

Professor of Chemistry.—G. D. Liveing, M.A., F.R.S.

Jacksonian Professor of Natural and Experimental Philosophy.—J. Dewar, M.A., F.R.S.

Demonstrators.—J. W. Hicks, M.A., W. J. Sell, B.A., and H. J. H. Fenton, B.A.

The Student must enter at one of the Colleges, or as a Non-collegiate Student, and keep terms for three years by residence in the University. He must pass the previous examination in Classics and Mathematics, which may be done in the first or second term of residence, or, through the Oxford and Cambridge Schools Examination Board, or through the Senior Local Examinations, before commencing residence. He may then proceed to take a Degree in Arts, either continuing mathematical and classical study, and passing the ordinary examinations for B.A., or going out in one of the Honour Triposes.

The scholarships, ranging in value from £20 to £80 a year, are chiefly given for mathematical and classical proficiency. Scholarships are given for Natural Science in Trinity, St. John's, St. Peter's, Clare, Christ's, Sidney, Pembroke, Caius, and Downing Colleges; the examinations being at Easter, and in June and October.

The Chemical Laboratory of the University is open daily for the use of the Students. The Demonstrators nteatddaily to give instructions.

Non-collegiate Students are allowed to attend certain of the College Lectures and all the Professors' Lectures, and have the same University status and privileges as the other Students. They are under the superintendence of the Rev. R. B. Somerset, Orford House, Cambridge, from whom further information may be obtained.

The following are the Lectures on Chemistry for the ensuing Academical Year:—

Michaelmas Term, 1881.

General Course, by the Professor of Chemistry, on Tuesdays, Thursdays, and Saturdays, at 12 noon. Begin Oct. 13.

Physical Chemistry, by the Jacksonian Professor, on Mondays, Wednesdays, and Fridays, at 12 noon. Begin Oct. 14.

Organic Chemistry, by Mr. Main, at St. John's College, on Tuesdays, Thursdays, and Saturdays, at 11 a.m. Begin Oct. 15.

Metals, by Mr. Pattison Muir, Caius College, Monday, Wednesday, and Friday, at 10 a.m. Begin Oct. 14.

General Principles of Chemistry, by Mr. Pattison Muir, Caius College, Tuesdays, Thursdays, and Saturdays, at 10 a.m. Begin Oct. 17.

Catechetical Lectures, by Mr. Lewis, at Downing College, on Mondays, Wednesdays, and Fridays, at 10 a.m. Begin Oct. 14.

Spectroscopic Analysis, by the Professor of Chemistry, on Tuesdays, Thursdays, and Saturdays, at 1.30 p.m. Begin Oct. 18.

Analysis, by the Professor and the Demonstrators of Chemistry. Also at St. John's, Caius, Sidney, and Downing Colleges. Daily. Begin Oct. 13.

Lent Term, 1882.

General Course continued, by the Professor of Chemistry, on Tuesdays, Thursdays, and Saturdays, at 12 noon. Begin Feb. 2.

Organic Chemistry, by the Jacksonian Professor, on Mondays, Wednesdays, and Fridays, at 12 noon. Begin Feb. 3.

General Course of Chemistry, by Mr. Main, at St. John's College, on Tuesdays, Thursdays, and Saturdays, at 11 a.m. Begin Feb. 2.

Non-metallic Elements, by Mr. Pattison Muir, at Caius College, on Mondays, Wednesdays, and Fridays, at 10 a.m. Begin Feb. 1.

Organic Chemistry, by Mr. Walker, at Sidney College, on Mondays, Wednesdays, and Fridays, at 12 noon. Begin Feb. 1.

General Principles of Chemistry continued, by Mr. Pattison Muir, Caius College, on Tuesdays, Thursdays, and Saturdays, at 10 a.m. Begin Feb. 2.

Catechetical Lectures, by Mr. Lewis, at Downing College, on Mondays, Wednesdays, and Fridays, at 9 a.m. Begin Feb. 1.

Analysis, at the University Laboratory, daily. Begin Jan. 19. And at St. John's, Caius, and Sidney Colleges, daily. Begin Jan. 30.

Easter Term, 1882.

Some Special Department, by the Professor of Chemistry, on Tuesdays and Saturdays, at 12 noon. Begin May 3.

Elementary Chemistry, by a Demonstrator, on Mondays, Wednesdays, and Fridays, at 3 p.m. Begin April 24.

General Course continued, by Mr. Main, at St. John's College, on Tuesdays, Thursdays, and Saturdays, at 12 noon. Begin April 25.

Elementary Organic Chemistry, by Mr. Pattison Muir, at Caius Laboratory, on Mondays, Wednesdays, and Fridays, at 10 a.m. Begin April 26.

Catechetical Lectures, by Mr. Walker, at Sidney College, on Mondays, Wednesdays, and Fridays, at 12 noon, and by Mr. Lewis, at Downing College, same days, at 9 a.m. Begin April 24.

Analysis, at the University Laboratory, daily. Begin April 25. Also at St. John's College. Begin May 2. Also at Caius College. Begin April 20. Also at Sidney College. Begin April 27.

UNIVERSITY OF DUBLIN.—TRINITY COLLEGE.

The University Professor of Chemistry, Dr. Emerson Reynolds, F.R.S., assisted by the Demonstrator of Chemistry, Mr. Early, conducts the undermentioned Courses of Laboratory instruction:—

The First Course of Practical Chemistry.—Michaelmas Term:—Qualitative Analysis and the Use of the Spectroscope. Hilary Term: Volumetric and Simple Gravimetric Analysis. Trinity Term: Organic Preparations and Analysis.

Students can also attend the Professor's Lectures on General Chemistry, and repeat most of the experiments performed in the Theatre.

The Second or Advanced Course includes instruction in the higher branches of Experimental and Analytical Chemistry, and in Methods of Research. Students who take out this Course are free to devote their chief attention to the study of special departments of Chemistry as applied to Arts and Industries.

Summer Course of Practical Chemistry for Medical Students.—This Course commences on the first Monday in April and terminates on the 30th of June following. Students experiment in the Laboratory from 2 to 4 o'clock on Tuesdays, Thursdays, and Saturdays.

Special Courses.—Students can enter at any time throughout the academic year for short terms of Laboratory instruction in Medical or Pharmaceutical Chemistry, or in the Methods of Analyses of Water, Air, &c., for Sanitary Purposes.

Lectures in Medical and Pharmaceutical Chemistry.—Dr. Reynolds lectures at 2 o'clock on Tuesdays, Thursdays, and Saturdays, from the 1st of November to the 31st of March following.

All the classes are open to extra-Academic Students.

KING'S COLLEGE.

(DEPARTMENT OF ENGINEERING AND APPLIED SCIENCE.)

Professor of Chemistry.—C. L. Bloxam, F.C.S.

Demonstrator of Practical Chemistry.—J. M. Thomson, F.C.S.

Assistant Demonstrator.—G. S. Johnson, F.C.S.

On Tuesday and Friday at 10.20 a.m. Students of the First Year are admitted to the Course of Theoretical and Applied Chemistry. The Course commences with a View of the Forces which concur to the production of Chemical Phenomena, after which the laws of Chemical Attraction are discussed, and the Non-metallic elements and their principal Compounds are described.

The Metals and their principal compounds are next examined, care being taken to point out the applications of the Science to the Arts; and the processes of the different Manufactures, of Metallurgy, and of Domestic Economy, are explained and illustrated.

Examinations of the Class, both *vivâ voce* and by written papers, are held at interval during the course at the usual Lecture hour.

Second Year.—Students attend in the Laboratory twice a week, on Tuesday and Friday, at 10.20, and they go through a course of Manipulation in the most important operations of Chemistry, including the first steps of Analysis.

Any Student of this Department may be admitted to this Class at any period of his study on payment of an extra fee.

Experimental and Analytical Chemistry in the Laboratory.—The object of this Class is to afford to Students who are desirous of acquiring a knowledge of analysis, or of prosecuting original research, an opportunity of doing so under the superintendence of the Professor and Demonstrator; Students may enter, upon payment of extra Fees, at any time except during the vacation, and for a period of one, three, six, or nine months, as may best suit their convenience. The laboratory hours are from ten till four daily, except Saturday, on which day the hours are from ten till one.

In addition to the Laboratory Fee, each Student defrays the expenses of his own Experiments. The amount of this expense, which is comparatively trifling, is entirely under his own control.

Special hours and fees are arranged for the convenience of such Third Year Students as wish to study Analytical Chemistry.

Fees.—Chemistry per term, £3 3s. od.; per ann., £8 8s. od.; Practical Chemistry per term, £4 4s. od.; per ann., £10 10s. od.; Experimental and Analytical Chemistry—One Month (daily attendance), £4 4s. od.; Three Months (daily attendance), £10 10s. od.; Six Months (daily attendance), £18 18s. od.; Nine Months (daily attendance), £26 5s. od. A student taking a month's ticket may attend daily during 1 month, or 3 days a week during 2 months, or 2 days a week during 3 months.

Rules as to Admission of Students.

I. The Academical Year consists of Three terms: Michaelmas Term, from beginning of October to the week before Christmas; Lent Term, from the middle of January to the week before Easter; Easter Term, from Easter to the beginning of July.

II. The days fixed for the Admission of New Students in the Academical Year 1881-82, are Tuesday, October 4, Wednesday, January 11, and Wednesday, April 19.

UNIVERSITY COLLEGE.

FACULTY OF SCIENCE.

Chemistry.—Professor Williamson, Ph.D., F.R.S.

I. GENERAL COURSE.

Lectures daily (except Saturday) from 11 to 12 a.m., up to the last week in March.

Exercises on Tuesdays, Wednesdays, Thursdays, and Fridays, from 9 to 10 a.m. First Meeting, October 6, 1881.

Fees for the Course, £7 7s.; Perpetual, £9 9s.; for the Half Course, £4 4s.; for the Organic Course alone, £2 2s.

Fee for the Exercise Class, £2 2s.

The instruction in this Class is of two kinds, consisting partly of Experimental Lectures by the Professor, partly of Exercises and personal instruction on the subject of the Lectures by an Assistant.

Attendance on the Exercise Class (conducted by Mr. Temple A. Orme, F.C.S.) enables Students to do their work more effectually and rapidly than they can do it by themselves.

A. *The first half* of the course, to Christmas, includes those parts of Chemistry which are required for the Matriculation Examination of the University of London.

B. *The second half* of the Course, from January to March, includes the following subjects:—

1. Preparation and properties of the chief *Metals*, including their characteristic reactions and most important salts. Detection of metallic poisons. Quantitative estimation of metals. Principles of classification. Monatomic, diatomic metals, &c.

Organic Chemistry commences in the second week in February, and occupies five Lectures weekly till about the end of March. It includes a study of the characteristics and metamorphoses of the chief organic acids, bases, alcohols, ethers, colouring-matters, &c. Methods of ultimate and proximate analysis. Determination of molecular weights. Theory of types; of compound radicals. Phenomena of fermentation, &c.

Training of Teachers.

Teachers of Chemistry are trained in the theory and practice of their profession. A two years' Course is absolutely requisite for this purpose; but Students will with advantage devote a longer period to it.

The first year is occupied with attendance on the Courses of Chemistry and of Analytical Chemistry. In the second year the Student again attends the Course of Chemistry, and is intrusted with teaching-work in conjunction with the Tutors of the class. At the same time he continues to work in the Laboratory at analysis and original research.

In order to qualify themselves for rising to the higher ranks of the Profession, gentlemen remain for a further period, in which case they may obtain remunerative work in teaching through the recommendation of the Professor.

It must not, however, be supposed that a study of Chemistry alone, however complete, is sufficient to qualify a man to teach the Science effectively. A competent knowledge of Physics, Mathematics, and either French or German must necessarily be acquired at some period of the Student's Course.

II.—ANALYTICAL AND PRACTICAL CHEMISTRY.

A. *Birkbeck Laboratory.*

When accompanied or preceded by attendance on the lectures on Chemistry, the Laboratory Course qualifies Students in the application of Chemistry to the Manufacturing Arts, Metallurgy, Medicine, or Agriculture, &c.

Instruction is given in the principles and processes of gas-analysis.

The Laboratory and offices are open daily from 9 a.m. to 4 p.m., from the 6th of October until the middle of July, with a short recess at Christmas and at Easter. Saturday, from 9 to 2.

Fees, for the Session, 25 guineas; six months, 18 guineas; three months, 10 guineas; one month, 4 guineas; exclusive of the expense of materials.

A Gold Medal and Certificates of Honour are competed for by students entered for the session.

B.—Summer Practical Courses.

Chemical Theatre.

1. *Elementary Course.* (*Men.*)—About Forty Lessons of one hour each, commencing in the first week of May.; The first six weeks of the Course are occupied by the study of the chief non-metallic elements and their simple compounds. Metallic salts, &c., are subsequently studied.

Fees—including the cost of materials and apparatus: for the Course, £5 5s.; for a Second Course, £3 3s.

2. *Senior Course.* (*Men.*)—This Course consists of Twenty Lessons of two hours each, commencing in the first week in May.

The first half of the Course includes tests for fixed and volatile organic acids, nitrogenised acids, sugars, glycerin, alkaloids, &c.

The second half of the Course includes tests for mineral poisons in organic mixtures; also tests for organic bodies, such as alkaloids, when mixed with other organic substances.

Volumetric methods of the quantitative analysis of sugar and urea, chlorides, phosphates, hardness of water, alkalimetry, are practised.

Analysis of milk and ashes of blood.

Fees—including cost of materials and apparatus: for the Course, £5 5s.; for a Second Course, £3 3s.

III.—Summer Matriculation Course. (*Men.*)

Temple A. Orme, F.C.S.

This Course includes those parts of Chemistry which are required for the Matriculation Examination of the University of London.

The Course consists of about Twenty Lessons in Practical Chemistry, and of an equal number of oral lessons. These lessons will begin on March 21, 1882, at 11.

Fee, including cost of materials and apparatus, £4 4s.

Elementary Chemistry.

Chemical Theatre. (*Women*).

Lectures—Wednesday and Friday, from 4 to 5.

A Class of Elementary Chemistry, including the subjects required for Matriculation, will be given during the Winter Session, commencing Wednesday, October 13.

The instruction will consist partly of Lectures, partly of Laboratory Experiments performed by the Students.

Fees for the Course, including use of apparatus and materials, £4 4s.

Chemical Technology.

Professor Charles Graham, D.Sc., F.I.C.

Assistant.—C. J. Wilson, F.C.S.

The Course of instruction in this Department is designed to afford to Students who propose to devote themselves to industrial pursuits in which Chemistry plays an important part, or to prepare themselves for the profession of Consulting Chemist, the instruction essential for their success in their future line of work. It will also be found of great value in two of the branches (Organic and Inorganic Chemistry) in which the Degree of Doctor of Science can be taken at the University of London.

Assuming that the Student enters for a three years' study, the following will give an idea of the nature of the work during the period:—

In the first year the Student will attend Lectures on Theoretical Chemistry, and work at Analytical Chemistry in the Chemical Laboratory, and will also attend Lectures on Mathematics, Mechanics, and Physics. The Mechanical Drawing Class should also be attended during the first year by all Students.

In the second year, the Student will again attend the Lectures on Theoretical Chemistry, also practical work in the Chemical and Physical Laboratories, and Lectures on Mineralogy and Geology.

The third year will also be chiefly occupied with attendance on the Lectures on Chemical Technology, and in practical work connected therewith in the Laboratory, and, during the Summer Term, Lectures on Botany.

The Student will, in addition to the foregoing subjects, which are common to all, attend Lectures and work at such other branches of Pure and Applied Science as may be deemed advisable after consultation with the Professor.

Students entering the College with more advanced scientific knowledge will be able to shorten the Course described to two years, or even one year, as may be found advisable.

For the convenience of those already engaged in business, and of those from other causes prevented from entering for a longer period of study, it is arranged that they can attend the Laboratory of Chemical Technology or a Course of Lectures upon any one subject of Applied Chemistry without being required to attend any other lectures, either in Applied Chemistry or in other subjects.

In the Session 1882-83, it is proposed to treat of the following subjects:—

(1) The Chemistry of the Alkali trade.
(2) Soap, Glass, Pottery, Cements.
(3) Agricultural Chemistry.
(4) Distilling, Vinegar-making, or the Chemistry of Brewing.

Should a sufficient number of Students desire a Course of Lectures on some subject of Applied Chemistry other than those above mentioned, the Professor will give such either in lieu of, or in addition to, those mentioned.

Students desirous of working at subjects not included in the foregoing Courses, such as Photography and Photographic materials, Paper-making, Gas-tar products, the products of the Distillation of Wood, Tanning, and other Chemical industries, will receive individual instruction in the Laboratory.

Fees—for each Course, £2 2s.; for the four Courses together, £5 5s.

Chemical Laboratory.

The instruction in the Laboratory in Chemical Technology will consist of the examination and valuation of raw materials used, and of the final products obtained in various manufacturing industries, and of experimental examination of the processes employed in the arts and manufactures.

The Laboratories are open daily from 9 a.m. to 4 p.m., from the 6th of October until the middle of July, with a short recess at Christmas and at Easter. Saturday, from 9 to 2.

Fees—for the Session, 25 guineas; six months, 18 guineas; three months, 10 guineas; one month, 4 guineas; exclusive of the expense of materials.

NORMAL SCHOOL OF SCIENCE AND ROYAL SCHOOL OF MINES.

Professors.—Dr. H. E. Roscoe, F.R.S., and Dr. W. J. Russell, F.R.S.

The Normal School of Science at South Kensington is intended, primarily, for the instruction of teachers, and of students of the industrial classes selected by competition in the examinations of the Science and Art Department. The Royal School of Mines is affiliated to the Normal School. Students entering for the Associateship of the School of Mines obtain their general scientific training in the Normal School. Other students are admitted so far as there may be accommodation for them, on the payment

of fees fixed at a scale sufficiently high to prevent undue competition with institutions which do not receive State aid. The instruction in the Normal School is arranged in such a manner as to give the Students a thorough training in the general principles of Science, followed by advanced instruction in one or more special branches of Science. The Associateship is granted in certain divisions or lines of study. Students who go through any one of the prescribed courses of instruction and pass the necessary Examinations receive a Certificate of Associateship of the Normal School, or of the Royal School of Mines. But students who are not candidates for the Associateship are permitted to take up the course of instruction in one or more special branches of science, and on passing the examination receive a Certificate to that effect. The Associateship of the Normal School of Science is given in one or more of the following divisions:—Mechanics, Physics, Chemistry, Biology, Geology, and Agriculture, and the Associateship of the Royal School of Mines in Metallurgy and Mining.

The course of instruction is the same for all the divisions during the first two years, after which it is specialised in accordance with the Scheme detailed in the Prospectus of the School.

The Session is divided into two Terms. The first Term begins about the 1st of October and ends about the middle of February. The second Term begins in the middle of February and ends about the middle of June.

Examinations are held at the end of each course of instruction and at such other periods as may be found necessary. On the results of these examinations the successful candidates are arranged in two classes, first and second. There are also "Honours" examinations for the subjects of the third and fourth years, the successful candidates being placed in order of merit. A student obtains the Associateship who passes in all the subjects of the first two years and of the special division he select for his Associateship. A student who goes through the prescribed course of instruction in any subject and passes the final examination in it receives a certificate to that effect.

The fees which are shown in the following table must be paid to the Registrar of the School before the commencement of each course.

	Part I. Lecs.	Part II. Lecs. & Lab.	Part III. Lecs. & Lab.	Part IV. Lecs. & Lab.
	£	£	£	£
Chemistry	5	16	18	18	
Physics	5	12	16	16	
Biology with Botany	4	8	8	4	8
Geology with Mineralogy ..	4	8	12		
Mechanics	4	6	10	10	
Metallurgy	2	16	18		
Assaying for Mining Students		12			
Mining	4	12			
Agriculture	4	10			
Astronomy	3				

Mathematics £3 per term. Practical Geometry and Mechanical Drawing £3 per term. Freehand Drawing £1 per term.

Thus the fees for the first two years amount to £75, and for the remainder of the course for the Associateship they vary from £30 to £40.

Both the private, and the State-aided, students are required to furnish themselves with certain instruments and apparatus before the commencement of the courses. These are enumerated in the syllabuses of the several subjects.

Students who do not wish to attend the lectures are admitted for short periods to the laboratories, at the discretion of the Professors. The fees for the Chemical and Metallurgical, and Physical laboratories are £5 per month; for the Biological and Geological laboratories £4 per month.

Admission is granted to persons desirous of attending the lectures without the laboratory instruction, on payment of the lecture fees.

Officers of the Army, Navy, and Civil Service, recommended by their respective Departments, are admitted to the Lectures and Laboratories at half the foregoing charges.

Associates of the Normal School of Science and of the Royal School of Mines have the privilege of free admission to the Library and to all the courses of lectures.

Science teachers actually engaged in teaching who have passsed in the advanced stage, or in honours, in any subject in the May examination of the Science and Art Department, or in the December examination in Training Colleges, may attend any course of lectures on the payment of £1.

Several valuable Exhibitions, Scholarships, and Prizes are attached to the studentship.

Summer Courses for Teachers.—Short courses of instruction are given aunually, about July, in different branches of science for the benefit of teachers of science schools in the country. The courses last three weeks. About 200 teachers are admitted to them and they receive 2nd class railway fare to and from London, and a bonus towards their incidental expenses of £2 each. (See Science Directory.)

Working Mén's Lectures.—Three or four courses of evening lectures for working men are given annually during the winter months by the Professors and Lecturers of the Normal School and the School of Mines. The admission to each course of six lectures, which will be given at South Kensington, Jermyn Street, or Bethnal Green, is 6d. The number of tickets is limited by the size of the lecture theatre.

UNIVERSITY OF ABERDEEN.

Professor of Chemistry.—J. S. Brazier, F.C.S.

I. *Systematic Course.*—The Lectures are delivered on the first five days of each week during the College session. They commence with the discussion of the General Principles of Chemical Philosophy, including the Atomic Theory and the Chemical Relations of Heat. The Non-metallic and Metallic Elements and their Compounds are fully treated of, together with their more important applications to the Arts. The latter part of the course is devoted to the subject of Organic Chemistry. Examinations are held at fixed periods during the Session. The fee is £3 3s.

II. *Practical Course.*—This course is given during the Summer Session. It is chiefly devoted to practice in Qualitative Analysis, with the view of enabling the Student to test unknown substances, poisons, the animal secretions, &c. The fee is £3 3s.

III. *Laboratory Pupils.*—The Chemical Laboratory is open during the College Session on the first five days in each week, from 10 a.m. till 3 p.m. The course of instruction is under the direction of the Professor of Chemistry and of the Teaching Assistant.

UNIVERSITY COLLEGE, BRISTOL.

Professor of Chemistry.—W. Ramsay, Ph.D.
Lecturer.—Adrian Blaikie, D.Sc.

Inorganic Chemistry.

This Course treats of the principles of Chemistry, and of the Chemistry of the Non-Metals and Metals.

Lectures will be given at 10 o'clock on Mondays, Wednesdays, Fridays, and Saturdays during the First and Second Terms; the last of these being a tutorial lecture, which will deal with points requiring detailed explanation.

The lectures will be illustrated with experiments and diagrams.

Examinations will be held from time to time during the courses.

Fee, £4 4s. for two Terms, £3 3s. for one Term.

Technical Chemistry.

Lectures will be given during the First and Second Terms on Thursdays at 11, on Manufacturing and

Metallurgical Processes with which Chemistry has specially to deal.

Fee, £2 2s. for two Terms, £1 5s. for one Term.

Organic Chemistry.

This Course will relate to the more important groups of the Compounds of Carbon.

Lectures will be given during the Second Term on Tuesdays and Thursdays at 10 o'clock; during the Third Term on Tuesdays, Thursdays, and Saturdays at 10 o'clock.

Fee, £3 3s.

Practical Chemistry.—Laboratory Instruction.

The Laboratory will be open daily from 10 a.m. to 5 p.m., except on Saturdays, when it will close at 1 p.m. Instruction will be given in the Laboratory in all branches of Practical Chemistry, including Qualitative and Quantitative Inorganic and Organic Analysis, the preparation of Chemical Products, and Inorganic and Organic Research. Special facilities will be afforded to those who desire to study Practical Chemistry as applied to the different processes employed in the Arts and Manufactures. The Laboratory is under the immediate supervision of the Professor and the Lecturer.

Fees in Guineas—

	Whole Day.			Half Day.	
	6 Days a Week.	3 Days a Week.	2 Days a Week.	6 Days a Week.	3 Days a Week.
Per Session	18	10	7½	12	7
„ Two Terms ..	13	7½	5½	8½	5
„ One Term ..	7	4	3	4½	3
„ Month	3	2	1½		

In order that Students may have an opportunity of acquiring some knowledge of Applied Chemistry, excursions to some of the Mines and Manufactories of the neighbourhood will be occasionally made. They will be conducted by the Professor or by the Lecturer.

Evening Lectures.

Lecturer.—Adrian Blaikie, D.Sc.

Wednesday and Friday, 8 to 9.

This course will consist of Two Lectures a week during the First and Second Terms; they will be devoted to the consideration of the Principles of Chemistry and Chemical Physics and the Study of the chief Non-Metallic Elements. A few Lectures at the end of the Course will be devoted to the consideration of Metals. In treating of the various products under the latter heading special attention will be devoted to those products which have a practical application in the Arts and Manufactures.

Fee, 10s. 6d. for Two Terms; 7s. for One Term.

Evening Course of Practical Chemistry.

Professor.—W. Ramsay, Ph.D.

Tuesday and Thursday, 7 to 9.

A Practical Class will be formed for instruction in Qualitative and Quantitative Analysis. The Fee for the course (extending over the first and second terms) will be £3 3s. for two terms. £2 2s. for one term, and no additional charge will be made for reagents or apparatus, provided the latter be returned undamaged.

Chemical Scholarship.—Among others, a Chemical Scholarship of £25 is offered for competition.

All particulars may be learned by application to J. N. Langley, LL.D., Registrar and Secretary.

ROYAL AGRICULTURAL COLLEGE, CIRENCESTER.

CHEMICAL DEPARTMENT.

Professor.—Prof. E. Kinch, F.C.S., F.I.C.

Assistants.—C. Rawson, F.C.S., and Mr. W. James.

Systematic courses of Lectures are given on Inorganic, Organic, and Agricultural Chemistry, illustrated by experiments, and by the collections in the College Museum. They comprise, as preliminary, the general study of Chemistry of inorganic bodies, and of the more frequently occurring bodies of organic origin, and, finally, the Chemistry of the atmosphere, of soils and manures, vegetation, animal nutrition and cattle feeding, and of Agricultural economy.

In the Laboratory practical instruction is given in Chemical manipulation and analysis, both qualitative and quantitative. The Students, on entering, are provided with a set of Chemical Apparatus, and after studying the properties of the more commonly occurring substances, are taught to analyse a series of compounds, proceeding from simple to mose complex cases, and apply the knowledge thus obtained to the analysis of manures, soils, waters, ashes of plants, foods and feeding stuffs, and other substances met with in the ordinary course of Agricultural practice. Chemico-agricultural researches are undertaken by the senior Students under the direction of the Professor and his Assistants.

THE YORKSHIRE COLLEGE, LEEDS.

Professor of Chemistry.—T. E. Thorpe, Ph.D., F.R.S., F.C.S.

Lecture Courses.

1. General Course on Inorganic and Organic Chemistry—Monday, Tuesday, Wednesday, and Friday, at 4 p.m., from October to the end of the second term. Fee for the Course, £4 4s.

2. Lectures on Laboratory Practice and Chemical Calculations—Wednesday, at 10 a.m., during the First and Second Terms. Fee, £1 1s.

3. Lectures on the Chemistry of the Non-Metals—Saturday, at 12, during the First and Second Terms. Fee, 10s. 6d.

Laboratory Courses.

The College Laboratory will be open daily from 9 a.m. to 1 p.m., and from 2 to 5 p.m., except on Saturdays, when it will close at 1 p.m.

Fees for the Session—Students working six days per week, £17 17s.; four, £13 13s.; three £11 11s.; two, £8 8s.; one, £4 4s.

Class in Practical Chemistry, Saturday mornings, from 9 to 12, during First and Second Terms. Fee £1 11s. 6d.

Practical Chemistry for Medical Students.—On Tuesday and Thursday, from 10 to 12 a.m., from May to July.

Evening Classes.

A Course of twenty Lectures by Mr. C. H. Bothamley, on the Elements of Inorganic Chemistry (the Non-Metals) will begin during the first and second Terms, on Thursdays, at 8 p.m., beginning October 13. Fee, 10s. 6d.

A Course of Twenty Lectures by Mr. C. H. Bothamley on the Metals will be given during the first and second Terms, on Mondays, at 8 p.m., beginning Oct. 10. Fee, 10s. 6d.

Dyeing Department.

Instructor.—J. J. Hummel, F.C.S.

Lecture Course, with practical work in the Dye-house, for Students who wish to receive, on leaving the College, a certificate of proficiency in Dyeing; such certificate to be obtained by special examination in the several subjects of the Course, the latter extending over a period of two years.

Scholarships.

For Associates.—The Cavendish Scholarship. Value £50 per annum, tenable for one year.

Advanced Scholarships.—

The Brown Scholarship. Value £35, tenable for two years.

The Akroyd Scholarship. Value £30 per annum, tenable for two years.

Entrance Scholarships.—

The Salt Scholarship. Value £20 per annum, tenable for two years.

The Goodall Exhibition of £10, tenable for one year, will be awarded to the candidate who shall take the second place in the competition for the Salt Scholarship.

The Akroyd Scholarships. One, value £25, and one, value £20, tenable for two years.

The Brown Scholarships. One, value £25, and one, value £20, tenable for two years.

The Clothworkers' Company Scholarships. For Textile Department four Scholarships, and for Dyeing Department two Scholarships, each of the value of £25 per annum, and tenable for one year.

LIVERPOOL COLLEGE OF CHEMISTRY.

Lecturers.—George Tate, Ph.D., F.C.S., and Granville H. Sharpe, F.C.S.

Day Courses.—A course of 100 lectures on Inorganic and Organic Chemistry on Mondays, Tuesdays, Thursdays, and Fridays, at 3, commencing October 7th and ending in May, by Dr. Tate.

The subjects embraced will be those required for the chemical examinations of London (2nd B.Sc. and 1st M.B.). Fee £4 4s.

A course of thirty lectures on the Alkali Manufacture on Saturdays, at 3, by Mr. Sharpe.

A course of thirty lectures on the Metallurgy of Iron, Copper, Tin, and Zinc, on Saturdays, at 4, by Dr. Tate.

In the summer term free courses will be held on :—

The Manufacture and Application of Chemical Manures, by Mr. Sharpe.

Technical Organic Chemistry (Sugar refining, Brewing, Tanning, Dyeing, &c.), by Dr. Tate.

The laboratories are open daily throughout the year. Fee for the full laboratory course of three months £10 10s., or six hours weekly £3 3s.

Special practical courses are arranged for Brewery pupils.

Evening lectures and practical courses are held on Mineralogy, Geology, Chemistry, and Physics.

UNIVERSITY OF DURHAM.
COLLEGE OF PHYSICAL SCIENCE, NEWCASTLE.

Professor of Chemistry.—A. Freire-Marreco, M.A. *Demonstrator*—J. T. Dunn, B.Sc.

Junior Division.—General Principles of Chemistry. History of the Non-Metallic Elements. History of the Metals and their more important Native and Artificial Compounds. Principles of Qualitative Analysis. Elements of Organic Chemistry. *Senior Division.*—Organic Chemistry. Elements of Applied Chemistry, including Chemical Mineralogy and Analysis.

Practical Chemistry.—The Laboratory is open from 10 a.m. to 1 p.m., and from 2 to 5 p.m., except on Saturdays, when it closes at 1 p.m. *Laboratory Fees.*—Students working six days per week, £5 5s. per term; alternate days, £3 3s.; one day per week, £1 1s.

Arrangements for Laboratory work in the evening and during vacation will be made.

The Session will commence on October 3.

Courses of Study.—Students will be distinguished into Regular and Occasional. Regular Students will be required to follow such a course of study in the subjects professed in the College as will enable them to pass the Examinations for the title of Associate in Physical Science. Occasional Students will attend such classes as they may select. Every candidate for admission as a regular student must pass an examination on entrance, in reading, writing from dictation, English or Latin Grammar, arithmetic (including decimals), and geography. Registered students in medicine are exempted from this examination, or students who produce a certificate of having passed either of the two following examinations :—

1. Durham Senior Examination of Persons not Members of the University, held in June.

2. Durham Examination for Students in Arts in their first year, or any examination of a similar nature that may be accepted by the Council.

Associateship in Physical Science.—Every candidate for the Associateship in Physical Science, will be required to satisfy the examiners in three, at least, of the four subjects,—Mathematics, Physics, Chemistry, and Geology,—in an examination, to be held at the beginning of his second year.

The examination in Chemistry comprises :—General Principles of Chemistry. Elements of Inorganic Chemistry. Elements of Qualitative Analysis, including a Practical Examination.

The examination in Chemistry for Candidates at the end of their second year comprises :—Elements of Organic Chemistry and Applied Chemistry. Advanced Qualitative Analysis, including a Practical Examination. Elements of Quantitative Analysis.

Exhibitions.—Three Exhibitions of the value of £25, £15, and £10 respectively will be awarded in October next to Candidates desirous of attending the first year course of study in the College.

Candidates must pass the entrance examination, and will, in addition, be examined in the following subjects :—Algebra, up to Quadratic Equations. Euclid, Books I., II., and III. And one of the following special subjects, to be selected by the Candidate :—Geology.—Text Book: Page's "Introductory Text Book." Heat.—Text Book: "Orme on Heat." Chemistry.—Text Book: Gill's "Chemistry for Schools," omitting chapters xiii., xvi., xx., and xxi. Natural History.—Text Book: Nicholson's "Elementary Text Book of Zoology," or Oliver's "Elementary Botany," Part I.

Candidates must send their names to the Secretary, on or before the 25th of September, and specify, at the same time, the special subject in which they desire to be examined.

The examination will be held at the College, and will commence on Monday, the 3rd October.

Two similar Exhibitions will be awarded at the next examination of 'Persons not members of the University," which will be held at Durham, and elsewhere, in June next, to those candidates who shall most distinguish themselves in subjects allied to Physical Science.

Scholarships.

T. Y. Hall Scholarship.—This Scholarship, of the yearly value of £20, tenable for three years by students attending two or more of the classes, will be awarded on the result of the first examination for the Associateship in Science.

Charles Mather Scholarship.—This Scholarship, of the yearly value of about £40, will be awarded on the result of the Final Examination for the Associateship in Science, and is tenable for one year from the time of obtaining the Associateship in Science, provided the Scholar continues his studies in the College to the satisfaction of the Professors.

Nathaniel Clark Scholarship.—This Scholarship, of the value of £15 for one year, will be awarded in October to that student who shall pass the First Examination for the Associateship in Science, and who shall be most distinguished in Chemistry and Geology. The Scholar will be required to attend the classes of Chemistry and Geology, so as to be qualified to take those subjects for the Final Examination for the Associateship in June next.

OWENS COLLEGE, MANCHESTER.

Professor and Director of the Chemical and Metallurgical Laboratories.—H. E. Roscoe, B.A., Ph.D., F.R.S., F.C.S.

Professor of Organic Chemistry.—C. Schorlemmer, F.R.S.

Demonstrators and Assistant Lecturers.—Mr. W. C. Williams, F.C.S., P. P. Bedson, D.Sc., and Watson Smith, F.C.S.

The Session begins on October 4, 1881, and ends on June 23, 1882.

Technological Chemistry.

Persons desiring to attend this course will be required to enter the College under the ordinary conditions of studentship.

The object of this course is to offer to students intending to devote themselves more especially to Applied Chemistry as complete a training as the College can provide in those branches of instruction which form the scientific foundation of the subject.

The complete course of instruction extends over four years, and embraces the following subjects:—

First Year.—Chemistry Lectures, Junior and Tutorial classes. Chemical Laboratory, 2 days per week, and Analytical Chemistry Lectures class. Mathematical class, Section I. Experimental Mechanics or Geology. French or German. Mechanical Drawing, Practical (evening class).

Second Year.—Chemistry Lectures, Junior,* Senior, and Tutorial classes. Chemical Laboratory, 3 days per week. Technological Chemistry Lectures. Experimental Physics or Mineralogy Lectures. German or French. Mechanical Drawing, Practical (evening class).

Third Year.—Chemistry Lectures, Senior and Tutorial classes. Organic Chemistry Lectures. Chemical Philosophy. Chemical Laboratory, 3 days per week. Technological Chemistry. Physical Laboratory, 1 day per week, or Practical Mineralogy and Technological Mineralogy. Mechanical Drawing, Practical (evening class).

Fourth Year.—Organic Chemistry Lectures.* Technological Chemistry. Chemical Laboratory, 4 days per week. Chemistry of Colouring-Matters, Dyeing, and Calico-Printing (4th evening course). Mechanical Drawing, Practical (evening class).

Fees.—First year (including College Admission and Library fees), £26 19s. 6d.; second year, £28; third year, £28 10s. 6d.; fourth year, £23 19s. 6d.

The aggregate of the fees in each year will vary slightly according to the particular class selected in French or German, or to the choice made in respect of the other alternatives proposed.

When a student is excused a second attendance on any of the Chemistry Lecture Courses the fee will be reduced accordingly.

Certificates will be granted to students on the successful completion of this course. Attendance on the full course of four years is expected of candidates for the Certificate, but students may obtain exemption (on cause shown) from the first or the first and second year's course. Students so excused will nevertheless be required to undergo examination in all the subjects specified.

The Certificate will state in which subjects the candidate has gained Honours, and in which he has merely satisfied the Examiners.

Entrance Exhibitions.

I. Victoria Exhibition (Classics), £15.

II. Wellington Exhibition (Greek Testament), £15.

III. Dalton Mathematical Exhibition, £15. Renewable for a second year.

IV. Grammar School Scholarship, £17 per annum, tenable for three years; open to scholars of the Manchester Grammar School only.

V. Two Oxford and Two Cambridge Local Exhibitions, giving free admission to lecture classes in the College for one year, and renewable for two years further, are awarded annually on the results of the Oxford and Cambridge Examinations held in Manchester in December, 1880, and June, 1881.

VI. Gilchrist Scholarship, £50 per annum, tenable for three years; awarded on the results of the Matriculation Examination of the University of London, in June, 1881.

VII. Rumney Scholarship, £45 per annum, tenable for three years.

VIII. Ramsbottom Scholarship, £40 per annum, tenable for two years. The next competition will take place in 1882.

IX. Crace-Calvert Scholarship, £25 per annum, tenable for two years. The next competition will take place in June, 1882. This scholarship is open only to duly qualified members of the Evening Chemistry Classes.

Fellowship.

The Langton Fellowship, £150 per annum, tenable for three years. Candidates must have been students in the College for not less than three sessions, and must during their studentship or within one year after the close of the same have obtained a degree of some University of the United Kingdom, or been elected to the Associateship of the College. The next competition for the Fellowship will take place in 1881.

Scholarships.

The following (except the Shakspere Scholarship) are open to the competition of students of the College only.

I. Victoria Scholarship (Classics), £40 per annum, tenable for two years.

II. Wellington Scholarship (Greek Testament), £20 per annum, tenable for two years.

III. Shuttleworth Scholarship (Political Economy), £50, tenable for one year.

IV. Shakspere Scholarship (English Language and Literature), £40 per annum, tenable for two years.

V. Bradford History Scholarship, £45 per annum, tenable for one year, and renewable for a second year.

VI. Dalton Chemical Scholarships, two, each of £50 per annum, tenable for two years.

VII. Dalton Mathematical Scholarships, one Senior and one Junior Scholarship, of the value of £25 each, tenable for one year.

VIII. Platt Scholarships (Physiology), two, one offered annually, £50 per annum, tenable for two years. (Two Platt Physiological Exhibitions of £20 each are offered for competition at the end of the Session 1880-1, open to first and second years' students in Physiology.)

IX. Heginbottom Physical Scholarship, £30 per annum, tenable for two years.

X. Ashbury Scholarships (Engineering), two, each of £25 per annum, tenable for two years.

Prizes.

I. Lee Greek Testament Prizes, one of £25 and one of £12 10s. value.

II. Classical Prizes.—Essay, value £5. Junior Class Prizes, value £5 and £2 10s.

III. Shuttleworth History Prize, value £5.

IV. English Essay and Poem Prizes, each of the value of £5.

V. Early English Text Society's Prizes.—A selection of the Society's publications offered to the competition of students in the Day and in the Evening Classes respectively.

VI. New Shakspere Society's Book Prizes.

VII. Cobden Club Book Prizes (Political Economy).

VIII. Dalton Natural History Prize, value £15.

IX. Engineering Essay Prize, value £5.

UNIVERSITY COLLEGE, NOTTINGHAM.

Professor of Chemistry—Frank Clowes, D.Sc. Lond., F.I.C., F.C.S.

Demonstrator—Mr. J. Hill Smith.

Inorganic Chemistry.

A systematic course of about twenty lectures on the non-metallic elements will be delivered on Tuesday and

* Students who gain a place in the First or Second class in the annual examinations will be excused a second attendance on these classes.

Thursday mornings. A tutorial class follows one lecture every week. The fee for the lecture course is one guinea, the inaugural lecture being free.

An evening course of eleven lectures on the same branch of chemistry will be delivered on Wednesdays; each lecture to be preceded by a tutorial class. Fee for lectures 3s. 6d.; for lectures and classes 5s. The first lecture will be free.

Practical and Technical Chemistry.

The chemical laboratory will be open on Monday, Wednesday, and Friday mornings, and at other times by arrangement with the Professor. Fee for one attendance per week one guinea.

An evening laboratory class will also meet every Tuesday evening. Fee, 10s. 6d., or 5s. for working men daily engaged in occupations involving the applications of chemistry.

Full information can be obtained by application to the Secretary at the College.

FIRTH COLLEGE, SHEFFIELD.

Professor of Chemistry and Experimental Physics.—T. Carnelley, D.Sc.

The Session will commence on Tuesday, October 4, 1881.

First Year's Course.—Chemistry of the Non-Metallic Elements. Tuesday, Thursday, Saturday, from 9 to 10 a.m. Fee, £3 13s. 6d.

Second Year's Course.—Chemistry of Metals: Organic Chemistry. Monday, Wednesday, Friday, from 9 to 10 a.m. Fee, £3 13s. 6d.

Laboratory.—Working hours to be arranged between Professor and Students. Students proposing to work six days a week can be entered for periods of one, two, or three months on payment of a certain proportion of the Sessional Fees, which are—For six days a week, £18 18s.; four, £14 14s.; three, £10 10s.; two, £7 10s. 6d.; one, £4 4s. Fees for short periods:—For one month, £3 13s. 6d.; two months, £6 6s.; three, £9 9s.; four, £12 1s. 6d.; five, £14 3s. 6d.

Evening Classes.—Lecture, Tuesday, 7 to 8; Class, 8 to 9. Fee, 5s. per term, or 9s. per two terms. Laboratory instruction, Wednesday, 7 to 9. Sessional Fee, £2 2s. (Students joining the laboratory at Christmas will be charged half the fee for the whole Session).

UNIVERSITY OF EDINBURGH.

Professor.—A. Crum Brown, F.R.S.E.

The Session will commence on October 25, 1881.

Two degrees in Science are conferred by the University of Edinburgh, viz., Bachelor of Science (B.Sc.) and Doctor of Science (D.Sc.). Both these degrees are conferred in Physical and Natural Science, in Public Health, and in Engineering.

Candidates for degrees in Physical and Natural Science must pass a preliminary examination in English, Latin, Arithmetic, the Elements of Mathematics, and the Elements of Mechanics, and in at least two of the following subjects, Greek, French, German, Higher Mathematics, Natural Philosophy, Logic, and Moral Philosophy.

The First B.Sc. Examination embraces Mathematics, Natural Philosophy, Chemistry, Zoology, including Comparative Anatomy, and Botany. The Second B.Sc. Examination the Higher Higher Mathematics, Natural Philosophy, Experimental Physics, Chemistry, Zoology, Botany, Physiology, and Geology.

The D.Sc. Examination embraces Mathematics, Applied Mathematics, Experimental Physics, Practical Astronomy, Chemistry, Zoology and Comparative Anatomy, Animal Physiology, Botany, and Geology, including Palæontology and Mineralogy.

ANDERSON'S COLLEGE, GLASGOW.

Professor of Chemistry.—William Dittmar, F.R.S.E.
Chief Assistant.—M. T. Buchanan.
Lecture Assistant.—John Lennox.
Junior Assistants.—R. N. Lennox, James M. Bowie, and John McArthur.

A Course of 100 Experimental Lectures on Chemistry: Daily, Saturdays excepted, from 10 to 11, commencing about the end of October. The Lectures up to the end of the year are devoted to the elements of Chemical Philosophy and to the Chemistry of the Non-metallic Elements. After the new year the Course divides into two branches, viz., the Chemistry of the Metals (on the Mondays and Tuesdays) and Organic Chemistry, select chapters (on the Wednesdays, Thursdays, and Fridays). Six written examinations are held during the Session, which all the members of the class are required to attend.

Fee, £2 2s.

The Laboratory for Practical Instruction in all branches of analysis, including technical assaying, and for original research is open daily (Saturdays excepted) during the Winter Session from 10 to 5, during Summer from 9.30 to 5. Advanced students may obtain permission to work privately on Saturday also until 11 p.m. The teaching is conducted on the tutorial system, each student working by himself and on his own subject. The Laboratory is furnished with all the necessaries for chemical investigation.

Fee for the Winter Session, £10 10s.; Summer Session, £6 6s.; two sessions, if paid in advance, £15 15s., or £2 2s. per month.

THE "YOUNG" CHAIR OF TECHNICAL CHEMISTRY ANDERSON'S COLLEGE.

Professor.—Edmund J. Mills, D.Sc. (Lond.), F.R.S.
Senior Assistant.—Mr. J. Snodgrass.
Junior Assistant.—Mr. J. Bicket.

This Chair has for its object the instruction of Students in Chemistry as applied to the various branches of industry in Chemical and other works, Metallurgy, Agriculture, &c.

Lectures.—*Principal Course.*—A Course of Fifty Lectures will be delivered on Mondays, Tuesdays, and Wednesdays, at 10 a.m., commencing on November 7th. The Lectures will be illustrated with Experiments, Diagrams, and Models, as well as by the actual Inspection of Manufacturing Processes; and the progress of the Students will be tested by periodical Examinations. The earlier Lectures will have reference to units of weight and measure, to the calculations necessitated by Chemical operations, and to the nature and laws both of the Chemical process and its results. A particular subject will then be considered in comparatively minute detail, embracing for this session Dyeing and Printing.

Fee for the Course, Two Guineas. To Laboratory Students, One Guinea.

Subsidiary Course.—A subsequent Course of Thirty Lectures will be delivered on Mondays, Tuesdays, and Wednesdays, at 10 a.m. These Lectures are more particularly intended for Dyers, Colour Manufacturers, Brewers and Distillers, Tar Rectifiers, Drysalters, and others interested in a knowledge of Technical *Organic* Chemistry.

Fee for the Course, Two Guineas.

Technical Physical Chemistry.—Mr. J. Snodgrass, Senior Assistant, has arranged to deliver a series of Thirty Lectures and Demonstrations on Physico-Chemical Measurements.

Fee for the Course, Half-a-Guinea. Laboratory Students, Half-a-crown.

Laboratories.—The Laboratories are open daily from 10 to 4, and on Saturday from 10 to 1 o'clock for practical working by the Students, under the superintendence of the Professor and his Assistants.

The Fee for attending the Laboratories is £20 per Session of Nine Months, £14 10s. for Six Months, £7 10s. for Three Months, or £2 10s. per month.

Students must have a fair acquaintance with elementary Chemistry.

The New Laboratory Buildings, immediately contiguous to the former site, are now erected and occupied. They comprise four stories, with a lecture room in the rear, and are exclusively devoted to the purposes of this Chair.

The Trustees, having had under consideration the requirements of Inventors, Patentees, and others whose investigations require isolation and privacy, as well as professional advice, have included in the arrangements Five Private Laboratories for Technical Research.

Library.—A Students' Library Society was founded in 1875. Its objects are to provide a collection of standard chemical works, and to maintain a regular supply of chemical journals. A large number of works have already been purchased or bestowed, and nine journals are received. Annual subscription, Half-a-crown.

Memorandum as to Bursaries.

The Trustees of the "Young" Chair have the superintendence of the Bursaries—regulating the appointment and terms on which they shall continue to be held.

The Nominees of Donors to be appointed if they pass the necessary examinations.

The Bursaries are of the amount of £50 each per annum, tenable for three years, during which the Bursars shall be required to give their whole time and attention to the Lectures and Laboratory duties of the "Young" Chair, paying the ordinary fees. Candidates to have attained sixteen years of age on application, to be of good moral character, and to pass such examinations as may be prescribed by the Trustees in the ordinary branches of an English education and the elementary principles of Chemistry. The Bursaries to be liable to forfeiture on the Bursars failing to exhibit approved progress under the Professor of the Chair, or being guilty of conduct, in the opinion of the Trustees, unworthy of their position. The Bursaries are only given to those whose means are limited, and who intend following some branch of Manufacturing Chemistry.

ROYAL COLLEGE OF SCIENCE FOR IRELAND, Stephen's Green, Dublin.

Professor of Practical and Theoretical Chemistry.—W. Noel Hartley, F.C.S.

The Session commences on October 3, 1881.

The Chemical and Metallurgical Laboratories, under the direction of Mr. Hartley, are open every week-day during the Session, except Saturday. Instruction is given in the different branches of Analytical Chemistry, including Assaying, and in the methods for performing Chemical Research. Fee, for the Session of nine months, £12; or for three months, £5; or for one month, £2.

There are four Royal Scholarships of the value of £50 each yearly, with Free Education, including Laboratory Instruction, tenable for two years; two become vacant each year; they are given to Students who have been a year in the College. There are also nine Exhibitions attached to the College, of the yearly value of £50 each, with Free Education, including Laboratory Instruction. tenable for three years; three become vacant each year.

A Diploma of Associate of the College is granted at the end of the three years' course.

Evening Classes.—A Course of about ten Lectures on Organic Chemistry will be given by Prof. Hartley on Fridays, at 8. Fee, 5s.

CHEMICAL LECTURES, CLASSES, AND LABORATORY INSTRUCTION.

City and Guilds of London Institute for the Advancement of Technical Education, Cowper Street, Finsbury.—Session commences October 4, 1881. Day and Evening Lectures and Laboratory instruction. Technical Chemistry, Prof. H. E. Armstrong, Ph.D., F.R.S. Technical Physics, Prof. W. E. Ayrton, F.R.S.

City of London College, 52, Leadenhall Street, E.C. —Chemical Lecturer—Dr. A. C. Maybury. The courses of lectures are as follows:—

Elementary Electricity	Mondays,	6.30—7.30.
Elementary Chemistry	,,	7.30—8.30.

The Session will commence on Monday, October 3. Fee, 6s. per term; per session, 15s.

These classes are specially arranged for Students preparing for the Science and Art Department Examinations, Matriculation, Chemists' Assistants, Teachers, &c.

Crystal Palace Company's School of Art, Science, and Literature. School of Practical Engineering. *Principal*—Mr. J. W. Wilson, Assoc. Inst. C.E.—This school was established with the purpose of affording to Students of Civil or of Mechanical Engineering the advantage of thorough practical instruction in the rudiments of either profession, and in the manipulation of materials. The leading object is to prepare Students, by systematic practical instruction, for professional articles, so that on entering an Engineer's office or works the pupil may at once be useful to his Principal, and enabled to take advantage of the opportunities for learning open to him, because he has mastered the elementary details of the profession. The school is also available for Students already articled, who desire instruction either in the offices or shops. The Colonial Section is designed particularly for gentlemen who are going to the Colonies or abroad, as explorers or settlers. The object proposed is to afford them so much practical knowledge of scientific and mechanical work and expedients as shall enable them best to utilise the means at their disposal, especially when entirely dependent on their own resources.

Ladies' Division.—The School was established to utilise the valuable Courts and Collections of the Crystal Palace for the purposes of instruction in Art, Science, &c., so that education of the highest class might be afforded on reasonable terms under most advantageous conditions. The system of tuition is, for some subjects, in the manner of private tutorial instruction by the best masters, but other subjects are taught on the University method, in accordance with the regulations laid down by the Syndicate of the University of Cambridge, by whom some of the lectures and classes are conducted. A student may take lessons in one or several studies at option. The School is a centre for both the University of Oxford and the University of Cambridge Local Examinations, the Oxford Examination for Women, and for the Cambridge Higher Local Examination. The following examinations will be holden in the Ladies' Division during 1881-82:—Cambridge Local, December, 1881; Oxford Local and Oxford Examination for Women, June and December, 1882; Cambridge Higher Examination, June, 1882. The session opens on October 1.

Charterhouse Institution.—The Session commences September 24, under the presidency of the Rev. Henry Swann, M.A, Lectures and Practical Work in a well-fitted laboratory capable of holding 60 students.

Berners College of Chemistry and the Experimental Sciences, 44, Berners Street, W.—Prof. E. V. Gardner, F.A.S., M.S.A. The Laboratory is open morning and evening throughout the year. A practical School of Science of a private character; the Courses of study are carried on by private class lectures in the various subjects, and by private Courses of study. These Courses are limited as to time, but are continued so long as is necessary to the Complete practical study of the subject or subjects by the Pupil or Pupils. The studies embrace the Experimental Sciences and Chemistry—Agricultural, Technical, and Analytical; the Science and Practice of Photography, Steam, Telegraphy, Electricity, Magnetism, and Galvanism, the Natural Sciences of Mineralogy, Geology, and Botany. The preparatian of Gentlemen for the various Examining Boards and investigations connected with Patents are prominent features of the work of this College.

Birkbeck Literary and Scientific Institution, Southampton Buildings, Chancery Lane. — Inorganic Chemistry. Lectures:—Elementary, Tuesdays, 8.30 to 9.30; Advanced, Saturdays, 7 to 8. Practice:—Elementary, Saturdays, 4 to 6; Advanced, Saturdays, 8 to 10. Teacher, Geo. Chaloner, F.C.S. Organic Chemistry:—Course of Thirty Lectures will be given on Tuesday evenings, at 7 o'clock, by Mr. H. Chapman Jones, F.C.S., commencing on October 4th. Practical Organic Chemistry:—This Class will meet in the Laboratory of the Institution, under Mr. Chapman Jones's direction, on Saturdays from 4 to 6 and from 8 to 10 p.m.

New Central School of Chemistry and Pharmacy, 173, Marylebone Road, London.—Mr. A. P. Luff, F.I.C., F.C.S., and Mr. J. Woodland, F.C.S., M.P.S.

Onslow College of Science, 183, Kings Road, Chelsea, S.W.—Special Evening Classes in Inorganic and Organic Chemistry, &c. The Chemical and Physical Laboratory is open every evening for practical work from 7 to 10 p.m.

South West London Central School of Chemistry and Pharmacy, 183, King's Road, Chelsea.—Daily Lectures by Mr. W. H. Martin.

Royal Veterinary College, Camden Town.—Professor of Chemistry, Mr. R. V. Tuson.

School of Pharmacy of the Pharmaceutical Society of Great Britain, 17, Bloomsbury Square.—The school opens on Monday, the 3rd of October. Lectures on Chemistry and Pharmacy, by Professor Redwood, on Monday, Tuesday, and Wednesday mornings, at 9 a.m. The Laboratories for Practical Instruction in Chemistry as applied to Pharmacy, &c., under the direction of Prof. Attfield, will be open daily at 10 a.m. throughout the Session. They are fitted up with every convenience for the study of the principles of Chemistry by personal experiment, synthetical as well as analytical. They are specially designed for the student of Pharmacy, but are also well adapted for the acquirements of a knowledge of Chemistry in its application to Medicine, Manufactures, Analysis, or Original Research. There is no general class for simultaneous instruction, each student following an independent course of study always determined by his previous knowledge pupils can therefore enter for any period at any date. Fees, One Course, £3 3s.; an entire Session—Two Courses, £4 4s.; Perpetual Admission, £5 5s. *Council Prizes.*—At the end of each of the five months' Courses of Lectures on Chemistry and Pharmacy, and Botany and Materia Medica, a Bronze Medal and Certificates of Merit, and at the close of the Session (ten months) a Silver Medal and Certificates of Honour and Merit, are offered for competition by the Council. In the Class of Practical Chemistry, the Silver Medal, two Bronze Medals, and Certificates of Honour and Merit, offered by the Council, are competed for at the end of the Session only.

South London School of Chemistry, 325, Kennington Road.—Dr. John Muter, F.C.S. Daily, at 10 a.m. Sixty Lectures on Theoretical Chemistry, and Junior and Senior Course of Practical Chemistry.

The Westminster College of Chemistry and Pharmacy, Trinity Square, S.E.—Messrs. Wills and Wootton. Daily, at 9.30 a.m. Theoretical and Practical Chemistry. Also Evening Classes.

Birmingham.—Queen's College.—Mr. A. Bostock Hill, M.D.

Mason Science College.—Evening Classes.

Bristol Medical School.—Mr. T. Coomber, F.C.S.

Liverpool Royal Infirmary School of Medicine.—J. Campbell Brown, D.Sc. Lond., F.C.S.

School of Technical Chemistry, 7 and 9, Hackin's Hey, Liverpool.—Mr. A. Norman Tate.

College of Chemistry, Liverpool — Mr. S. H. Johnson, F.C.S.

Royal Institution, Hull.—Mr. G. C. Robinson, F.R.S.E., F.C.S.

Leeds School of Medicine.—Prof. T. E. Thorpe, Ph.D., F.R.S.

Leeds Mechanics' Institution.—Mr. G. Ward, F.C.S.

Manchester Mechanics' Institution.—Evening Classes.

Queenwood College, near Stockbridge, Hants.—Dr. H. Wilson Hake, F.C.S., F.I.C. Lectures on Inorganic Chemistry and Physics and Laboratory Instruction.

Salford Working Men's College, Evening Classes.—Teacher of Chemistry, Mr. G. H. Hurst. Lectures on Organic and Inorganic Chemistry and practical laboratory instruction.

Sheffield School of Medicine.—Mr. A. H. Allen, F.C.S. A course of Lectures on Inorganic and Organic Chemistry is delivered by Mr. Alfred H. Allen during the Winter session. The Summer Course of Practical Chemistry is under the direction of Mr. A. H. Allen.

Sheffield Borough Analysts' Laboratory, 1 and 3, Surrey Street.—Mr. A. H. Allen, F.C.S. Day and Evening Classes.

Wesley College, Sheffield.—Lectures on Chemistry, Natural Philosophy, and Natural Science by the Rev. W. H. Dallinger, F.R.S.

Aberdeen School of Science and Art Mechanics' Institution.—Mr. Thomas Jamieson, F.C.S.

Dundee Literary Institution Chemical and Physical Laboratory.—Lecturers on Chemistry, Mr. Frank W. Young, F.C.S., Mr. John Thomson, and Mr. Robert Low. Classes and Evening Lectures daily.

School of Medicine, Edinburgh.—Dr. Stevenson Macadam, F.R.S.E., Mr. Falconer King, Mr. Ivison Macadam, Mr. Drinkwater, and Mr. Buchanan.

School of Pharmacy and Chemistry, Edinburgh.—The instruction qualifies for graduation in Medicine and Science in the University of Edinburgh and other Examining Boards. Chemistry, Mr. Drinkwater, F.C.S., L.R.C.P.; Materia Medica and Pharmacy, Dr. Urquhart; Botany, Mr. D. M'Alpine, B.Sc. Lond. Day and Evening Classes.

Minto House Medical School, Chambers Street, Edinburgh.—Mr. J. Falconer King. Lectures and Classes.

Glasgow University.—Prof. J. Ferguson.

Glasgow Mechanics' Institution.—Mr. R. R. Tatlock, F.R.S.E., F.C.S.

Glasgow Veterinary College.—Mr. Stephen Cooke, F.C.S.

School of Chemistry, 138, Bath Street, Glasgow.—Dr. Wallace, Mr. Tatlock, and Dr. Clark. Day and Evening Classes.

Chemical Laboratory, 180, West Regent Street, Glasgow.—Dr. Milne. Day and Evening Classes.

Queen's College, Belfast.—Dr. Letts.

Queen's College, Cork.—Dr. Maxwell Simpson.

Queen's College, Galway.—Dr. T. H. Rowney.

Royal College of Surgeons in Ireland.—Dr. C. A. Cameron, F.I.C. Assisted by Mr. F. Heron, F.I.C., Mr. P. A. Pick, Mr. J. Macallan, F.I.C., and Mr. A. Keating. The Laboratories of the College are provided with every appliance for the study of Chemistry, especially in its application to Medicine, Hygiene, and Pharmacy.

Dublin, Carmichael School.—Dr. C. R. C. Tichborne.

Dublin, Catholic University.—Mr. Campbell.

Dublin, Dr. Steevens's Hospital and Medical College.—Mr. McHugh.

Mechanics' Institute, Abbey Street, Dublin.—Mr. Clement J. Leaper.

CHEMICAL NOTICES FROM FOREIGN SOURCES.

Note.—All degrees of temperature are Centigrade, unless otherwise expressed.

Comptes Rendus Hebdomadaires des Séances, de l'Académie des Sciences. No. 4, July 25, 1881.

Hydrochloric Ether of Glycol.—M. Berthelot.—Glycolic ether has a greater tendency to combine with acids forming compound ethers than has glycol, or than have the simple ethers of the monatomic alcohols. Hence in certain respects it may be approximated to the bases properly so-called.

On Hemihedral Crystals with Inclined Surfaces, as Constant Sources of Electricity.—MM. Jacques and Pierre Curie.—A section suitably cut in a hemihedral crystal with inclined surfaces, and placed between two leaves of tin, constitutes a condenser which is capable of charging itself when compressed. With this system we may realise a new instrument, a condenser source, which possesses special properties. It may serve as a standard of static electricity for measuring charges and capacities. The authors give in this memoir an absolute measurement of the quantities of electricity liberated by tourmaline and quartz under a given pressure.

Determination of the Angular Distance of Colours. A. Rosenstiehl.—The projection of a table of colours upon the sides of an equilateral triangle renders it possible to determine the exact angular distance of the colours, a result which has not yet been obtained, and which suffices to connect together the facts at present known. The author gives a diagram representing the law of the mixture of colours, and which will be advantageously substituted for Newton's rule.

Electric tap: the Transformation, Transportation, and Use of Energy.—G. Cabanellas.—This paper is inserted at length.

Formation-heat of Explosives.—MM. Sarran and Veille.—The authors describe their manner of experimenting, and promise to give their results in a future memoir.

The Magnesia Industry.—If we cause a solution of magnesium chloride to be absorbed by dry slacked lime, the magnesia set at liberty plays the part of a cement, and the matter may be moulded into small porous fragments. If one of these fragments is suspended in a solution of magnesium chloride after some days the lime is entirely substituted by hydrate of magnesia. The fragment has been the seat of a double diffusion; the magnesium chloride has diffused itself from without to within, and is changed in the fragment into calcium chloride, which in turn becomes diffused from within to without. These two diffusions are simultaneous and come to an end when all the lime has been substituted by magnesia. Here, then, is a means of reducing into a small volume a precipitate which would have occupied the entire bulk of the solution, if the fragment of lime had been stirred up in it at first. The same phenomena are produced if a great number of such fragments are heaped up in a suitable vessel, where a solution of magnesia is made to circulate slowly from the top to the bottom. In five or six days the conversion is complete; the solution may be replaced by pure water, and the magnesia washed completely. On stirring up it becomes a white pulp, which, if dried in the air, gives a very friable mass. It is hydrated magnesia which may remain for a long time exposed to the air without becoming notably carbonated. Its purity depends on that of the lime employed. In working on the large scale the author uses a paste of lime, which he forces through a plate of metal pierced with small holes, so as to eliminate stones and unburnt pieces. If these "worms" fell upon the ground, or into water, they would at once return to their pasty state. He therefore receives them in a solution of magnesium chloride, where they become at once covered with a slender coating of magnesia, which consolidates them so well that they may be heaped up to the height of 1·50 metres, still leaving between them the interstices needful for the circulation of the liquid. The paste of lime should contain from 34 to 36 per cent of anhydrous lime. The solution of magnesian salt should contain from 25 grms. to 40 grms. of anhydrous magnesia per litre. The laws of diffusion laid down by Graham are here at fault. The acceleration of the phenomena, due to an increase of strength, is balanced by the resistance opposed by a more consistent deposit of magnesia. The presence of sodium chloride, always abundant in the water of salt marshes, is indifferent. Soluble sulphates must be removed by adding the water from a former operation, rich in calcium chloride, and allowing the calcium sulphate to settle, after which the clear liquor is run off for treatment.

Certain Reactions of Morphine and its Congeners.—E. Grimaux.—The author has treated morphine with formic aldehyd in presence of sulphuric acid, making use of morphine dissolved in glacial acetic acid, a few drops

of methylenic aceto-chlor-hydrin, and sulphuric acid in excess. He thus obtains a new base, which he is examining. All the ethers of morphine behave in a similar manner.

Boric Acid, its Existence in the Salt Lakes of the Modern Period and in Natural Saline Waters.—M. Dieulafait.—The author concludes that the boric acid existing in sedimentary deposits, always associated with saline substances, is derived from the spontaneous evaporation, at ordinary temperatures, of the waters of ancient seas.

Les Mondes, Revue Hebdomadaire des Sciences.
No. 3, May 19, 1881.

System of Annular Magnetic Compensators for the Correction of the Compass.—M. Duchemen.—This system consists in the application of annular magnets in place of the straight magnetic bars generally employed for the correction of the compass on board iron ships.

The Faure Battery.—Speaking of experiments performed in the Hall of the Société d'Encouragement, the writer declares that it was impossible to conceal from the eyes of connoisseurs the rapid decline of the luminous, thermic, and dynamic powers of the apparatus. He denies that M. Faure has succeeded in augmenting the accumulating power of the apparatus of M. Plan é in the proportion of 1 to 40.

No. 4, May 26, 1881.

M. Paul Laurencin gives a description in full of the Nihilist bombs as used for the assassination of the late Emperor of Russia. The editor adds the remark that "if science merely served to realise inventions so criminal there would be little reason to boast of its progress."

True Chemistry (No. 3).—M. Maumené.—The author advances as new proofs of the importance of his theory the decomposition of mercury cyanide and the action of nitric acid upon metals.

No. 5, June 2, 1881.

M. Macagno has been experimenting upon the influence of atmospheric electricity upon the growth of the vine. A copper wire with a platinum point was plunged into the extremity of a branch bearing fruits, whilst another wire connected the origin of the branch with the soil. An increase of vegetation was distinct, the wood of the branches contained less potash than that of other branches, whilst the grapes contained more sugar and less acid.

MISCELLANEOUS.

The Technological Society.—This Society, which has been recently established at Peckham, will meet every Friday at 8 p.m. at the Goldsmith Road Mission (adjoining St. Chrysostom's Church, Hill Street). An introductory lecture on "The Arts and Sciences," will be delivered on Friday evening, September 30th, 1881, by Hugh Clements, F.S.Sc., M.S.A.

Relation between Temperature and the Rate of Chemical Action.—R. B. Warder.—The speed of the reaction,

$$C_2H_5.O.C_2H_3O + NaOH = NaC_2H_3O_2 + C_2H_5OH,$$

in dilute aqueous solution, has been observed at temperatures from 3·6° to 37·7° C. This series of determinations nearly agrees with the equilateral hyperbola,

$$(7·5+a)\ (62·5°-t) = 521·4,$$

where t is the temperature, and a expresses the number of gram-equivalents per litre which would (according to the theory of the action of mass) react upon each other per minute in a solution kept of normal strength. Further details are deferred.—*Journal of the American Chemical Society.*

New Solid Flame Burner.—We have received from Mr. Fletcher, of Warrington, a sample of a new pattern of his patent solid flame burner. Although very small it will readily boil 7 or 8 gallons of water, with the ordinary day-pressure of gas. It will, at full power, burn about 10 cubic feet of gas per hour, and will boil a quart of water in a light kettle in about six minutes, requiring for this about 1 cubic foot of gas. The flame is perfectly solid, with a brilliant green centre when at its full power, and is intensely hot, giving the highest duty ever obtained for the quantity of gas consumed. The tests, as reported in the *Proceedings* of the British Association of Gas Managers (1880), show a duty nearly double that obtained from an ordinary Bunsen, burning the same quantity of gas. The burner is an improvement on the previous patterns which have been so highly spoken of, and is peculiarly adapted for general domestic purposes. It is designed for the roughest and hardest work, retaining at the same time the high duty obtained from the original and more delicately made patterns, which were not so well fitted for rough usage and were more costly.

THE STUDENT'S TEXT-BOOK of ELECTRICITY. By HENRY M. NOAD, Ph.D., F.R.S., F.C.S. New Edition, carefully Revised. With an Introduction and Additional Chapters, by W. H. PREECE, M.I.C.E., Vice-President of the Society of Telegraph Engineers, &c.

"A reflex of the existing state of electrical science, adapted for students."—W. H. PREECE, Esq., in Introduction.

"We can recommend Dr. Noad's book for clear style, great range of subject, a good index, and a plethora of Woodcuts. Such collections as the present are indispensable."—*Athenæum.*

"Dr. Noad's text-book has earned for itself the reputation of a truly scientific manual for the student of electricity, and we gladly hail this new amended edition, which brings it once more to the front."—*Telegraphic Journal.*

"An admirable text-book for every student—beginner or advanced—of electricity."—*Engineering.*

"An admirable handbook."—*We tmins er Review.*

CROSBY LOCKWOOD and CO., 7, Stationers' Hall Court, London, E.C.

City of London—King Street, Corner of Cheapside. NEW HANDSOME LOFTY SHOP, with GOOD GALLERY, to be Let, with or without the excellent light BASEMENT, forming large Show, Consulting, or Dispensing Room. Suitable for a Chemist or Professional Gentleman.—Apply to Mr. Mead, on the premises, or at 102, Southwark Street, S.E.

SILICATE OF SODA, Solid and in Solutions of Various Degrees of Concentration: the finest quality obtainable, and especially adapted for the use of Soap Makers and other Consumers.—JOSEPH CROSFIELD and SONS, Soap Makers, &c., Warrington.

London Agent—H. R. CLARKE, Great Tower Street, E.C.

THE CHEMICAL NEWS.

Vol. XLIV. No. 1140.

ON THE SEPARATION OF HYDROCARBON OILS FROM FAT OILS.*

By ALFRED H. ALLEN, F.C.S., F.I.C.

The extensive production of various hydrocarbon oils suitable for lubricating purposes, together with their low price, has resulted in their being largely employed for the adulteration of animal and vegetable oils. The hydrocarbons most commonly employed for such purposes are:—

1. Oils produced by the distillation of *petroleum* and bituminous *shale*, having a density usually ranging between 0·870 and 0·915.
2. Oils produced by the distillation of common *rosin*, having a density of 0·965 and upwards.
3. Neutral *coal oil*: being the portion of the products of the distillation of coal-tar boiling about 200° C, and freed from phenols by treatment with soda.
4. *Solid paraffin*, used for the adulteration of bees'-wax and spermaceti, and employed in admixture with stearic acid for making candles.

The methods for the detection of hydrocarbon oils in fat oils are based on the *density* of the sample; the lowered *flashing* and *boiling-points*; the *fluorescent characters* of the oils of the first two classes; and the *incomplete saponification* of the oil by alkalies. The *taste* of the oil, and its *odour* on heating are also useful indications.

If undoubtedly fluorescent, an oil certainly contains a mixture of some hydrocarbon, but the converse is not strictly true, as the fluorescence of some varieties of mineral oil can be destroyed by chemical treatment, and in other cases fluorescence is wholly wanting. Still, by far the greater number of hydrocarbon oils employed for lubricating purposes are strongly fluorescent, and the remainder usually become so on treatment with an equal measure of strong sulphuric acid.

If strongly marked, the fluorescence of a hydrocarbon oil may be observed in presence of a very large proportion of fixed oil, but if any doubt exist the hydrocarbon oil may be isolated. As a rule, the fluorescence may be seen by holding a test-tube filled with the oil in a vertical position in front of a window, when a bluish "bloom" will be perceived on looking at the sides of the test-tube from above. A better method is to lay a glass rod, previously dipped in the oil, down on a table in front of a window, so that the oily end of the rod shall project over the edge and be seen against the dark back-ground of the floor. Another excellent plan is to make a thick streak of the oil on a piece of black-marble, or glass smoked at the back, and to place the streaked surface in a horizontal point in front of and at right angles to a well-lighted window.† Examined in this manner, a very slight fluorescence is readily perceptible. If at all turbid the oil should be filtered before applying the test, as the reflection of light from minute particles is apt to be mistaken for true fluorescence. In some cases, it is desirable to dilute the oil with ether, and examine the resultant liquid for fluorescence. An exceedingly small amount of mineral oil suffices to impart a strong blue fluorescence to ether.

The quantitative analysis of mixtures of fat oils with hydrocarbon oils has till recently been very uncertain, the published methods professing to solve the problem being for the most part of very limited applicability, and in some cases wholly untrustworthy.

When the hydrocarbon oil in admixture happens to be of comparatively low boiling-point, it may often be driven off by exposing the sample to a temperature of about 150° C., but the estimation thus effected is generally too low, and often quite untrustworthy.

When it is merely desired to estimate approximately the proportion of hydrocarbon oil present, and not to isolate it or examine its exact character, Kœttstorfer's titration-process may be used, as suggested by Messrs. Stoddart. But the best and most accurate method of detecting hydrocarbon oils in, and quantitatively separating them from, fat oils, is to saponify the sample, and then agitate the *aqueous solution* of the soap with ether.* On separating the ethereal layer and evaporating it at or below a steam heat the hydrocarbon oil is recovered in a state of purity.

Either caustic potash or soda may be employed for the saponification, but the former alkali is preferable, owing to its greater solubility in alcohol and the more fusible character of the soaps formed. A convenient proportion to work with consists of 5 grms. of the sample of oil, and 25 c.c. of a solution of caustic potash in methylated spirit, containing about 80 grms. of KHO per litre. Complete saponification may usually be effected by boiling down the mixture in a porcelain dish, with frequent stirring, until it froths strongly. In the case of butter, cod-liver oil, and other fats which undergo saponification with difficulty, it is preferable to precede this treatment by digestion of the mixture for half an hour at 100° C. in a closed bottle. After evaporating off the alcohol, the soap is dissolved in water, brought to a volume of 70 to 80 c.c., and agitated with ether. The ethereal solution is separated, washed with a little water and carefully evaporated. The agitation with ether must be repeated several times to effect a complete extraction of the hydrocarbon oil from the soap solution.

The foregoing process has been proved to be accurate on numerous mixtures of fat oils with hydrocarbon oils. The results obtained are correct to within about 1 per cent in all ordinary cases. In cases where extreme accuracy is desired, it is necessary to remember that most, if not all, animal and vegetable oils contain traces of matter wholly unacted on by alkalies. In certain cases, as butter and cod-liver oil, this consists largely of *cholesterin*, $C_{26}H_{44}O$.† The proportion of unsaponifiable matter soluble in ether which is naturally present in fixed oils and fats rarely exceeds 1½ per cent, and is usually much less. Sperm oil, however, constitutes an exception, yielding by the process about 40 per cent of matter soluble in ether.‡ This peculiarity has no practical effect on the applicability of the process, as sperm oil, being the most valuable of commercial fixed oils, is never present without due acknowledgment of the fact. Spermaceti and the other waxes yield, after saponification, large percentages of matter to ether, and hence the process is not available for the determination of paraffin wax in admixture with these bodies, though it gives accurate results with the mixtures of paraffin and stearic acid so largely employed for making candles.

The following figures obtained in my laboratory by the analysis of substances of known purity and of mixtures of known composition, show the accuracy of which the pro-

* A Paper read before the Chemical Section of the British Association, York Meeting, 1881.

† Either of these plans is infinitely superior to the polished tin-plate usually recommended. In short, the back-ground should be black, not white.

* According to my experience, treatment of the *dry* soap with ether, petroleum spirit, or other solvent, is liable to cause error from solution of the soap itself, if much hydrocarbon oil be present.

† The process affords a very rapid and simple means of isolating cholesterin. Thus, on dissolving the traces of unsaponifiable matter left by butter in a little hot alcohol, and allowing the liquid to cool, abundant crystals are deposited, which may be identified as cholesterin by their microscopic and chemical characters. A sample of butterine gave no cholesterin.

‡ I am investigating this interesting fact, and have obtained full confirmation of Chevreul's observation that sperm oil when saponified yields a peculiar solid alcohol instead of glycerin. It is distinct from cetyl alcohol, and distils, apparently without decomposition, at a very high temperature.

cess is capable. The process was in each case on about 5 grms. of the sample in the manner already described. The results are expressed in percentages.

Composition of Substance taken.				Unsaponifiable Matter found.
Fat Oil.		Hydrocarbon Oil.		
Olive.. ..	40	Shale oil ..	60	58·03

Japan wax	100	0		1·14
Lard	100	0		0·23*
Cacao butter	100	0		0·22

The following table indicates the general behaviour of the constituents of complex fats, oils, and waxes when the aqueous solution of the saponified substance is shaken with ether:—

Dissolved by the Ether.	Remaining in the Aqueous Liquid.
Hydrocarbon oils; including, Shale and petroleum oils.	*Fatty acids.* In combination with the alkalies used.
Rosin oil.	*Resin acids.*
Coal-tar oil.	
Paraffin wax and ozokerite.	*Carbolic* and
Vaseline.	†*Cresylic acids.*
Neutral resins.	
Unsaponified fat or oil.	*Glycerol* (Glycerin).
Unsaponifiable matter; as cholesterin.	
Spermyl alcohol; from sperm oil.	
Cetyl alcohol; from spermaceti.	
Myricyl alcohol; from bees'-wax.	

The hydrocarbon oil having been duly isolated by saponifying the sample and agitating the solution of the resultant soap with ether, its nature may be ascertained by observing its density, taste and smell, behaviour with acids, &c.

I have to express my indebtedness to Mr. Charles Harrison for the valuable assistance he has rendered me in establishing the analytical facts described in the foregoing paper.

Present Chemical Doctrines: General Theory of Chemical Action.—E. J. Maumené.—All chemical reactions may be regarded as actions either of contact or of mixture, and are regulated in the former case by specific gravity and molecular weight: in a word, by the molecular volume of the bodies present, and in the second case, by their molecular weight. He rejects the notions of molecule and atom, and employs the terms equivalent and atomic volume.—*Les Mondes.*

* The experiments marked with an asterisk were not made strictly by the same process as the majority.

† In a previous research I found that carbolic and cresylic acids were wholly removed from their ethereal solutions by agitation with caust soda.

ELECTRIC LIGHTING BY INCANDESCENCE.

At the recent meeting of the British Association Mr. J. W. Swan read a paper on the incandescent lamp invented by him. He said that the difficulty in producing electric light with carbon points was to make it steady and to moderate its excessive brilliance. By dint of improvements in the form and quality of the charcoal pencils and ingenious mechanism for maintaining the points of these pencils at one constant distance from each other, the first of these difficulties had to a very large extent been overcome. But the second had remained, and must remain as an insuperable obstacle to the application of this form of electric light to the general purposes of artificial illumination. That form of electric light was only exceptionally applicable, leaving the greater number and the more important of our wants in respect of artificial light unprovided for. It was, in his opinion, inapplicable to domestic lighting, and it was there that we experienced the most keenly the evils of the existing modes of artificial illumination by means of gas and oil lamps. In order to adapt electric light to house illumination it was necessary to entirely change the method of producing it. Electric light produced on the principle of incandescence had many good properties which the electric light known as the arc light had not. If the electric current which produced the incandescence was quite constant, the light emitted by the white-hot carbon was absolutely constant. There was not the slightest flicker or variation in it. It was, moreover, quite under control as to its brilliance, and might be made as yellow as gaslight or as white almost as sunlight. It communicated no noxious vapours to the air, and was not too costly. But the crowning merit of the electric light produced on the principle of incandescence was that it was indefinitely divisible without sacrifice of economy. A lamp might be so constructed as to give a light of 10 candles, or it might be constructed with larger carbon conductors so as to obtain a light of 100 candles from the incandescent carbon, and the smaller lamp would be almost as economical as the larger light for light. This property of divisibility into as small centres of illumination as might be required, which was inherent in this method of electric lighting to fully the same extent as in gaslight, combined with its steadiness, its good colour, and its wholesomeness, gave it a character of general applicability which was not possessed by any other kind of electric light. Nothing could well be simpler than the ideal incandescence lamp, A slip of carbon in a vacuum—that was all. To realise this idea much experimentation had to be gone through, and much disappointment to be suffered. In the vacuum lamps of earlier date it was neither possible to produce nor to maintain a perfect vacuum. There were always screws and washers about them, and these and the carbon itself in a cold state formed a reservoir of air quite sufficient to cause the disintegration and rupture of the carbon after a few hours' ignition. Four years ago he proceeded to experiment on this matter. His main idea was to employ in a good Sprengel pump vacuum a form of carbon made by carbonising paper at a high temperature, with which he had experimented many years before. The carrying out of his idea was made easy by the assistance he received from Mr. Stearn. Mr. Stearn undertook to mount some of his paper carbons in a good vacuum, and after many failures from carbons breaking, he at last succeeded in making some bulbs very highly exhausted, containing his paper carbons attached by electrically deposited copper to platinum strips, which carried the current in and out of the lamp. He showed a lamp lighted at a lecture he delivered before the Philosophical Society of Newcastle in February, 1879. The final results of the experiments were that when the vacuum was good the carbon did not appreciably wear away, and that when the contact between the ends of the carbon and the metallic conductors was good the globes did not blacken. Thenceforth it was possible to produce a durable electric

lamp that emitted a steady light of moderate power. Since then the manufacture of lamps on this principle, with slight modifications in the material out of which the carbon was made and the manner of making it, had been established on an extensive scale both in England and America, and in the electric exhibition now open in Paris electric light produced by incandescence occupied an important position. Already in this country the method has been put to actual use in house illumination and for lighting the saloons of passenger steamers. It had also been tried experimentally in coal-mines. Sir Wm. Thomson and Mr. Bottomley had made careful measurements of the energy expended in the production of light with his lamps, from which it appeared that with a small lamp, when rather less than one-sixth of a horse-power was expended on it, a light of 42 candles was emitted, or an aggregate of 270 candles per horse power. With a higher electromotive force, and therefore a larger current, 102-candle light was obtained from the same lamp. This amount of light was produced by the expenditure of rather more than one-fourth of a horse power—that is, one-horse power under the circumstances yielded 390 candles. By producing light in this manner, and employing the gas-engine as a motor to drive a dynamo-electric machine, the very interesting result was arrived at that more light was obtained from a given quantity of gas exploded in the gas-engine than could be obtained by burning the same quantity in the usual way to produce light directly. It was clear that the time was now ripe for the almost unlimited application of electric light to general purposes, and that engineers might with much advantage give their immediate attention to the many details which fell within their province in connection with the mechanical production and distribution of electricity on a large scale.

The subject of Electric Lighting by Incandescence was subsequently brought forward at the Mechanical Section, when Mr. Andrew Jamieson, Principal of the College of Science and Arts, Glasgow, read a paper on "Electric Lighting for Coal Mines." He said that in the discussion which followed the exhibition of Swan's lamp at the Society of Telegraphic Engineers in October last, Professor Tyndall remarked that probably this form of incandescent lamp could be adapted for use in coal mines as a safety lamp. Since then two practical trials had been made with that object in view—one at Pleaseby Colliery, near Nottingham, by Messrs. R. E. Crompton and Co., and the other at Earnock Colliery, near Glasgow (still working). Mr. Jamieson reviewed what had been done at these collieries, explaining the apparatus and appliances adopted at Earnock by means of a large wall diagram, made from scale drawings kindly lent to him by Mr. Gilchrist, the Manager. He showed working models of strong miners' lanterns encasing Swan's lamps and of air-tight contact makers of various designs and patterns, for preventing the inevitable spark which always takes place upon disconnecting leading wires or lamps from causing danger in a fiery mine. He showed by calculations and sketches on the blackboard that a plan of joining up a number of Swan's lamps in single parallel with a self-exciting Gramme, Siemens, or other form of dynamo machine, was neither the most economical nor handy for management, from the fact that the lamps required to be specially ordered and made of a slightly decreasing resistance in proportion to their distance along the main leads from the generator, and that without a costly and delicate current regulation there was considerable risk in spoiling the remaining lamps upon turning out a number of them. The plan of introducing an equivalent resistance to that of the lamps turned out was equivalent to throwing away so much energy or coal, because the resistance so introduced absorbed power equal in fact to that of the lamp or lamps which it replaced. He gave several plans for joining up the lamps which, in his opinion, were more economical and better, and he stated that by using Siemens's Dynamo Exciters, with their alternate current machines, the danger accruing from suddenly turning out a number of lamps was avoided, as the electromotive force remained practically constant (with low resistance leads and generator coil), and, therefore, the current passing the remaining lamp or lamps was always the same. For example, if 49 out of 50 lamps were suddenly switched out of circuit the remaining lamp would not be endangered, and would have the same current passing through it and give the same light as before. He described mechanical and electrical apparatus which he had designed for installing electric lighting in coal mines, and mentioned that he had found by experiment that good Swan's lamps would give forth light at the rate of 220 candle power per horse power absorbed by them. When incandescent at 20 candles.

Mr. Crompton, of the Pleasely Colliery, gave some details of this application of the light to their Colliery, and said, in contradiction of a remark by Mr. Jamieson, that the self-exciting Gramme machines could be made perfectly self-regulating. He was now carrying out the lighting of the Risca Colliery, thus going from one of the safest to one of the most dangerous pits in England, and they were applying there this experience they gained at Pleasely. The lighting of pits was a far more important matter than people thought; and with a view to settle the question of whether it was possible to explode the gases, he had asked Professor Abel to help him, and they were going to carry out some experiments. They hoped to be able to show that it was possible to make the lamps so that without any additional complication they could be used in mines in the midst of a dangerous mixture of gases.

Mr. J. W. Swan said the miners' lamp shown there that morning were intended to be used by attaching Brush wires to main wires in the colliery. The continual attachment of these wires was a drawback, as it limited the portability of the lamp, necessitating long lines of conducting wire of considerable thickness, which were expensive, and the retention of these conducting wires was attended with a possible source of danger. They were unable to eliminate completely danger arising from the breaking or contracting of the wires. He had therefore thought that a completely self-contained and portable miners' lamp would be an advantage, and he had in his hand a specimen of a lamp which possibly could be used in this manner. The lamp could be kept lit for six hours by a two-cell Faure secondary battery, and would give a light of 1 or 2 candle power during the time. The weight of the battery would not exceed 10 pounds, and to charge it afresh it would only be necessary to place it for a time in connection with the wires of a dynamo near the pit's mouth. The lamp and its attached battery need never come out of the pit.

Sir John Hawkshaw said he was in want of some means of lighting with electricity the Channel tunnel. The detached lamp mentioned by Mr. Swan seemed to remove one great difficulty in the way of using the electric light in mines or tunnels.

The Chairman (Dr. C. W. Siemens) said the application of the electric light to mines was a matter of great practical importance, and one involving many difficulties. He confessed that when the question was put to him by the Royal Commission whether he thought the electrical illumination of mines was a desirable object, and one that could be easily accomplished, he could not find a satisfactory answer. With regard to the second part of the question, many difficulties in the way had been manfully dealt with by the gentlemen who had addressed the section, and certainly there seemed to be a far greater promised success than he anticipated so soon. The backbone of the whole question was the incandescent lamp, through which we had the means of putting the source of the light away from all contact with the atmosphere of the mine. As Mr. Swan had shown, he could produce a lamp of two candle-power, such a power as a miner would require at the end of his working. The greatest difficulty which presented itself to every electrician was that of the con-

ductor. If the conductor should be broken or contact take place between two conductors, a flash of light would ensue, which might fire the mine. In dealing with this subject Mr. Jamieson and other gentlemen had devised several means of connecting and disconnecting the wires without risk of an electric spark, and that was the first condition to the successful application of electricity for lighting mines. Another condition was to insulate the conductors in such a way as to render an accidental contact between the two lines almost an impossibility; and he must say that he went much with Mr. Jamieson in contradistinction to the views expressed by Mr. Crompton, that low tension was a desideratum. By putting all the lamps in parallel circuits they avoided the necessity of high tension, and reduced the risk of accidental flashes of light through contact of the electric conductors. Mr. Swan had brought before them a system of lighting which commended itself very much to his mind, and that was to make an electric lamp which could be carried away from the conductor altogether. The Faure Battery gave them a means of storing electricity, and the miner might go to a central station and fill his electric lamp, not with electricity exactly, but with a chemical charge capable of producing electricity, the same as he went now to fill his lamp with oil, and with this store of energy he could probably go and work during the whole shift without being hampered by conducting wires, which no doubt were a matter of serious difficulty in coal mines. Taking it all in all, he thought means had been shown of avoiding the risks that would at first sight appear inevitable in attempting to light fiery mines by electricity, and he very much hoped to see the system largely introducing. He thought the object Sir John Hawkshaw mentioned could be accomplished without difficulty.

ON THE MOLECULAR WEIGHT OF HYDROFLUORIC ACID.*

By Prof. J. W. MALLET, F.R.S.

THE analogies of fluorine with the halogens on the one hand and with oxygen on the other have often been remarked upon. The general resemblance of fluorine compounds to the corresponding compounds of chlorine is manifest, and the two elements are usually classed together; but some striking differences force themselves upon the attention, such as those existing between the chloride and fluoride of calcium, chloride and fluoride of silver, &c., and the marked tendency of the fluorides to the formation of double salts with formulæ analogous to those of oxygen compounds, as well as the formation of many salts including both oxygen and fluorine, suggests some close natural relation between these elements themselves.

When the principle of quantivalence or atomicity first began to assume distinct shape, it became a matter of special interest to decide whether fluorine should be classed with chlorine amongst the monad elements, with the formula HF for hydrofluoric acid, and the atomic weight 19 for fluorine itself, or should be placed with oxygen amongst the dyads, writing H_2F for hydrofluoric acid, and assuming the atomic weight of fluorine as 38. For some time, although analogies were chiefly in favour of the former view, no direct evidence was available for the settlement of this question, but in 1869 it seemed to be supplied by the researches of Gore,† who, heating silver fluoride in contact with an equivalent quantity of pure and dry hydrogen, observed that "one volume of hydrogen in uniting with fluorine produces, not simply one volume of gaseous product, as it does when uniting with oxygen, but two volumes, as in the case of its union with chlorine." Further on, in the same paper, after giving his results as to the amount of silver in the fluoride used, he says: "These results, combined with the foregoing experiments on molecular volume, agree with the conclusion that a volume of hydrogen weighing 1 unites with 19 parts by weight of fluorine to form 2 volumes of hydrofluoric acid, and that the specific gravity of gaseous anhydrous hydrofluoric acid is ten times the amount of that of hydrogen."

Gore's experiments were made with somewhat small quantities of the materials used (about a gramme of silver fluoride and 90 or 100 c.c. of hydrogen), and in opaque vessels of platinum, the volume assumed by the gaseous hydrofluoric acid being ingeniously determined by raising or lowering the cylindrical platinum receiver, so that the level of the mercury in which it was placed remained the same inside and out, and reading off an external scale. The whole apparatus was heated in an air-bath to 93° to 100° C. before making the final reading. It is stated that fourteen separate attempts were made to ascertain the volume of gaseous product formed, but the numerical results of only two of these are given. They seem fairly to establish the fact that at temperatures near 100° hydrofluoric acid exists as HF, 93·3 and 98·5 per cent respectively of the theoretical volume being obtained after allowance for expansion at the temperature employed. The atomic weight of fluorine is thus established as 19, not 38.

Certain measurements of the gaseous acid are, however, given for lower temperatures, though far above the boiling-point (67° F., as found by Gore himself = 19·5° C.), which represent distinctly smaller volumes. Thus at 139° F. (59·5° C.) the volume was but 85·8 per cent of that required by theory, and at 160° F. (71° C.) it was 88·1 per cent.

Hence it seemed still desirable to try to ascertain whether the acid exhibits a different but definite vapour density at a temperature nearer the boiling-point, though high enough to preclude any actual liquid acid remaining, with even rough weighings, and if possible in transparent or translucent vessels. With this object in view I have made the following experiments.

Perfectly pure Greenland cryolite, carefully selected in choice fragments, was pulverised in a clean iron mortar, heated to 300° C. for some time, and transferred while still warm to a well dried and warm bottle. Sulphuric acid was prepared of full strength by adding to a quantity of the purified acid of 95 or 96 per cent a small excess of pure sulphur trioxide, and passing for several hours a well dried and gently warmed current of air through the liquid; this was also preserved in a well stoppered bottle until needed. The cryolite and acid were heated together in a leaden retort, the capital of which was clamped on without lute, and the hydrofluoric acid vapour given off was conducted downwards through a worm of leaden tube, 6 m.m. in interior diameter and 3·5 metres long, surrounded by crushed ice, into a leaden bottle cooled by a freezing mixture of ice and salt. The interior of all the leaden apparatus had been previously crusted over by passing hydrofluoric acid vapour through for some time. The joints were made by simply wrapping tightly with lead foil, and ligating with wire. The quantity of the materials used was such as to produce eight times the amount of hydrofluoric acid necessary to fill with vapour the leaden bottle and the flask and connecting tubes to be afterwards used, even assuming the highest vapour density that could well be expected.

The flask in which the vapour was to be weighed was of good Bohemian glass, and held nearly 4½ litres, being as large as could be well managed in the balance case. It was slung in a light network of platinum wire, with a suspending ring at top, and was, after thorough drying, carefully coated over the whole inside surface with clear,

* The substance of this paper was verbally presented, by invitation, at a meeting of the National Academy of Sciences at Washington, April 22, 1881.

† *Philosophical Transactions* for 1869. A further paper, on silver fluoride, appeared in 1870.

colourless paraffin,* poured in in the melted state, and evenly distributed by turning round and round the gently-warmed flask. The melting-point of the paraffin was 56° C., well above the temperature to be afterwards applied. The neck of the flask was accurately fitted with a sound, soft cork, previously well dried and soaked in paraffin. Through this cork passed two glass tubes of about 5 m.m. bore, one of which extended about two-thirds of the way to the bottom of the flask, and just above the cork was bent at right angles, the short projecting limb being some 20 m.m. long. The other tube ended just below the cork on the inside of the flask, came out straight, and projected also about 20 m.m. on the outside. Both were drawn down a little in diameter, about 5 m.m. from the outside ends, so as to form a little socket for the small cork by which each tube was to be closed, insuring this cork coming to exactly the same position when inserted. The two small corks, the whole of the interior of the glass tubes, and so much of their exterior surface as was to be inside the flask were thoroughly protected by paraffin. The specific gravities of the glass, paraffin, platinum, and paraffin-coated corks with tubes were taken at about the temperature to be used, and the figures obtained corrected for buoyancy in air by the formula—

$$G_r = G_a - \rho(G_a - 1).\dagger$$

From the thus corrected specific gravities, and careful weighings in air of observed temperature and pressure, the volumes and absolute weights *in vacuo* of all the materials concerned were deduced, save in the case of the hydrofluoric acid vapour itself, the volume of which was obtained by an actual calibration‡ of the part of the flask and tubes occupied by it.

As soon as the distillation of the acid and its collection in the leaden bottle was complete, the retort and capital were disconnected from the worm, and the upper end of the latter connected with the bent tube of the paraffin-lined flask, interposing in the first experiment another small flask, also protected by paraffin, and containing a little phosphorus pentoxide, as the means of removing any last traces of aqueous vapour. Removing the freezing mixture from about the leaden bottle, the latter was surrounded with water at 25° C.; and the water surrounding the worm was brought to the same temperature, while the flask was at 1° or 2° lower. The hydrofluoric acid thus vapourised filled the whole apparatus, gradually expelling the air, and the excess escaped through a long india-rubber tube attached to the exit glass tube, and carried through a hole in the door-casing to the outside atmosphere, thus avoiding danger to the lungs and eyes, and risk of corrosion of the outside of the flask. When the escape of vapour slackened, the two tubes entering the flask were quickly disconnected from the rest of the apparatus and the little paraffin-soaked corks at once inserted. In doing this but one tube at a time was open, and that but for a moment.

The flask was then placed in a deep cylinder of sheet zinc, of diameter to just fit it, and this was immersed in a much larger cylinder, containing some 30 litres of water, at a little over 30° C., a cover with small openings in it being fitted over both. Previous experiment with a similar flask of air and enclosed thermometer showed what small allowance to make in the temperature of the water in order to bring the flask and its gaseous contents to the desired point. In the actual experiments with hydrofluoric acid a thermometer was placed on the upper part of the outside of the flask, while another was immersed in the water of the outer vessel. From time to time, as the temperature of the flask rose, the little cork was partly withdrawn for a moment from the straight vertical exit tube, and the surplus vapour was thus allowed to escape. In doing this one or two small, but bad, burns were made upon the fingers by the frightfully corrosive dry acid, of whose dangerous character one can hardly speak too strongly.

When the temperature of the flask had become stationary at or very close to 30° the little corks were firmly inserted in their seats, the flask was removed from the zinc cylinder, allowed to cool to the temperature of the balance-room, which had, however, been warmed up for several hours by a stove to a little over 25°, and was then accurately weighed.

The following result was obtained in the first experiment:—

Weight of flask, &c., and vapour, *in vacuo*,	393·781 grms.
" " " empty, "	386·531 "
Weight, *in vacuo*, of 4347·4 c.c. of vapour at 29° C. and 743·7 m.m. (cor.) = 3846 c.c. at 0° C. and 760° m.m.	7·250 grms.
Hence, 1 litre of vapour at 0° and 760 m.m. .. .. =	1·885 grms.
Hence, specific gravity of vapour (H* = 1) =	21·06 grms.
Or molecular weight .. .. =	42·12 grms.

As soon as the weighing was over the flask was washed out with distilled water enough to largely dilute the acid, into a platinum dish, and the purity of the liquid examined. It was quite clear and free from silicon or lead, and gave no reaction for sulphuric or sulphurous acid, but on testing with ammonium molybdate very distinct evidence was obtained of the presence of phosphoric acid. This had been suspected from the energy with which the phosphorus pentoxide, of which fortunately but little had been used, was attacked by the vapour. In all probability phosphorus penta-fluoride had been formed and carried forward with the hydrofluoric acid. This may serve to account for the vapour density of the latter coming out somewhat too high for even the formula H_2F_2 (requiring sp. gr. = 20). Any traces of air or aqueous vapour which might have been present would, of course, have tended, on the contrary, to produce a lower result.

In order to avoid this ascertained source of error in a second experiment, the phosphorus pentoxide was omitted altogether, the upper end of the leaden worm was directly connected to the large flask, and as the means of finally drying the vapour, a little sulphuric acid of full strength (pure H_2SO_4—not SO_3) was added to the liquid hydrofluoric acid in a leaden bottle while it was still in the freezing mixture, before proceeding to vapourise the latter acid at the very moderate temperature of 25°. A new flask, lined with paraffin and fitted with tubes as before was used, and the following result was obtained:—

Weight of flask, &c., and vapour *in vacuo*	428·255 grms.
" " " empty "	421·436 "
Weight, *in vacuo*, of 4394·7 c.c. of vapour at 30·5° C. and 745·2 m.m. (cor.) = 3876·5 c.c. at 0° C. and 760 m.m.	6·819 grms.
Hence 1 litre of vapour at 0° and 760 m.m. .. .. =	1·759 grms.
Hence specific gravity of vapour (H = 1) =	19·66 grms.
Or molecular weight.. .. .. =	39·32 grms.

In this case the dilute acid washed out from the flask after the experiment seemed to be quite pure, or at any rate was free from silicon, lead, sulphuric, and sulphurous acids. In both experiments the flask was, immediately after weighing, carefully inspected in a strong light, and no visible trace of liquid could be observed on the inside surface.

* The dry acid in the gaseous state does not act upon glass, but, as it did not seem certain that, by the process used, perfect exclusion of moisture would be secured, it was thought better to take this precaution.

† G_r being the real specific gravity of the body, G_a the apparent specific gravity of same taken without air correction by simple weighings in air and water, and ρ the ratio of the densities of air and water under existing conditions of temperature and pressure.

‡ With water of known temperature, as the weight of mercury necessary would hardly have been safely borne by the flask.

* One litre of hydrogen at 0° and 760 m.m. at Univ. of Va. = 0·089488 grm.

The glass, examined after removal of the paraffine, was found quite uninjured, except a slight trace of corrosion on the outside close to the exit.

The figures obtained obviously justify the assumption that at 30° C. the molecule of hydrofluoric acid vapour should be represented not as HF, but as H_2F_2, since the agreement with this assumption of the vapour density obtained in the two experiments is too close to be fairly accounted for by the mere general idea of imperfect gaseous condition, and it is certain that no such quantity of actually liquid acid as would be necessary to account for the double weight could possibly have escaped detection on the inner surface of the flask. At higher temperatures, such as those at which Gore's measurements were made, dissociation manifestly takes place, leading to the production of di-atomic molecules of HF.

The structure of the molecule of double weight, H_2F_2, may be well viewed as resulting from fluorine behaving not only as a monad but also as a triad, and acting in double atoms,

$$-F=F-,$$

like those of nitrogen,

$$-N=N-$$

in the di-azo compounds. In such a condition the element presents a pseudo-dyad character, and becomes capable of replacing oxygen, and manifesting the *linking* function of the latter. Admitting, therefore, that the atomic weight of fluorine remains fixed at 19, we can see that the molecule of hydrofluoric acid may at high temperatures be H—F, analogous to that of hydrochloric acid, while at a little above the boiling-point under ordinary pressure the structure may be H—F=F—H, and thus analogous to that of water.*

This assumption, supported by the experimental evidence now brought forward, serves conveniently to explain the constitution of a number of fluorine compounds, whose formulæ are difficult to write in a satisfactory way if fluorine be considered as exclusively monad.

Thus we may view:

Potassium hydro-fluoride—KHF_2 as

Potassium boro-fluoride—KBF_4 as

Potassium silico-fluoride—K_2SiF_6 as

Potassium fluo-tantalate—K_2TaF_7 as

Potassium fluoxy-niobate—K_2NbF_5O as

Potassium fluoxy-niobate (cuboid-Marignac)—K_3NbF_6O as

* Gore sums up the results of his numerous experiments on the chemical behaviour of this interesting substance with the sentence: "From the various experiments already described, we may conlude that hydrofluoric acid is by its properties placed between hydrochloric acid and water, but is much more closely allied to the former than to the latter."

† On the type of a meta-silicate. Like formulæ apply to the analogous compounds of titanium, zirconium, and tin.

‡ Or these formulæ may be doubled, so as to correspond exactly with the oxygen pyro-tantalate and pyro-niobate.

§ On the type of an ortho-niobate.

Potassium fluoxy-tungstate—$K_2WF_4O_2$ as

Cryolite—NA_3AlF_6 as

Chiolite—$Na_3Al_2F_9$ as

Chodneffite—Na_2AlF_5 as

Topaz—$Al_2SiF_2O_4$ as

Apatite—$Ca_5P_3FO_{12}$—might be written:

but, in view of the replacement of fluorine by chlorine in this mineral, as in the analogous pyromorphite and mimetite, it is doubtless better, as well as simpler, to suppose the molecule to be merely—

ON A CURIOUS ACTINIC PHENOMENON.

By J. CAWLEY.

I NOTE, with some surprise, that Dr. Phipson, in his second note on the above-named subject, takes not the slightest notice of my criticism of his analytical and other results. I pointed out that his analysis was obviously erroneous, and that his other results differed widely from those obtained by myself, and he replies that I "do not appear to have the least idea of the cause of the phenomenon under consideration."

It appears to me that such an answer is somewhat inconsequent, and his inference from my remarks not all justified. But Dr. Phipson seems to have a peculiar talent for making large inductions from scanty and inadequate data. For example, he assumes that a new element Actinium (would not Phipsonium be a more suitable name if the new body should be isolated ?) may exist in the pigment examined by him, and cause the discolouration in question. The new body he supposes may also give rise to the colour which blende generally possesses. Most chemists would, I opine, consider the presence of iron, manganese, &c., in the mineral as sufficiently explanatory of the colour. Should Dr. Phipson fail to ascertain the origin of the photogenic character of zinc-sulphide pigments, it will surely not be owing to a lack of hypothesis. He has successively assumed that the discolouration was caused by a double sulphate of iron and barium, by the new body Actinium, by an equally hypothetical sub-oxide of zinc, and an alternate reducing and oxidising process. But unfortunately none of the theories are entirely satisfactory. I notice too that in his second note he speaks of the zinc pigments examined by him, as containing "minute" quantities of iron, &c., while in his first note he finds 2 per cent of FeO in a typical pigment of the same class. Does he call 2 per cent a "minute" quantity? I am afraid such a "minute" quantity would hopelessly ruin any zinc-sulphide pigment by causing it to be more nearly black than white.

I hope shortly to be able to send a brief account of my own results in connection with the matter under consideration. I have repeated the experiments a large number of times, and I am, in consequence, confident in the general accuracy of my results.

But as I do not possess Dr. Phipson's talent for inventing hypotheses, I have not yet devised a theory that will agree well with all the facts of the case. But some fellow-reader may be more successful.

Newark, N. J., U.S.A.

PROCEEDINGS OF SOCIETIES

AMERICAN CHEMICAL SOCIETY.*

September 2, 1881.

Dr. ALBERT R. LEEDS, Vice-President, in the Chair.

THE minutes of the previous meeting were read and approved.

As there was no meeting of the Board of Directors, the Committee on Papers and Publications was next called upon to report. Dr. ENDEMANN, speaking in reference to the *Journal*, said that all the matter is now in type, and that he expects the *Proceedings* will be out in a few days.

The LIBRARIAN then reported that the collection of books presented to the Society by Dr. Lindsley is composed of—Pharmaceutical works, 7; 10 volumes; physics and chemistry, 13 works; 30 volumes. Special subjects (Physics and chemistry), 6 works and 6 volumes; metallurgy and mineralogy, 26 works, 29 vols. Total, 52 works and 75 volumes.

No members to be elected.

The following gentlemen were then nominated:—As Member—Albert L. Colby, Ph.B.; proposed by Arthur H. Elliott, Elwyn Waller, A. R. Leeds. As Member—Dr. Lawver; proposed by Benj. S. Thedrik, P. Casamajor, H. Endemann. As Member—Dr. Harry von Bauer; H. Endemann, James H. Stebbins, jun., P. Casamajor. As Member—Dr. P. Radenhausen; proposed by H. Endemann, James H. Stebbins, jun., P. Casamajor. As Member—Dr. Louis Habel; proposed by H. Endemann, J. F. Battershall, M. Benjamin. As Member—H. C. Heipe; proposed by H. Endemann, James H. Stebbins, jun., J. F. Battershall. As Member—Wm. L. Leman; proposed by Q. J. Parker, P. Casamajor, E. Waller. The resignation of Mr. W. P. Mason was then read and accepted.

The first paper of the evening, "*On the Detection of Oleomargarine*, by P. CASAMAJOR, was then read. The detection of this substance is based upon the specific gravity of fats in methyl alcohol of about 54 per cent, butter floating in it, while the oleomargarine sinks to the bottom.

The second paper read was "*On Starch-Sugar Syrup mixed with Sugar-House Syrup*," by P. CASAMAJOR, was then read. This test depends upon the solubility of sugar-house syrup in methyl alcohol, whereas the starch-sugar syrup is thrown down as a white precipitate. For 10 vols. of syrup it requires about eight times as much alcohol to complete the separation.

The third paper, "*On a Short Table for Testing Sugar by Inversion*," by P. CASAMAJOR, then followed.

The fourth paper of the evening, "*On a New Form of Apparatus for Gas Analyses*," by ARTHUR H. ELLIOTT, was then read. With this apparatus the large amount of washing (as with the Wilkinson apparatus) is obviated, which Mr. Elliott found to reduce the illuminants as much as 2 per cent.

Some remarks by Dr. Endemann, Mr. Elliott, and Mr. Stebbins then followed, after which the meeting adjourned.

* Communicated by James H. Stebbins, jun., Recording Secretary.

NOTICES OF BOOKS.

Annals of Chemical Medicine including the Application of Chemistry to Physiology, Pathology, Therapeutics, Pharmacy, Toxicology, and Hygiene. Vol. II. Edited by J. L. W. THUDICHUM, M.D. London: Longmans, Green, and Co.

THERE is very little matter in this work which might not be legitimately and profitably discussed in our pages. Of capital importance is the first memoir, "Researches on the Chemical Composition of the Non-phosphorised Group of Nitrogenised Principles of the Brain." Among the substances isolated may be mentioned cerebrose, $C_6H_{12}O_6$, a new crystalline sugar; sphingosine, a new alkaloid; psychosine, also a nitrogenous compound; aesthesine, probably a compound of sphingosine and neuro-stearic acid. The author considers that phrenosine is made up of 1 mol. each of sphingosine, 1 of neuro-stearic acid, and 1 of cerebrose, minus 2 mols. water. Psychosine is the cerebroside of sphingosine; it is an alkaloid, but of a less pronounced character than sphingosine. Aesthesine is a compound of sphingosine with neuro-stearic acid minus water. Cerebrenic acid has not yet been obtained in a state of purity, but from preliminary analyses Dr. Thudichum considers it as consisting of the same radicles as phrenosine, *i.e.*, cerebrose, sphingosine, and neuro-stearic acid, though in different proportions.

In a paper on "Hemisymmetry in the Chemical Constitution of Gelatin, Semiglutin, and Hemicolline, and the Relation of Collogen to Gelatin," the existence of chondrinogen and chondrine is questioned. It is suggested that

chondrine may be a mixture of gelatin and mucine held in solution by salts.

The memoir on the "Colouring Matter of the Rods and the Cells of the Choroid Coat of the Retina" contains some appropriate remarks on a substance doubtless well known to our readers as visual purple. "Hardly had the presence of a coloured ingredient of the retina sensitive to light been perceived, when we heard at once of a 'photo-chemistry' of the retina, there being in the whole of the observations not a chemical fact, except, perhaps, that the red matter bleaches in light and now and then becomes red again in the dark, and that the red matter is soluble in biliary salts. The enthusiasm extended alike to the terminology, so that a matter of which its discoverer said that 'it is red and not purple' was, in spite of him, named purple, and, thus robed, the sensation was held up to the profession and the public as the discovery of 'seeing matter' or 'visual substance.' The existence of such a visual substance seemed to be pre-determined in the inner consciousness of some physiologists who believe that 'a knowledge of the changes of the visual substances would at once enable us to bridge over the assumed gap between the waves of the luminous ether and the waves of the visual nervous impulses.' But we perceive that there are already so many gaps in the structure of the retina which the luminous and nervous impulses, nevertheless, get over without particular bridges that the gap alluded to does not add much to their difficulties or to the problems to be solved by physiologists. The particular delusion of 'photo chemistry' by means of a 'visual substance' is born out of a particular bias of this photographing age. . . . The discovery of the visual matter had not even the traditional four years' run of most modern physiological discoveries, but perished, mainly by the hands of its author, after a short lived notoriety, and it is now admitted that the presence of this red matter is not essential to even the most accurate vision."

There is something in this quotation which strongly reminds us of the manner in which Prof. Kolbe disposes of speculations whose authors have allowed too loose rein to the imagination.

We much regret that want of space does not allow us to extend any further our notice of this interesting volume.

CHEMICAL NOTICES FROM FOREIGN SOURCES.

NOTE.—All degrees of temperature are Centigrade, unless otherwise expressed.

Comptes Rendus Hebdomadaires des Séances, de l'Académie des Sciences. No. 5, August 1, 1881.

Modification of the Electric Lamp.—M. Jamin.—Inserted at length.

Researches on Perchloric Acid.—M. Berthelot.—A thermo-chemical study. The facts observed explain the differences of stability and activity between pure perchloric acid and the same acid combined with different proportions of water. The author has succeeded in obtaining the mono-hydrated acid in a crystalline form. The heat of solution of the liquid mono-hydrate in 100 parts of water at 19°= +20·3 cals., or more than double that of ordinary mono-hydrated sulphuric acid. This enormous heat of hydration explains the extreme difference between the reactions of this acid diluted with water, when it is almost as stable as dilute sulphuric acid, and the reactions of the mono-hydrated acid which acts with explosive violence upon oxidisable bodies. In dilute solution it is not decomposed by sulphurous, hydrosulphurous, hydriodic acids, sulphuretted hydrogen, free hydrogen, zinc in presence of acids, sodium amalgam in presence of water, either pure, alkaline, or acidulated, or by electrolysis.

Application of Electro-motors and of the Secondary Batteries of M. G. Planté to the Direction of Aërostates.—G. Tissandier.—Not suitable for abstraction.

Wave-lengths of the Spectral Bands given by the Compounds of Carbon.—M. Thollon.—The results are given in a table.

Spectra of the Comets Cruls and Schæberle.—P. Tacchini.—Useless without the diagrams.

Theory of Dissociation: Influence of Pressure.—G. Lemoine.—The author examines mathematically the speed of combination according to the probability of the meeting of the molecules, the dissociation of homogeneous systems, and the influence of pressure upon dissociation, both according to theory and experiment.

Formation-heat of Explosives: Numerical Data.—MM. Sarrau and Vieille.—The determinations given refer to nitro-glycerin, nitro-mannite, gun-cotton, and potassium and ammonium picrates.

Lead, Cadmium, and Mercury Oxycyanides.—M. Joannis.—The author describes the preparation and properties of these compounds.

Combustion-heats of Heptan and Hexa-hydro-toluen.—W. Louguinine.—A thermo-chemical study. The combustion-heat of heptan is at most from 6000 to 8000 cals., and that of hexa-hydro-toluen is 149,000 cals.

The Magnesia Industry.—T. Schlœsing.—The author proposes to obtain magnesia from sea-water by means of lime. After precipitation and settling for a day 1 cubic metre of sea-water yields a gelatinous precipitate of magnesia occupying the bulk of 80 litres. He mixes with his magnesian mud a calculated quantity of phosphoric acid in dilute solution, and thus obtains a precipitate of tribasic magnesian phosphate, which condenses on settling, is capable of filtration through cloth or on the filter-press, and in a few minutes combines with ammonia to form an ammonium-magnesium phosphate.

Colorimetric Determination of Salicylic Acid in Alimentary Substances.—H. Pellet and J. de Grobert.—The authors prepare a series of eight test-tubes, of from 0·20 to 0·22 metre in height, and of 0·015 to 0·018 metre in diameter, into which are put respectively 1 c.c., 0·75 c.c., 0·50 c.c., 0·30 c.c., 0·20 c.c., 0·1 c.c., 0·05 c.c. of a solution of salicylic acid containing 1 grm. per litre. The volume is in each case made up to 10 c.c. with distilled water. Three drops of ferric chloride of from 1·005 to 1·010 sp. gr. are then added to the first tube, two to the second and the third, and one drop to the others, except the last, where it is sufficient to touch the inside of the test-tube with the point of the pipette containing the ferric chloride. An excess of the salt of iron considerably modifies the tint produced. They take then, *e.g.*, 100 c.c. of wine, to which are added 100 c.c. of ether and 5 drops of sulphuric acid at 30° B., to displace the salicylic acid from its combinations. Agitate, let settle, draw off the supernatant ether by means of a pipette. This operation is twice repeated, and the decanted ether is rapidly distilled in the water-bath. The residue is transferred into a porcelain capsule of 0·06 metre in diameter. The retort is washed with a few c.c. of ether, and the whole placed for a few moments on a stove at 35° to 50° to expel the bulk of the ether. Add at most 1·5 c.c. of a solution of caustic soda, of which 10 c.c. = 0·4 grm. NaO. This quantity is capable of saturating 0·2 grm. salicylic acid. It is then evaporated to dryness in the water-bath, when the salicylic acid remains as sodium salicylate. The residue of this second evaporation to dryness is mixed with 5 drops sulphuric acid at 30° B., and 20 c.c. benzol are then added. The whole is poured into a test-tube, shaken, and filtered. Take 10 c.c. of the filtrate and place them in a test-tube of the same size as those containing the colour standards. Add 10 c.c. of distilled water, and one or two drops of dilute ferric chloride, and shake several times. If sali-

cylic acid is present it passes into the lower part of the liquid and occasions a violet colour. The shade obtained is then compared with those of the colour-standards.

Saccharine Matter of Soja Hispida.—A. Levallois.—This sugar approaches in some of its properties to cane sugar, but it agrees with mellitose in producing mucic acid on treatment with nitric acid.

Applications of Electric Motors.—G. Trouvé.—A motor on the author's principle worked by six Planté's secondary elements was placed on a tricycle, the weight of which, including the rider and the batteries, was 160 kilos. The speed produced was 12 kilometres per hour. On June 26 a boat was propelled with this motor on the Upper Lake in the Bois de Boulogne. The speed reached was 3 metres per second, which, after five hours' working, declined to 2·30 metres per second.

No. 7, August 16, 1881.

The Alcamines.—A. Ladenburg.—This name is given by the author to an entire class of bases, which, like atropine, possess the property of becoming etherified in a hydrochloric solution, yielding, like tropine, ethers, which are always bases, and which approach the natural alkaloids, both in their properties and their composition. These new bases fulfil a double function, that of an alcohol and an amine. They are formed by the action of the chlor-hydrides on the secondary amines. The author has prepared and examined piper-ethyl-alcamine, tri-ethyl-alcamine, di-allyl-ethyl-alcamine, di-piper-allyl-alcamine, and piper-propyl-alcamine.

Solubility of Magnesium Carbonate in Water charged with Carbonic Acid.—P. Engel and J. Ville.—The authors give their results in the form of tables.

The Cobaltamines.—M. Porumbaru.—An account of the acid and neutral pyro-phosphates of the roseo-cobaltamines.

Bulletin de la Société Chimique de Paris.
No. 9, May 5, 1881.

A New Eudiometer.—J. Riban.—The apparatus cannot be usefully described without the four accompanying figures.

Attack of Platinum on Exposure to Flame.—A. Rémont.—The carbonaceous deposit formed on platinum after exposure for some time to an oxidation flame, contains an amount of platinum so small that it is generally neglected, when wiping the base of a crucible blackened in the flame before weighing. On calcining 0·022 grm. of a carbonaceous deposit formed on a platinum capsule on exposure for half an hour to a red heat in the upper part of a Bunsen flame, the author obtained 0·01 grm. of the metal. Further experiments showed that the corrosion of the platinum is due not to carbon in suspension, but to one or more of the gaseous elements of the flame.

Spontaneous Oxidation of Mercury and other Metals.—M. Berthelot.—The author finds that perfectly pure, dry mercury, exposed to the air at 10° in a place free from the fumes of the laboratory, and covered with paper to keep off dust, becomes slowly covered with a pellicle of mercurous oxide, which is reproduced if removed. Hence mercury, like iron, zinc, cadmium, lead, copper, and tin, undergoes a superficial oxidation on exposure to the air.

Purification of Carbon Disulphide.—E. Allary.—The author covers the sulphide with a layer of water, to which a solution of permanganate is added frequently in small quantities. Each addition is followed by stirring and is repeated till the supernatant liquid retains its purple colour. The permanganate is then removed by washing and decantation, and freed from water by means of a tap-funnel, and filtered through a dry double filter of Prat-Dumas paper. The purified sulphide must not be exposed to light.

A Solution of Cadmium Tungsto-borate.—D. Klein.—This solution, sp. gr. 3·28, is proposed for effecting the proximate analysis of rocks, as the lighter minerals float and the heavier constituents only sink.

Sodium Tungsto-borate.—D. Klein.—In this paper the author describes the formation of the tungsto-borates.

Action of Phosphorus Perchloride upon Isobutylic Aldehyd.—S. Œconomides.—The principal product of the reaction is isobutylene chloride.

Preparation of Isobutylic Acetal.—S. Œconomides.—This compound is obtained by passing a current of hydrochloric acid gas to saturation into a well-cooled mixture containing equal weights of isobutylic aldehyd and of absolute alcohol. The upper of the two layers formed is a mixture of chlor-ethyline and of isobutylic acetal. This product is mixed with sodium ethylate, and heated for several hours to 100°. Isobutylic acetal is then separated by means of water.

MISCELLANEOUS.

Schools of Chemistry, &c.—The following information was received too late for insertion in our Students' Number:—

Normal School of Science.—Dr. Frankland, F.R.S., is Professor of Chemistry at this Science School, and Dr. Roscoe and Dr. Russell are the Examiners.

Birkbeck Literary and Scientific Institution, Southampton Buildings, Chancery Lane.—The 59th Session of this Institution will commence on Monday next. Evening Classes, which are open to both sexes, are held for the study of Ancient and Modern Languages, Mathematics, Natural, Applied, and Mental Science, Literature, History, Law, Art, Music, &c.; in fact every opportunity is offered at this Institution for students to prepare for any occupation or profession. The fees are very moderate, and the classes meet at hours which are convenient to persons occupied during the day. The 58th Anniversary will be held in December, under the the Presidency of the Earl of Lytton, and the Countess of Lytton has kindly consented to distribute the prizes to the successful candidates of the past session. The committee again appeal for contributions towards the New Building, and, inasmuch as the present Institution is utterly inadequate for the work carried on, it is hoped that the £4000 asked for prior to the laying of the Foundation Stone will be subscribed by those friends of popular education who are anxious to perpetuate and extend the work carried on by this the parent and largest Evening Educational Institution.

Mason Science College, Birmingham.—The Session will commence on Monday, October 3rd.—*Chemistry and Metallurgy.*—Prof. W. A. Tilden, F.R.S., assisted by Mr. W. W. J. Nicol, M.A., and Mr. G. H. Morris, F.C.S. The instruction embraces twenty elementary lectures, about sixty lectures on Inorganic Chemistry, about forty lectures on Organic Chemistry, and a course of about twenty lectures on Metallurgy, with laboratory practice and instruction in both Chemistry and Metallurgy. Excursions are also arranged to some of the great factories in and near Birmingham in which Chemical and Metallurgical industries are carried on. *Physics.*—Prof. J. H. Poynting, M.A., assisted by Mr. J. H. Riley. The complete course in Physics extends over three years, and consists of lectures and laboratory instruction and practice. In the lecture classes examples will be set to be worked out of class. Further particulars as to fees, &c., can be obtained in the College "Calendar," published by Cornish Bros., New Street, Birmingham.

College of Science and Arts, Glasgow.—Lecturer on Chemistry, Mr. R. R. Tatlock, F.R.S.E., F.C.S., &c., assisted by Mr. J. Clark, Ph.D., F.C.S. The course will

consist of twenty-eight lectures, extending over seven months, commencing with an introductory lecture (free) on Friday evening, October 7th. Fee, for private students, 5s.; for students going in for Science and Art Examinations in May, 5s. Practical Classes: Elementary, Thursday; Advanced, Tuesday—Fee, £3 3s. Lectures on Magnetism and Electricity by the Principal, Mr. Andrew Jamieson, C.E., on Tuesday evenings. Fees as for chemical lectures.

COLLEGE OF AGRICULTURE, DOWNTON, SALISBURY.—Chemical Department.—*Professor*, J. M. H. Munro, D.Sc. Lond., F.C.S. Courses of lectures are given on Inorganic and Organic Chemistry, with special reference to their bearing on Agricultural Chemistry. The chemistry of the soil and the atmosphere, of plant and animal life, of manures, feeding-stuffs, farm and dairy products, are fully dealt with. The laboratory course consists of three sections, dealing respectively with chemical manipulation, qualitative analysis, and quantitative analysis, and is based on the system laid down by Professor A. H. Church, M.A., F.C S., F.I.C., in his "Laboratory Guide."

WESLEY COLLEGE, SHEFFIELD.—Mr. A. H. Allen, F.C.S., gives lectures and lessons in Chemistry. The Rev. W. H. Dallinger, F.R.S., gives lectures and demonstrations in Biology, Palæontology, and Geology.

London: SIMPKIN & CO.

TENDERS FOR SULPHURIC ACID.

The Directors of the Bath Gas Light and Coke Company are prepared to receive Tenders for the supply and delivery at their Works by Midland Railway of about 300 Tons of Sulphuric Acid in the year from 1st of November next; delivery to be made in such quantities and at such times as may be directed.

Particulars, with form of Tender, may be had upon application.

Tenders, endorsed "Tender for Acid," to be sent in on or before the 18th of October next.

The Directors do not bind themselves to accept the lowest or any Tender.—By order,

GEORGE HELPS, Secretary.

Gas Works, Bath, Sept. 23, 1881.

LIVERPOOL COLLEGE OF CHEMISTRY.
DUKE STREET.

The Day Courses will commence on October 7th. The Evening Courses on Chemistry and Physics, Mineralogy and Geology, on the 3rd, 4th, and 6th respectively. For full prospectuses of courses apply to Dr. GEO. TATE or Mr. GRANVILLE H. SHARPE.

NORMAL SCHOOL OF SCIENCE and ROYAL SCHOOL OF MINES,
SOUTH KENSINGTON, and JERMYN STREET.

The School will open on MONDAY, 3rd OCTOBER. The Prospectus may be obtained on application by letter to the Secretary, Science and Art Department, South Kensington, S.W.

THE LONDON HOSPITAL & MEDICAL COLLEGE, MILE END, E.

The SESSION 1881-2 will commence on SATURDAY, OCTOBER 1st, 1881. Four entrance Scholarships, value £60, £40, £30, and £20, will be offered for competition at the end of September to new Students. Entries on or before September 20th. Fees for Lectures and Hospital Practice 90 guineas in one payment, or 100 guineas in three instalments. All resident and other hospital appointments are free. The resident appointments consist of Five House Physiciancies, Four House Surgeoncies, and One Accoucheurship; Two Dressers and Two Maternity Pupils also reside in the Hospital. Special entries may be made for Medical and Surgical practice. The London Hospital is now in direct communication by rail and tram with all parts of the metropolis.

MUNRO SCOTT, Warden.

METALLURGICAL LABORATORY,
KING'S COLLEGE, STRAND, LONDON,
Under the direction of Prof. A. K. HUNTINGTON.

Methods of extracting Metals from their Ores.—Assaying and Mineral Analysis.—Refractory Materials.—The relation between the Mechanical and Chemical Properties of Metals and Alloys, studied with the aid of Testing Machinery.—Electro-Metallurgy, &c.

Laboratory open every day from October 1st, and on Friday evenings from October 14th. It is optional to attend the Laboratory during any portion of a week.

BERNERS COLLEGE of CHEMISTRY.

Instruction and preparation in CHEMISTRY and the EXPERIMENTAL SCIENCES under the direction of Professor E. V. GARDNER, F.A.S., M.S.A.

The Class Rooms are open from 11 to 5 a.m. and from 7 to 10 p.m daily.

Especial facilities for persons preparing for Government and other examinations.

Private Pupils will find every convenience.

Analyses, Assays, and Practical Investigations conducted with Patents, &c., conducted.

Prospectuses and full particulars on application to Prof. Gardner at Berners College, 44, Berners-street W.

SOUTH LONDON SCHOOL OF CHEMISTRY.

VACATION ARRANGEMENTS.

Gentlemen can be privately instructed in any branch of Practical Chemistry during the months of July, August and September. Those desirous of working out any Research or Patent (with or without advice) can secure a Private Laboratory to themselves.—For terms apply to W. BAXTER, Secretary, South London Central Public Laboratory, Kennington Cross, S.E

THE MASON SCIENCE COLLEGE,
BIRMINGHAM.

SESSION 1881-82.

I. DEPARTMENT OF SCIENCE AND ARTS.

The Session will commence on Monday, the 3rd of October, 1881.

Students under sixteen years of age will be required to pass a preliminary examination.

II. EVENING CLASSES.

These will commence on Wednesday, the 5th of October, 1881.

The Calendar of the ensuing Session, containing full information as to the aim and objects of the College and the courses of instruction, is now ready, and may be obtained from the publishers, Messrs. Cornish Brothers, Birmingham and Manchester, price 1s.

GEO. H. MORLEY, Secretary.

HENRY WIGGIN & CO.,
NICKEL AND COBALT REFINERS,
BIRMINGHAM.

Patentees and Manufacturers of Rolled Nickel Anodes for Electro-Nickel-Plating.

Malleable Nickel Sheets, Grain and Cube Nickel, German Silver, and other Nickel Alloys, Oxides of Cobalt, &c.

THE CHEMICAL NEWS.

VOL. XLIV. No. 1141.

MINERALOGICAL NOTES.*

By B. SILLIMAN.

I. VANADINITE AND OTHER VANADATES, WULFENITE CROCOITE, VAUQUELINITE, &c., FROM ARIZONA.

I HERE record the discovery of two important and very interesting mineral localities, or districts, in the Territory of Arizona, from one of which I have obtained vanadinite of remarkable beauty of colour and perfection of crystalline form, associated with almost equally beautiful wulfenite of an orange-red colour: and from the other, four (perhaps more than four) species containing vanadium. The last named district has also furnished crocoite and vauquelinite never found before, I believe, in North America.

I am greatly indebted to my faithful and intelligent correspondent, Mr. George A. Treadwell, of Vulture, Arizona, for sending me, for some years past, a great number of minerals and ores collected by him in that Territory, among which are those now to be described. I mention also with pleasure the aid afforded me by Mr. Edward Farley, of Wickenburg, owner of several interesting veins, and Dr. Jones, of Phœnix. Mr. F. F. Thomas, lately in charge of Silverlead Furnaces, near Silent in Arizona, and Mr. John McDougal, Superintendent of Mines, have also contributed important data in extending our knowledge of that interesting Territory.

Vanadinite.—This hitherto rare species promises now to be comparatively abundant. In the so-called "Silver District," in Yuma County, Arizona, about fifty miles north of Fort Yuma, is a large area traversed by veins of quartz carrying argentiferous galena, with salts of lead, but no gold, and rather extensively explored. The lead salts which I have seen from this region are wulfenite, of remarkable beauty, vanadinite, and massive anglesite with galenite. Vanadinite occurs in three mines, near together the "Hamburg," the "Princess" and the "Red Cloud." The crystals of vanadinite are extremely beautiful, alike for billiancy of colour, lustre, and perfection of form. Only a single vanadate appears to occur in the Silver District; but there may be an exception to this remark, since a greenish yellow incrustation on one specimen may turn out to be volborthite or one of the other amorphous vanadium minerals. All the veins of this district occur, as I am informed by Mr. Thomas, between a foot-wall of granite and a hanging-wall of porphyry, specimens of which rocks I have in hand. The foot-wall of granite is somewhat irregular, but the porphyritic hanging-wall is well defined. I have not yet made sections of the latter rock; it closely resembles the augite trachytes of Nevada and elsewhere, the usual associates of silver ores the world over. All these lodes abound in calcareous matter, but there are no limestone beds in the vicinity; and in the absence of any organic remains, we are ignorant of the probable geological horizon.

"The Hamburg" mine has furnished the most numerous and, on the whole, the best specimens of vanadinite. The crystals vary in colour from deep orange-red—deeper than potassium bichromate, but not ruby—through lighter shades of orange-red to reddish-yellow and brown. They are always highly lustrous. The size is small, the length being not over two millimetres and usually less than one; and the diameter about half the length to equal dimensions. The hexagonal prisms are modified usually by one, sometimes by two, planes on each terminal edge, and occasionally the angles are replaced. These crystals are implanted singly and in crusts on a dark chocolate-coloured siliceous gangue, with occasional obscure crystals of cerussite, and rarely a dark-coloured cleavable lime-rock (impure calcite). The "Red Cloud" mine furnishes vanadinite of a rich orange-red or flame-colour, associated with beautiful orange-red wulfenite. At the depth of 280 feet, measured on the slope of the vein, wulfenite takes the place of vanadinite almost to its exclusion. The crystals of vanadinite at this mine are smaller and grouped in more confused masses than at the Hamburg mine.

At the "Princess" mine, the vanadinite occurs in slender crystals of a brilliant red colour almost identical with that of crocoite, implanted upon white calcite. The habit of the species is unlike either of those before mentioned; the crystals are at least four diameters long and are very slightly modified. They are not over half a millimetre in diameter, but are very perfect in form, lustre, and colour. They have, naturally enough, been mistaken for chromate of lead.

The genesis of the vanadates of these mines is obscure. A single small specimen only of the galena has reached me. It forms the nucleus of a surrounding mass of amorphous anglesite, upon the outer surface of which appear obscure crusts of vanadinite. Analyses of a series of samples selected on the spot, by a careful examination might reveal the origin of the vanadic acid.

Vulture District, as I have called it, another and quite distinct district in Arizona, has furnished at a number of places vanadinite with other rare species. This area embraces the country between the Hassayampa River on the west and Agua Fria on the east, and extends in a north and south direction from the well known Vulture Mine to Antelope Mountains, Weaver district, on the road to Prescott. It is partly in the lower portion of Yavapai County, and partly in the northern portion of Maricopa County. Within this area are numerous veins of gold-bearing quartz carrying lead and sometimes a little copper or perhaps both at the same time. I have become familiar with the mineralogical character of these veins through Mr. G. A. Treadwell; and Mr. Edward Farley, owner of some of the mines which have furnished the most interesting species of this area, has prepared for me a sketch map on which the localities are laid down with sufficient accuracy for identification by reference to the Government map.

Farley's "Collateral Mine," about twenty miles north-east of Vulture, is perhaps the most interesting locality of vanadinite in this area. The vein is about four and a half feet wide, and occurs in soft grey talcose rock. About one-half of the thickness of the vein, on the hanging wall side, is quartz stained green with chrysocolla, and chocolate-brown with a ground mass which I find carries vanadium, and showing lemon-yellow stains resembling plumbic ochre, also a vanadate. Any portion of these yellow and brown masses (if pulverised, digested with dilute nitric acid, and the filtrate treated with ether) gives a strong reaction for vanadic acid. Unless led to test this gangue-stone for vanadium by the occurrence of vanadinite in other parts of the vein, no suspicion of its presence would be aroused. A seam of very red ferric oxide with calcite follows next, and the red oxide of iron reacts decidedly for vanadium, while the calcite is penetrated with yellowish and white fibrous crystals of vanadinite. Next, there is a seam, of about six inches, of very soft material filled with abundant lemon-yellow acicular crystals of vanadinite in tufts and aggregated masses, the whole quite friable, forming the centre of the vein, which also carries in this zone masses of cerussite. The whole mass of this soft material reacts very strongly for vanadic acid. Then follow on the foot wall, about twenty inches of vein-matter composed of quartz with calcite. The calcite is penetrated with acicular crystals of vanadinite arranged in threads and in stellar tufts, usually not over a line in thickness, but

* Communicated by the Author. From advance sheets of the September number of *Silliman's Journal of Science.*

occasionally opening into small cavities, like geodes, lined with distinct hexagonal prisms of this species. The common colour is yellow, but they are often nearly white. The cleavage fragments of calcite carrying the vanadium crystals form specimens of rare beauty. Quartz, similar to that in the upper section of the vein, is found in this lower member, and this is also somewhat stained with copper silicates. In its open joints occur hexagonal crystals of vanadinite of a fine yellow colour; they closely resemble mimetite, but give no arsenical reaction, and I failed to obtain a trace of arsenic from the included crystals in the calcite, when tested by soda and potassium cyanide in the closed tube. This quartz carries crystals of vanadinite in habit very unlike those which occur at the Hamburg mine in the Yuma district; they are long, slender needles, hardly a line in thickness, of a delicate straw-yellow colour, quite transparent. They are associated with others of a rich orange-yellow colour and not so well defined. There are also confused tufts of crystals of the same species, not thicker than hairs, of a pure chrome-yellow colour, implanted in cavities in the red iron-stained gangue.

Descloizite (?)—A mineral which may prove to be descloizite occurs among the ores of the Collateral Mine which have reached me. It is found in blue-black and brownish-black semi-transparent and very brilliant crusts, the individuals imperfectly developed, hardness about 3—3·5, streak, yellow to brownish-yellow. Alone in the closed tube it fuses and gives off abundant water. It reacts very strongly for vanadium and for lead, also for copper, manganese, and zinc. Since this paper was in hand I have received from Mr. Farley, under date of June 25th, additional specimens of this mineral not only from the "Collateral" but also from the "Chromate" veins near the former, on one of which are seen very well defined, but very small tabular crystals, the study of which will probably show them to be the species indicated. They resemble some of the forms figured by Websky from La Plata, province of Cordoba.* We must await the arrival of more specimens before the study of this interesting mineral can be completed.

Volborthite (?)—A single well characterised specimen provisionally referred to this species came among the products of the Collateral Mines. It exists in small botryoidal masses adhering to the polished faces of deep red quartz crystals. The streak is bright yellow. In thin scales the mineral is transparent and of a clear olive-green. The lustre is vitreous and dull. No crystals were detected. Alone in the matrass it fuses readily, adhering to the glass. It gives off no water and dissolves in dilute hydrochloric acid to a greenish solution, from which alcohol throws down the lead in tufts of plumbic chloride. On charcoal it fuses to a black shining bead, which alone gives off lead fumes, and copper appears on crushing the bead in the agate mortar. With soda it gives a globule of lead enclosing one of copper. Zinc oxide stains the coal when the assay is gently heated. It may be that it will turn out to be a new species.

An anhydrous crypto-crystalline mineral containing vanadium occurs among the "Collateral" ores. It varies in colour from light yellow-brown to black-brown; gives the reactions for Domeyko's *chileite*, but it is not a clay-like mineral. It yields readily a globule of lead containing a nucleus of copper. No arsenic was found. It occurs also in the "Chromate" vein.

Gold in coarse crystalline grains occurs in the quartz of the "Collateral" vein.

The Phœnix Mine, one mile east of the mine last named, furnishes specimens similar to those just described. The vanadinite is light yellow and deep orange-yellow to reddish, in large well-formed crystals, which react for chlorine but not for arsenic. The gangue is quartz, which carries gold but no calcite in the samples which have reached me.

Among the specimens sent to me by Mr. Farley on the 25th of June, which I have just examined, I find crystals of vanadinite in the gangue of both the "Collateral" and the "Chromate" veins, quite unlike those before described and very closely resembling in habit, colour, and form the brilliant red crystals from the Hamburg mine in the Yuma Silver District.

The Montezuma lead mine, eleven miles east of Vulture and south-west of Collateral, abounds in vanadinite which occurs in drusy crusts of a rich deep yellow and brown colour on masses of cerussite. Observed with a lens these crusts are seen to be well defined hexagonal prisms. It appears to be an abundant source for the supply of vanadium.

At "the Frenchman's Mine," a gold bearing vein, of about 18 inches thickness, consists of deeply iron-stained quartz, showing amorphous yellow-green masses of a mineral very rich in vanadic acid, and reacting for lead, copper, and chlorine. It is also hydrous. It may perhaps be *mottramite*. There is a buff-coloured amorphous substance with it also rich in vanadinite. Calcite occurs in the gangue.

There are localities in this district in which vanadium is found, but the foregoing will suffice.

Mimetite occurs in considerable masses north of Domingo mine on Castle Creek in the extreme north-west of the Vulture District, as here described. I have seen only a single mass of about 80 grms. found by Mr. Farley. It was without gangue or associated species, and quite amorphous.

From "Bethesda Mine," in Los Cerillos, New Mexico, I collected in April, 1880, specimens showing greenish crusts of vanadinite in botryoidal forms and sometimes nearly black. It is there associated with wulfenite and cerussite. This vein is the southerly extension of the "Mina del Tiro," worked by Mexicans of old.

It is interesting to note the wide area over which this species is now known to exist, compared to the single locality at Zimpan, in Mexico, where Del Rio in 1803 first identified it. No doubt it will be found in equal or yet greater abundance at other localities as the work of exploration goes on. Many years since, in a paper on the Mineralogy of the Wahsatch and other Utah ranges of mountains,* I called attention to the occurrence of the molybdate of lead (wulfenite), as replacing the phosphate (pyromorphite) among the salts of lead, the latter being rarely if ever found there. Subsequently the wulfenite of Tecoma and of Eureka, in Nevada, confirmed this generalisation, and I have since had very frequent occasion to notice the wide distribution of wulfenite in New Mexico and Arizona. We may now add vanadic acid as having the same wide distribution.

Wulfenite crystals of rare beauty are found in the "Red Cloud" Mine, already mentioned as furnishing the vanadinite. The specimens sent me are from a depth of about 300 feet. They show very solid tabular crystals of large size, brilliant lustre, and rich orange-yellow to orange-red colour. The colour at once suggests the presence of vanadic acid, like the well-known specimens from Wheatley Mines as detected by Smith. But I have not found a trace of vanadic acid in these Red Cloud or other Arizona wulfenites. From the "Melissa Mine" in Silver District adjacent to the Red Cloud, wulfenite is found in octagonal prismatic forms, the basal plane being almost wanting in some specimens, giving them the appearance of simple octahedrons. This interesting form I believe has not been before observed in any American locality. The colour of the species at this locality is pure orange-red; the gangue is brown, almost black, calcite. The "Rover" is another mine of the same district which furnishes wulfenite nearly identical in form with the Red Cloud specimens, but of a little lighter orange-red colour.

Crocoite-group.—Three if not four of the species of this group occur among the ores of the Vulture region, and especially in the "Collateral" and "Chromate" veins. These two veins together with the "Blue Jay" and the "Phœnix mine" form a group of singular mineralogical interest, furnishing, among more common minerals, the

* *Monatsbericht der Akad. zu Berlin*, July, 1880, 672.

* *Am. Journ. Sci.*, III., iii., 195.

species crocoite, phœnicochroite, vauquelinite, joassite (?), vanadinite, volborthite (?), Descloizite (?), Chileite (?), wulfenite. *Vauquelinite* occurs quite abundantly associated with galenite and crocoite in a gold quartz gangue or vein stone. The genesis of the chromate is very manifest. The nucleus of unaltered galenite is surrounded with a bright pea-green and apple-green areola of vauquelinite, sometimes semi-transparent, and uncrystalline. This green mass is succeeded by crystalline and transparent crocoite of orange-red and cinnabar-red colour, giving the familiar scarlet and chrome-yellow streak. The crocoite as yet has not been found well crystallised. Besides the associated species already named, occur cerussite, gold, and magnetite. The magnetic sand collected in washing the gold out of the crushed vein stone was examined for chromite without success.

It is an interesting question, whence came the chromic acid? Perhaps an analysis of the galenite may detect chromium in that species. Smith has described a meteoric chromium sulphide, Daubréelite,* and there is no chemical reason why this species may not coexist with galenite. In the paragenesis of the chromates in this district the change has evidently proceeded from without inwards, and the occurrence of specimens in which the whole of the galenite is transformed is not unfrequent, as also the change of the crocoite to the lemon-yellow phœnicochroite.

Small orange-yellow crystals occur in the vauquelinite of the Vulture region, which may be the *joassite*; but more study is required before they can be proved to be this mineral.

In conclusion, I will add that before the study of these interesting localities can be complete a personal visit must be made by a mineralogist to the mines, and sufficient material obtained on the spot to allow of chemical analyses.

2. Thenardite from Rio Verde Arizona Territory.

Some months since I received a lump of a saline minera marked "Salt," reported by my informent, Mr. Treadwell, of Phœnix, to occur in abundance on the River Verde, in Maricopa County. It proved, on examination, to be anhydrous sodium sulphate or *thenardite*, a species which has hitherto been found in very limited quantity. In an analysis in the Sheffield laboratory under the supervision of Prof. O. D. Allen, by Dr. Geo. M. Dunham, its constitution was found to be as follows:—

	I.	II.
Chlorine	0·095	0·097
SO_3	56·410	56·310
CaO	0·120	0·130
MgO	0·021	0·023
Na_2O	[42·964]	[43·070]
Insoluble	0·390	0·370
	100·000	100·000

I. $Na_2O : SO_3 = 6·91 : 7·02$; II. $Na_2O : SO_3 = 6·93 : 7·01$.

The mineral is therefore nearly pure Na_2SO_4. The insoluble matter out, the impurities are only 0·24 per cent of the mass.

The specific gravity of a fragment quite free from visible impurity, taken in petroleum, I find to be 2·681. This mineral occurs in large masses, some of which, in the rough, are distinctly crystals with imperfect faces, showing eminent cleavage in the direction of the basal plane of the prism and a hackly cleavage in the opposite direction. The "insoluble" matter (=0·38 per cent) in the mineral—chiefly clay, gives it a prevailing shade of yellowish grey. Its hardness is below that of calcite; lustre vitreous; fracture conchoidal to hackly.

Occurring in an almost rainless country, it has suffered little change, small portions only at surface being altered to a dry white powder of exanthalose, $Na_2SO_4.2H_2O$.

As this is, so far as known, the only locality of this species where it exists in great abundance, I have taken steps to secure all the information available respecting it. Mr. Thos. F. Hopkins, of Vulture, Arizona, has forwarded to me the following statement, which I present in his own words, in a letter dated—

"Vulture Mine, A.T., June 18, 1881.

"Mr. Boyd, a resident of the Verde Valley during the past five years, is quite familiar with the large thenardite deposit, and furnishes the following details.

"The 'Salt Mine,' as it is popularly called, is situated about two and a half miles south-west of Fort Verde (the present post), on the west side of the Verde River. Squaw Peak is distant eight miles from Fort Verde, and this mine lies between these two points.

"It occurs on a 'bench' about fifty or sixty feet above the Verde River, and itself forms one of a series of benches gradually sloping toward the river. The deposit crops out boldly in the face of the bank, and seems to extend along a distance of from eight hundred to one thousand feet. It occurs in a white chalky-looking formation, and the surface opening is probably about ten feet wide. From this opening immense masses have been carried away during more than five years past, every rancher of the district taking off huge wagon loads for the use of his stock, &c. The deposit is solid, and is removed by blasting. It is not under water at any time, for both its sloping situation and its elevation above the river forbid such a condition.

"No systematic openings of the deposit have ever been made, and hence its extent is not known. It is simply 'gouged out' according to the whim and convenience of each new comer; but it seems practically inexhaustible."

I am informed by several persons who have seen this thenardite used for the salting of cattle—among them my friend Mr. James Douglass Junr., who was recently in that portion of Arizona—that the animals resort to it very freely, licking it as they are wont to do common salt, and with only good results.

Thenardite has been found in Nevada and elsewhere in the arid regions of the West Coast, but not before in sufficient quantity to be of commercial importance.

G. Vom Rath (*Zeitsch. f. Kryst.*,) lately names Lake Balschasch in Central Asia as a locality the flat shores of which furnish *thenardite* in very considerable quantity.

On the

COLORIMETRICAL ESTIMATION OF CARBON IN IRON.

By Prof. EGGERTZ.

In the working out of this method as described in the *Jern Kontorets Annaler*, 1862, p. 54, with some additions made in 1874, p. 176, I believed that the amount of carbon estimated with an accuracy of about 0·1 per cent, would fulfil all practical purposes; but claims upon it have afterwards arisen, and it seems now to require an exactness of a little more than 0·01 per cent.

Meanwhile the iron sent out in commerce is usually stamped with only whole and half-tenths of the percentage of carbon, and it is specially for the softest kinds of iron, with carbon between 0·1 and 0·25 per cent, which appears to claim a greater precision in carbon estimation.

When pure ferric hydrate free from chlorine, containing 0·1 grm. iron, is dissolved in 2·5 c.c. nitric acid, free from chlorine, and 1·2 sp. gr., a yellow green solution is got, when, put into a burette as commonly used for colorimetric carbon testing, about 12 m.m. diameter, and a further addition of 1·5 c.c. nitric acid made, it clears somewhat, but not so much as when water is added instead of nitric acid. The warm solution has a much stronger colour than the cold. Add afterwards in both cases 4 c.c. water, so that the volume of the solution amounts to 8 c.c. Note now that the iron colour has gone. It

follows, as a rule in colorimetric carbon testing, that the iron solution is to be diluted with at *least* the same quantity of water as of nitric acid used for solution, also that the volume of the solution never ought to exceed 8 c.c. when the colour is read off.

The nitric acid as well as the diluting water ought to be free from chlorine or hydrochloric acid. Whenever a very slight trace of such is present it communicates to the iron solution a yellowish colour.* The quantity of nitric acid required for solution is regulated to a certain degree by the supposed amount of carbon in the iron. Thus, employ for solution of iron with a lower amount of carbon than 0·25 per cent, only 2·5 c.c. nitric acid, with carbon of 0·3 per cent use 3 c.c., with carbon 0·5 per cent use 3·5 c.c., and for carbon 0·8 per cent use 4 c.c. nitric acid. For steel with a greater amount of carbon take 5 c.c. nitric acid, as also for white cast-iron, but only 0·05 grm. of it should be weighed, with great accuracy.

When the amount of carbon is altogether unknown, begin with 2·5 c.c. nitric acid, and afterwards add more as soon as the colour of the solution, or the amount of separated carbon, shows that more acid is required. A little more acid than here given does no harm, only afterwards add at least the same volume of water, and for white cast-iron 7 c.c. may be taken to prevent the quick precipitation of a humus-like substance after dilution. If too little acid has been used, the solution will have too deep a shade. For example, if steel of 0·8 per cent carbon is dissolved in only 2·5 c.c. nitric acid, instead of 4 c.c., the colour of the solution after dilution will correspond with that of a steel containing about 0·9 per cent carbon.

The iron to be tested must be finely divided either by filing by means of a clean and sharp file;† or, better, by boreing or planing by means of a steel edge, for which an old three-cornered file can be adapted by grinding off the teeth, and furnishing with a handle at each end; or, if very hard, crush the iron in a steel mortar.

For solution of the iron use test-tubes of about 15 m.m. diameter and 120 m.m. long; dry with clean clippings of filter-paper thickly rolled together. Transfer into the test-tube from the weighing scoop with the help of a hair pencil the accurately weighed amount of iron, 0·1 grm., or, if white cast-iron, 0·05 grm.; then add 2·5 c.c. or more nitric acid of 1·2 sp. gr., and free from chlorine. The measuring of the acid can be best done by means of a small pipette, 10 m.m. diameter, graduated to whole and half cubic centimetres. The test-tube is covered with a small watch-glass (23 m.m. diameter), and it is now placed into a cylindrical copper dish, 100 m.m. deep, and at least 120 m.m. diameter; upon this is placed a copper lid furnished with a thermometer tube hole, and holes for the test-tubes, marked with numbers. The dish is previously provided with water, also some grammes of paraffin wax to hinder evaporation. Heat up the dish over a gas or spirit flame to 80°, and maintain at this temperature the whole time. Shake the tube while the iron is dissolving. Solution is ended when no gas bubbles are evolved; this may require one and a half to two hours, or sometimes more, according to the amount of carbon in the iron.

This has been the ordinary method followed hitherto, but experience has shown that the maintaining of the temperature of 80° demanded attention which could by no means be always given. It was also of less consequence whether or no a normal solution was dissolved every time in the same manner as the iron whose carbon contents was to be estimated. But if this is to be avoided, and unchangeable normal solutions used as described under, the solution must he always made at the same temperature, and to this end it is safer to place the test-tube in boiling water. By this method the time for solution is shortened to about three-quarters of an hour, and the colour of the solution will be a little stronger than by dissolving at 80°. If an occasional necessity calls for still greater speed, the solution can be made in about a quarter of an hour by means of gentle boiling over a lamp flame, between which and the test-tube a suitable brass wire gauze is placed, on which the tube may rest, but the colour of this solution will commonly be a little darker than when using the temperature of 100°. The reason for employing 80° instead of 100° was, that at the latter temperature a reddish yellow sublimate-like film was obtained in the tube, which afterwards came into the solution and made it dim. When such happens, try to dissolve the film in the solution by violent shaking, and if this is not successful, filter it off. The film is composed only of nitric acid and ferric oxide, as it appears in heating pure ferric hydrate in nitric acid.

As soon as all evolution of gas ceases, take out the test-tube and place in a beaker with water to cool, when it ought to be covered with a cap of pasteboard to protect it from daylight, by which the solution is soon bleached. When protected from light in this manner the solution maintains its colour for several days. The burettes employed for carbon estimations ought to have a volume of 30 c.c., and be graduated in 1-10th c.c. also, furnished with an opening and spout. The solution is then placed in the burette, which may be done through the filter. If the solution is not clear, or graphite is present, at least an equal amount of distilled water (including the wash-water from the test-tube used for boiling) must be added to the nitric acid used, and the volume made up to at least 8 c.c. before comparison with the normal solution. The normal steel is prepared in like manner, and diluted with so much water that every c.c. of it corresponds to 0·1 per cent carbon; this can afterwards, by careful dilution with water, be made of such strength that every c.c. corresponds to 0·05, 0·02, 0·01, or 0·005 per cent carbon in 0·1 grm. iron. From normal steel with, for example, 0·80 per cent carbon, dissolve 0·1 grm. in 4 c.c. nitric acid, and dilute with water to 8 c.c. Mix carefully after every dilution, because the lower strata of the solution will otherwise be of too deep a colour. Before reading off (which is done from the upper edge of the solution) allow it at least one minute to flow down from the sides of the burette.

The above-named special normal solutions can be marked and employed as follows:—

	Carbon per cent per c.c. of 0·1 grm. Iron.	Used for Iron with Carbon per cent.
Normal ..	0·10	0·8 and higher
½ N ..	0·05	0·4 to 0·8
1-5th N ..	0·02	0·16 to 0·5
1-10th N ..	0·01	0·08 to 0·25
1-20th N ..	0·005	0·04 to 0·08

The lowest amount of carbon found in any iron is 0·04 per cent,* and in employing the last-named normal solution, good daylight is required; this is also best for all colorimetric testing.

Greater dilution than twenty times cannot be used in common burettes of about 12 m.m. diameter, but by using tubes of 24 m.m. diameter, the difference is well marked between a forty times diluted normal solution and distilled water, and in this way approximate estimations ought to be made of carbon in iron of about 0·02 per cent in the case of iron so poor in carbon being produced. Measure in a small pipette 1 c.c. normal solution, dilute to 40 c.c. corresponding to 0·0025 per cent carbon per c.c.; introduce this into a 24 m m. test-tube, which accurately agrees with another graduated tube, in which 0·4 grm. iron is dissolved in 10 c.c. nitric acid, and diluted with

* Only 0·0001 grm. chlorine in a solution of 0·1 grm. iron from ferric hydrate in 2·5 c.c. nitric acid produces a decided yellow colour. Dilute this solution with 1·5 c.c. nitric acid and 4 c.c. water, the colour is still observed, but less in proportion as the solution is diluted.

† Through the wearing of the file the amount of carbon in the iron can be considerably increased.

* By means of the iodine method, in a sample of 8 grms. of Lancashire hearth iron, 0·038 per cent carbon was obtained.

water first to 32 c.c., and then, further, till their colours agree. Should such happen, for example, when the volume of the solution is 35 c.c., the amount of carbon in the iron will be $0{\cdot}0025 \times 35 : 4 = 0{\cdot}022$ per cent.

In comparing the solutions with each other by the method hitherto commonly used, in which a thin paper-filter is held behind the tube, it has been seen that much depends on the distribution of the light in the apartment, and that a room with only one window is best. Before most eyes it is seen, however, that the tube held on the right is a little weaker in colour than that placed on the left; therefore, as also prescribed from the first, the burette containing the assay should always be held in like manner, or to the right. That we may be more independent on the nature of the room, and equalise the difference in colour caused by placing the tubes to the right or left, I have with great advantage now begun to use a little camera in which the tubes are placed. This is made of deal 6 m.m. thick, in the form of a box open in both ends, blackened inside. The height inside is 80 m.m., the breadth in front 26 m.m., at the back 120 m.m. The front of the upper side is cut out to insert the tubes, and these are kept in their places by means of a brass wire fixed in the upper front edge; also by a little trough of sheet copper on the lower outer edge. The opening is covered with a thin filter-paper fastened with a pin.* The burette and test-tube must in respect to the quality of the glass agree exactly in colour, and be dried outside with clean cloth before placing in the camera.

As normal steel and normal iron, two sorts made by the Bessemer process have been used lately, one adopted with 0·80 and the other with 0·16 per cent carbon. The size is 12 m.m. square, and testing shavings are always taken at right angles to its length. The carbon has been estimated by the iodine method as described in *Jern Kontorets Annaler*, 1862, p. 47, and 5 grms. taken for every testing. From this steel three estimations gave 0·79, 0·80, and 0·82 per cent carbon, and from the iron 0·16 was obtained in two closely-agreeing estimations. These carbon estimations have also agreed with the combustion analyses executed by Dr. A. Tamm in iron and steel with the nearest comparable amounts of carbon, as mentioned in the *Jern Kontorets Annaler*, 1874. Instead of immediately employing iodine, as was done at first, and in view of the difficulty of obtaining it pure, for these estimations iodine dissolved in iodide of iron has been used. This solution is prepared by adding to a solution of 10 grms. of iron in 50 grms. iodine, further 50 grms. iodine, in which it is quickly dissolved, then filter the solution into a measure, pass water through the filter till the volume is 100 c.c. One gramme iron requires 10 c.c. of this solution. In consequence of the loss of weight in treating filter-paper with acids, platinum filters have been used to take up the carbon mass; but it is difficult to obtain them good. It appears that inconvenience is removed by using filter-paper treated with hydrochloric acid and hydrofluoric acid (see *Fresenius Zeitschrift*, 1879. p. 582), by which the inorganic components are nearly completely extracted. One of these filters 60 m.m. diameter gave less than 0·0001 grm. ash. Drying of the carbon mass is safest done in a water-bath at a temperature of 95° to 98°, wherein the crucible is placed in a test-tube of about 130 m.m. long and 35 m.m. diameter; the open end is closed with a cork through which passes a thermometer. By means of a bent brass wire the crucible can be inserted and drawn out.

With white cast-iron the colorimetric method has given better results than could at first be expected (see *Jern Kontorets Annaler*, 1874. p. 177), when only 0·05 is taken for testing, yet the solution must be diluted to a larger volume, whereby a little error in observation in respect to the colour will have a great influence. These solutions ought to be quickly read off, because they soon become a little dim from a humus-like substance which precipitates. By using for solution 7 instead of 5 c.c. nitric acid this inconvenience is lessened.

The different nature of the carbon, such as the so-called cement carbon, and hardening carbon has not made itself known in any other way in colorimetric testing than that the colour of the solution of the latter is less than the former, so that a steel of 0·8 per cent carbon, after strongly hardening and pulverising, gives only 0·55 per cent. After heating the hardened steel to a brown heat, the original amount of carbon is again found. By the iodine process on 5 grms. of the hardened steel 0·8 per cent carbon was obtained. Iron with 0·3 per cent carbon, reduced by cold hammering from 12 to 6 m.m. thickness, showed the same amount of carbon.

During solution the various sorts of iron behaves with so wide a difference that the solution will sometimes be coloured instantly, at other times only after a little warming. The final colour after dilution with water will usually agree very well with the colour of the normal solution. Should any little inequality of colour remain (such as approaching to yellow or brown) less regard ought to be fixed on it than on the intensity of the colour, or on the distinctness with which the small inequalities in the paper held behind the test-tubes can be seen. From the nature of the case it follows that individuals with more or less good eyesight are found to perform these tests with more or less sharpness, but experience has also shown that the ability to see in this respect can be considerably improved by practice, and at most only few persons have found it impossible to do this work.

With reference to the presence of foreign substances in iron, and their influence upon the colour of the solution the following experiments have been made:—

Manganese, 0·05 grm., in the form of carbonate, dissolved in 2·5 and in 5 c.c. nitric acid with a brown colour, from the presence of a little manganese oxide. Heating to 100° produced a little precipitate (probably from hydrate of manganese peroxide); thereafter the solution had only a weak red-violet colour, which on diluting with water to 8 or 10 c.c. could be regarded as vanished. It seems from this that the colorimetric method would be serviceable for the estimation of the amount of carbon in ferro-manganese. One sample of such with about 80 per cent manganese showed carbon approximately 4 per cent.

Phosphorus, 0·001 grm. in the form of soda phosphate added to a solution of 0·1 grm. iron as ferric hydrate in 2·5 c.c. nitric acid and 2·5 c.c. water, showed no difference in colour with a similar solution without phosphorus. Iron with 5 per cent phosphorus is difficultly soluble, and with 10 per cent phosphorus insoluble in nitric acid.

Sulphur, 0·001 grm. in the form of magnesium sulphate, added to 0·1 grm. iron, dissolved in 2·5 c.c. nitric acid and 2·5 c.c. water, was without influence.

0·01 grm. manganese, 0·01 grm. phosphorus, and 0·001 grm. sulphur (all in the forms given above), added to a solution of 0·1 grm. iron as ferric hydrate in 5 c.c. nitric acid and 5 c.c. water, showed no colour. The same quantities added to 0·1 grm. normal steel with 0·8 per cent carbon, dissolved as usual, made no change in the solution or in its colour.

Copper, 0·001 grm., dissolved in 2·5 c.c. nitric acid and 2·5 c.c. water, gave no colour to the solution.

Silicon in iron dissolves to a considerable amount in nitric acid on warming, and particles of silica begin to appear in the solution. 0·4 per cent silicon in steel has at least not shown any influence in colorimetric testing. In cast-iron rich in silicon graphite is always present, and must, with possibly the insoluble silica, be filtered off.

Tungsten becomes tungstic acid on dissolving the iron; it is then insoluble and must be filtered off.

Chromium, 0·002 grm. in the form of chromic hydrate, dissolved in 2·5 c.c. nitric acid and 2·5 c.c. water, gives to the solution a greyish blue colour, which on dilution with water to double its volume is less noticeable. On greater dilution the colour diminishes, and when diluted to 40 c.c.

* The wide opening of the camera can, if desired, be covered by a screen, in the centre of which is placed a suitable convex or concave glass of about 40 m.m. diameter.

may be said to disappear. Iron containing much chromium is difficultly soluble, or even insoluble, in nitric acid.

Vanadium, 0·001 grm. in the form of vanadic acid, dissolved in 2·5 c.c. nitric acid, gives to the solution a weak yellowish colour, which disappears on addition of 2·5 c.c. water.

Nickel, 0·001 grm., dissolved in 2·5 c.c. nitric acid, gives a green colour on solution, which is still apparent on addition of 2·5 c.c. water, but can be regarded as absent on diluting to 8 or 10 c.c.

Cobalt, 0·001 grm., dissolved in 2·5 c.c. nitric acid, gives, as is well known, a red-coloured solution, which is little noticeable on dilution with water to 24 c.c., but scarcely can be regarded as absent before dilution to 40 c.c.

In my note of 1862, I showed the desirability of obtaining from inorganic substances unchangeable normal solutions, instead of those of burnt sugar in spirit used by me which bleached with time, and this the quicker in proportion as they were more often exposed to sunlight. Several proposals with this object have been brought forward lately, in which iron, cobalt, and nickel salts, bichromate of potash, &c., have been recommended. After experimenting with several such mixtures, I have, upon the suggestion of Prof. F. L. Ekman, tried chlorides of iron, cobalt, and copper, which give the best results, because with them we can, as desired, produce colour tones in yellow, brown, and green. Such mixtures, diluted with water, containing 0·5 per cent hydrochloric acid of 1·12 sp. gr., have been found stable, even after standing a long time in sunlight. By only adding hydrochloric acid in drops the mixture is strongly drawn towards yellow. From the neutral chlorides I have, by adding water containing 1·5 per cent hydrochloric acid for ferric chloride, and 0·5 per cent for both the other salts, prepared solutions of such strength that they contained 0·01 grm. metal per c.c. Then taking of these solutions 8 c.c. iron solution, 6 c.c. cobalt solution, 3 c c. copper solution, and about 5 c.c. water containing 0·5 per cent hydrochloric acid, a mixture has been obtained of a colour entirely similar to a solution in dilute nitric acid, of iron containing carbon corresponding to 0·1 per cent per c.c. This solution can afterwards be diluted with water containing 0·5 per cent hydrochloric acid to whatever normal colour is desired, and the water added in the nearest proportion with the amount of carbon. It may be necessary to bear in mind that the weights of 0·1 and 0·05 grm. for weighing off the iron must be very accurate when such artificial normal solutions are used.

Now that unchangeable normal solutions can be obtained, the time may now be come for those desiring such to apply the old method used for copper estimation in ammonia solutions, as adopted by J. B. Britton, of Philadelphia, for colorimetric carbon estimations in iron.* He employed a number of tubes alike in size, containing equal volumes of normal solutions of different strengths; and dissolved the iron in a similar tube, and diluted with water to the same volume as the normal solutions. By comparison with these he can at once tell the amount of carbon, and thus avoid the inconvenience of the successive dilutions. Mr. Britton uses fifteen separate normal solutions for carbon amounts between 0·02 and 0·3 per cent, and he says by taking 1 to 2 grms. iron for estimation the carbon can be determined to an accuracy of 0·01 per cent. He uses for his normal solutions roasted coffee, which he found better than burnt sugar.

A greater exactness in colorimetric carbon estimations may be gained by observing the solutions in the tube from above instead of from the side; but for this purpose it is necessary that the tubes completely correspond at the bottom, that they are obtained suitably clear, and that the depth in all the tubes are alike.

By these observations now communicated I hope that the difficulties which sometimes appeared in colorimetric carbon estimations, both here and elsewhere, may be in some degree removed. At the same time it ought to be remembered that the essential properties of iron and steel do not exclusively depend on the amount of carbon.

I gratefully acknowledge the assistance rendered me by Mr. C. G. Dahlerus in the above estimations.—*Jern Kontorets Annaler*, 1881, Part 5, p. 301.

NOTES ON WATER ANALYSIS.

By A. WAGNER.

I. Notes on the Determination of the Solid Residues.

If about half a litre of the water under examination is very slowly evaporated in small porcelain or platinum capsules over a gas flame turned so low that its point does not touch the wire gauze under the capsule, we find—at least with the Munich gas—that the part of the capsule turned towards the flame appears after the evaporation of a blackish grey colour, the meshes of the wire being often plainly to be recognised. This coating might be taken for soot, but if the capsule is exposed to the air for some time this layer becomes smeary and moist, and if touched with the tongue has an intensely acid taste. It is evidently sulphuric acid and ammonium sulphate, due to the sulphur present in the gas. With a platinum capsule this deposit is more considerable than with a porcelain capsule. If it is not removed before weighing the residue of the evaporation a notable error may be occasioned. To wipe off the deposit, especially with a platinum capsule, is always doubtful.

For this reason, when evaporating the water, I place below the capsule, instead of a wire gauze, a thin piece of sheet platinum, so that the bottom is entirely protected. The following experiment shows the importance of this precaution:—Two half litres of water were simultaneously evaporated in platinum capsules, No. 1 being placed over a piece of wire gauze and No. 2 upon sheet-platinum. On weighing the two residues, after drying at 150°, that of No. 1 was the heavier by 12 m.g. If the dry residue is used for determining the organic matter in the water by ignition, the aforesaid coating of sulphuric acid and ammonium sulphate is expelled by the heat, and thereby the quantity of organic matter is made to appear too large.

II. Remarks on the Determination of the Organic Matter.

In performing a complete quantitative analysis of drinking-water it is necessary to give an absolute figure for the quantity of the organic matter. The chemist is thus compelled to give a numerical result which he cannot possibly guarantee, as up to the present time there does not exist any practicable method for the certain determination of the organic ingredients of a water.

Kubel and Tiemann remark with perfect truth that a determination of the organic matter in water is impossible until we know what is to be determined.

Formerly, when there was no practicable method for the determination of nitrates in spring-water, it was customary to get over the difficulty by maintaining that nitrates were either totally absent in such waters or present merely in quantities which might be neglected—an assertion which has been thoroughly refuted by numerous analyses of the water of different towns. Similar was the case with the determination of organic substances. They were simply described as crenic and apo-crenic acids, perfectly harmless, and it was assumed that in consequence of the absorbent and oxidising properties of the soil, the constituents of urine, &c., could not occur in spring-water.

The nature of the organic matter in such water is far more complicated. Scherer and Fresenius found in the mineral springs of Brückenau and Weilbach butyric and propionic acid. It is also undeniable that in populous places the ground-water is directly polluted by the constituents of human and animal excretions, whether un-

changed or putrescent, owing to the leakage from sewers and cesspools. Thus I found for years at Munich, in the water of a group of wells, all the characteristics of the urine of horses. On account of the introduction of town sewage into rivers, their waters must hold in solution matters very different from harmless crenic acid. According to Kubel and Tiemann a part of the organic matters contained in Berlin spring-waters is of the nature of organic bases, with which a part of the acids present in the water is of course combined. For the Munich waters I must, after long experience, consider it as certain that a part of the organic matter of the spring water consists of organic acids, combined with bases. If a large quantity of Munich spring-water is evaporated to dryness, the residue treated with distilled water, and in the soluble portion the mineral acids and bases, including ammonia, are carefully determined, there is generally found a larger proportion of bases than corresponds to the mineral acids. That this excess of bases does not consist of re-dissolved calcium or magnesium carbonate appears from the fact that if the soluble portion is re-evaporated to dryness the residue does not effervesce with dilute acids. A part of the organic matter must therefore consist of acids, combined with bases.

The methods proposed for the quantitative determination of the organic matters depend on different principles.

Frankland and Armstrong seek to determine the quantity of organic matter by ultimate analysis, and calculate from the carbonic acid found, on the assumption that humoid bodies contain 58 per cent of carbon. This process is only admissible when proof can be furnished that the water in question contains no organic matter save such as is of a humoid nature. In the analysis of the well-waters of populous city districts, or of river-waters which have received town sewage or the waste waters of manufactures, this method is completely excluded.

The same conclusion holds good of the methods which depend upon the reduction of silver oxide or potassium permanganate. Such methods give a datum for expressing comparatively the safety of a water, but they do not enable us to advance a definite number for the absolute weight of the organic matters present. In the permanganate process the organic matter is found by multiplying by 5 the quantity of permanganate consumed. Concerning this procedure, Kubel and Tiemann are of opinion that it can no longer be upheld. To show what strange results may be obtained by the use of such methods I will give, as a curiosity, the following example:—In an investigation, to which a prize was awarded by the University of Munich, and which is published in the *Zeitschrift für Biologie*, 14, 190-280, there are cited many analyses of waters, where the organic matters are thus calculated:—

Canal water: residue on evaporation, 0·466 per litre; organic matter, 1·063; lime, 0·146.

Hofgrabenbach: residue on evaporation, 0·468; organic matter, 0·496; lime, 0·105.

Hence this useless procedure shows the organic matter as considerably greater than the whole solid residue, though salts of lime and other mineral matters were present.

If it is compulsory to express the quantity of organic matter in a sample of water by an absolute figure, I consider it incumbent upon the chemist to state by what process such number has been obtained, and to explain to the lay public that such numbers must be considered and compared with due caution.

As the simple loss on ignition is never decisive, I consider the following process the most suitable for the determination of organic matter. It has proved very satisfactory for the Munich waters, which contain calcium carbonate as a greatly predominating constituent.

After the determination of all the other constituents of the water, I evaporate suitable quantities to dryness, and separate the dry residue by means of distilled water into an insoluble and a soluble portion, which latter contains the chief bulk of the organic bodies. In the insoluble portion, which in the waters of this district consists almost entirely of calcium and magnesium carbonates, I determine the organic matter by igniting a dried specimen in a platinum capsule and treating subsequently with ammonium carbonate in the customary manner. The portion soluble in water, if nitrates are absent, or present only in a quantity too small to be determined, is dried after evaporation in a platinum capsule, weighed, heated to a very low redness, and weighed again. But if the nitrates are present in larger quantities, so that the existing organic matter would not suffice to convert the nitrates into carbonates, I add to the soluble portion, after drying and weighing, a little pure solution of sugar, evaporate to dryness, and heat the platinum capsule gradually and by piecemeal with a very small gas flame, so that no deflagration may happen. After prolonged but very gentle ignition the sugar-charcoal is found burnt away, when the residue is moistened with water containing carbonic acid, and weighed again after drying. The loss of weight in this case expresses the weight of the organic substances and the difference between the equivalent of the nitric acid which was present, and of the carbonic acid which has taken its place. This difference can be easily calculated from the quantity of the nitrates, as previously ascertained, and must be deducted.

This process is of course by no means absolutely accurrate, since on ignition not merely carbonates, but cyanides may be formed, and since carbon reduces the sulphates, which on subsequent ignition with access of air are not certainly and completely re-oxidised. If the temperature is raised too high a loss of the alkalies is possible.—*Zeitschrift für Analytische Chemie.*

PROCEEDINGS OF SOCIETIES.

MANCHESTER LITERARY AND PHILOSOPHICAL SOCIETY.

Ordinary Meeting, April 5, 1881.

E. W. Binney, F.R.S., F.G.S., President in the Chair.

The President said that he had, on several occasions brought before the Society a notice of the *Eucalyptus globulus* growing near to the sea in his garden at Douglas, in the Isle of Man. It was planted in 1875, and grew about 7 feet in height annually during the three following years; after these its top reached higher than the wall sheltering it, and it was exposed to the east winds from the sea, which stopped its rapid growth. It has attained a height of thirty feet. During the winter it fared pretty well until the beginning of March, when the strong gales made bad work with its foliage, but the tree is still alive, and he has every hope it will rally again in the summer. It grows about six feet above the ordinary high water mark of the sea in Douglas Bay.

"*Note on the Presence of Arsenic in Paper Hangings*," by Harry Grimshaw, F.C.S.

That arsenic in various states of combination is very often present in the colouring matter of paperhangings is a very well ascertained fact. That it is not confined, as was at one time generally supposed, to those papers which are coloured green, is also pretty well understood, many chemists having found it in papers of all shades and colours, including even white and grey.

A case which illustrates very well this general distribution of arsenic in papers of various colours and shades, and also illustrates one or two other interesting features in connection with this subject, has been brought under my notice by Mr. R. Le Neve Foster, F.C.S., and it will perhaps be of some little interest to this Society. One of the two series of specimens of wall paper which I now show you consists of six papers of varying colours. Three greens, of different shades, light brown, dark brown, and

pink, are the tints comprised, and all of them without exception contain arsenic largely. The pink, which is a very light shade, contains the least arsenic, and the brightest green contains the most, though one of the brown shades contains a very large amount. I have not determined the amount of arsenic quantitatively, as that was not needed to condemn the papers, but probably the pink paper contains a sufficiently large quantity of arsenic on one square foot to poison an adult person.

When these papers were selected from a Lancashire manufacturer it was particularly specified that they should be free from arsenic. The absence of this body was assured in a positive manner, and no doubt the papers would have been definitely guaranteed to be absolutely free from arsenic. This assurance, however, from previous experience, was not relied on, and the papers were qualitatively analysed for arsenic with the result above stated.

The injurious effects which might have resulted, in fact would almost certainly have resulted, from papering six rooms in a house with arsenical paperhangings, do not need enlarging upon any more than does the almost criminal foolishness of stating that such papers were free from arsenic.

The second series of six samples which I have placed along with the six arsenical papers illustrates very conclusively the fact that arsenical compounds are certainly not essential to the production of the colours required in the decoration of paper. These second papers were obtained from a London manufacturer to replace those which I have described, and will be seen to be so near them in shade and colour that in one or two cases it is difficult to perceive any difference at all. None of the second series of papers yield the least indication of arsenic with Marsh's test, and therefore entirely justify their warrant as free from arsenic, and were of course selected for use. We have therefore in these six self-tinted papers and the two-patterned papers, which I have also here, tints which alone or in combination will serve to demonstrate that any colour almost which is desired can be obtained without the addition of arsenic. If there is a difference in the appearance of the arsenical and non-arsenical colours, it is that the former are rather brighter. This, however, is not altogether a merit, for wall colours may very easily be *too bright*.

It is to be regretted that non-arsenical paperhangings are at present, as a rule, somewhat dearer than the ordinary ones, but there is not much reason to doubt that this will be materially changed when the former are more largely made and used than at present. The cheapness of arsenic and its compounds is an unfortunate circumstance which favours its adoption, but when it is more generally acknowledged that the "brightness" yielded by these arsenical colours is not at all indispensable, this cheapness will not be an insuperable objection.

In papers which contain arsenic the hardness of the surface and the comparative firmness with which the colour is fixed on the paper are of course important factors in the danger which attends their use; a paper on which the colour is but loosely attached, though it may contain less arsenic, will be much more dangerous than one containing a much larger amount with the colour firmly adherent, the minimum of danger being reached in a "glazed" paper or a sized and varnished one. In any case, however, a sensible person will prefer not to live continually surrounded by so many square feet of arsenic-covered walls, and it is to be hoped that the promiscuous use of arsenical paperhangings will receive a permament check on the completion of the labours of the Committee of the Society of Arts, which is, I understand, at present drafting an Act of Parliament to regulate the application of this poisonous substance, and endeavouring to decide upon a test to which suspected papers may be uniformly subjected.

It is not a point to congratulate ourselves upon, that it appears to be the opinion that the Lancashire paperhanging manufacturers have the unenviable reputation of being greater offenders with respect to the presence of arsenic in papers than their fellows nearer the metropolis, and there can be no necessity, with the local scientific and technological knowledge which is attainable, that this should be the case.

It appears to be a moot point whether the cheaper or the more expensive papers usually contain more arsenic, and also in which class is it oftenest found. I hope to have an opportunity of making a communication to the Society on this point on a future occasion.

Dr. Joule, F.R.S., said that since Mr. Grimshaw read his paper on the sulphuric acid produced by gas lights, he had hung two finely perforated zinc plates over one of his burners. The nearest plate was 12 inches above the flame, the other 3 inches above it. The burner was a large one, and lighted on the average five hours each day. The zinc plates were examined after three months, when it was found that the lower one had accumulated the usual brownish black deposit and also a furring of sulphate of zinc. The upper plate of zinc was little affected, which leads him to the belief that a single plate of perforated zinc of about a foot square is sufficient to remove the greatest part of the noxious emanations, and obviates to a great extent the necessity of a globe or chimney.

"*On the Relation of Electrical Resistance to the Chemical Composition of Steel Wire*," by William H. Johnson, B.Sc.

I showed in a paper read before the Society in March last year, and entitled "On the Electrical Resistance and its Relation to the Tensile Strain and other Mechanical Properties of Iron and Steel Wire," that in cast-steel wires drawn in the same way but manufactured so as to contain different quantities of carbon, &c., the electrical resistance increased with the resistance to tensile strain; *vide* Table B in the report of my paper (*Proceedings of the Manchester Lit. and Phil. Society*, No. 12, vol. xix.

During the last year Dr. Burghardt has very carefully analysed the identical samples of annealed steel wire whose electrical resistance and other mechanical tests are given in Table B just mentioned. The results for all samples with the exception of No. 6, not yet analysed, are shown in Table C.

A glance at this table shows us that five of the samples have only four elements other than iron present in quantity, namely, carbon in two forms combined and graphite, silicon and manganese, and traces only of sulphur and phosphorus.

Now, how do these elements effect the conductivity of the steel? Let us examine them in detail.

First, graphite carbon must be present in the steel as a mechanical mixture, and so can scarcely exercise any influence on the conductivity. Then manganese will probably be present in the form of an oxide; as manganese oxidises at the high temperatures steel is cast more readily than any of the other constituents of the steel. Now, oxide of manganese can hardly be present in the steel other than as a mechanical mixture, and thus we may disregard its influence.

There are now left combined carbon and silicon, and in Samples 1 and 2 a little sulphur or phosphorus. From analogy with copper, sulphur and phosphorus should increase the electrical resistance of iron very much. Perhaps we may estimate in a rough way the total effect of these elements on the conductivity by taking their sum as shown at foot of Table C. If this is correct, we are led to the interesting result that within the range of these experiments any increase in the percentage of sulphur, phosphorus, carbon, and silicon present in a steel is accompanied by an increase in its electrical resistance, and, further, an increased electrical resistance is concurrent with an increase in the resistance to tensile strain.

The quantity of carbon, silicon, sulphur, and manganese in the samples of steel is so very small that the most careful analyses give results which must be regarded as approximate rather than definite; hence I have much diffidence in laying these figures before you. But however

TABLE C.

Analysis of Cast-Steel Wires, Nos. 1 to 8, and Electrical Tests as given in Table B, "Proc. Man. Lit. and Phil. Soc., March, 1880.

Sample No.	1.	2.	3.	4.	5.	7.	8.
Metallic iron	98·980	99·070	98·870	98·880	99·030	99·170	99·007
Combined carbon	0·391	0·438	0·270	0·280	0·182	0·226	0·268
Graphite carbon	0·040	0·060	0·150	0 150	0·130	0·150	0·080
Silicon	0·157	0 011	0·190	0·150	0·140	0·080	0·033
Manganese	0·088	0·300	0·470	0·410	0·390	0·340	0·380
Sulphur	0·080	0·031	trace	trace	trace	trace	trace
Phosphorus	0·096	trace	trace	trace	trace	trace	trace
Total	99·832	99·910	99·950	99·870	99·872	99·966	99·768
Combined carbon, silicon, sulphur, and phosphorus	0·724	0·479	0·460	0·430	0·322	0·306	0·301
Electrical resistance of annealed steel wire in Ohm's per metre gramme	2·140	1·903	1·560	1·519	1·450	1·430	1·070

much the ultimate accuracy of these figures may be called in question, I think we may fairly say that the electrical resistance of a piece of iron or steel is a measure of its resistance to tensile strain and of the amount of combined carbon, sulphur, silicon, and phosphorus it contains.

NOTICES OF BOOKS.

Essays on the Floating Matter of the Air in relation to Putrefaction and Infection. By JOHN TYNDALL, F.R.S. London: Longmans, Green, and Co.

THE immediate objects of the work before us cannot be ranked as chemical or physical. The researches here described concern the vexed question of abiogenesis or spontaneous generation. In the interest of practical surgery and of preventive medicine it is exceedingly important to know whether low forms of organic life, and especially morbific bacteria, micrococci, and the like, can appear spontaneously in a fluid or solid affording a suitable pabulum, or whether even in their case the saying *omne vivum ex ovo* holds strictly good. Prof. Tyndall adopts the latter view. Without denying the possibility of spontaneous generation, he contents himself with showing that all the evidence advanced in its favour is untrustworthy, and depends on errors of observation. As a specimen of a carefully conducted experimental enquiry and of inductive reasoning this work may be advantageously studied, even by such as have no especial interest in its subject-matter.

The contention of the advocates of abiogenesis is that the living organisms which sooner or later appear in the decoctions of animal and vegetable matter are absolutely spontaneous. Their opponents maintain that all such life has its origin in germs or spores introduced from the air adhering to the vessels, or present in the water used in making the infusions or solutions. To decide the question is an exceedingly delicate matter, seeing that we have to do with spores or germs not merely invisible to the naked eye, but so small as often to elude the microscope. The first experiment made was to place the organic liquid in a narrow-necked flask, to boil for a considerable time, seal the neck before the blowpipe, and await the result. The abiogenists contend that if life appears in a solution which has been thus treated it must be regarded as of spontaneous origin. As, in fact, life was frequently manifested in such liquids they claimed a triumph. But the researches of Drysdale and Dallinger, who have carried microscopic research to a degree of perfection previously unknown, show that though a boiling heat destroys mature bacteria, the germs of these beings have a power of resisting heat greater in the proportion of 11 to 6. The sugestion was then made that if an organic liquid was heated not once, but repeatedly, the germs present would be successively destroyed as they reached the adult state, and the solution would finally be sterilised. When this is done without any flaw in the process the result is as expected. But the precautions requisite are exceedingly minute and tedious. Prof. Tyndall has in some cases prepared his flasks and tubes for boiling experimental solutions by washing first with carbolic acid, then with caustic soda, then with distilled water, and lastly heats them to redness. Sometimes the contents of a flask or tube thus carefully prepared would grow turbid and show signs of life. On examination it was then found that some tiny crack in the closed end of the flask had admitted the external air and with it the germs of life. To this it was objected that by the successive heatings and coolings the liquid had been rendered incapable of originating life. If shown that such a tube or flask on being opened speedily swarmed with microbia, the abiogenists replied that the free admission of air had restored the necessary qualities to the liquid. It is often said that if abiogenesis were possible life would surely sometimes originate in the many thousands of tins of mutton, beef, fish, fruits, and vegetables which are now important articles of commerce. Dr. Bastian replies that a rarefied atmosphere is conducive to spontaneous generation, whilst that inside a "tin" is condensed. Dr. Tyndall proves that this view is erroneous. If a "tin" is opened under water, the water rushes in to fill up the partial vacuum. Dr. Bastian's contention thus damages his own cause.

But Prof. Tyndall's most decisive experiment is based upon the fact that air if kept at perfect rest for a few days deposits all its suspended matter, organic or inorganic, the spores or germs of microbia included. Liquids boiled with proper precautions and exposed to such air remain barren. It is impossible to describe this apparatus without the aid of the accompanying cuts. The experiment appears to us, however, most satisfactory, and we do not see what valid reply can be made by the upholders of spontaneous generation.

It must be remembered that neither the experiments of Pouchet and Bastian, nor of Pasteur and Tyndall, have any direct bearing upon the first appearance of life upon our globe. All four have operated with organic matter only, which in the azoic ages was *ex hypothesi* absent. Dr. Tyndall may, however, urge that if organic matter will not give spontaneous rise to life, neither, *a fortiori*, will inorganic bodies.

Modification of Ruhmkorff's Coil.—MM. Scarpa and Baldo.—With an induced coil, arranged in two blocks placed on the poles of the magnetic nucleus and communicating with each other, so that their points of junction may be at equal distances from the nucleus, effects are obtained of much greater power than with the ordinary arrangement.—*Les Mondes.*

CHEMICAL NOTICES FROM FOREIGN SOURCES.

Comptes Rendus Hebdomadaires des Séances, de l'Académie des Sciences. No. 8, August 22, 1881.

Existence of a New Metallic Element, Actinium, in the Zinc of Commerce.—Dr. T. L. Phipson.—The author gives the substance in question the name of Actinium, on account of the curious actinic phenomenon which he has described in two communications (CHEMICAL NEWS, vol. xliii., p. 283, and vol. xliv., p. 73). The phenomenon appears due to the presence of a new metallic element, Actinium. The sulphide of this metal is white, but becomes brown, and finally black, under the reductive action of the sun's rays; a plate of glass hinders this blackening. In darkness the white colour is restored by oxidation. The new metal differs from indium and gallium in not being precipitable by metallic zinc.

On a New Series of Phosphates and Arseniates.—MM. E. Filhol and Senderens.—In their researches on the quantities of heat liberated by the addition of successive quantities of soda to one equivalent of phosphoric acid, MM. Berthelot and Louguinine have observed that in order to obtain solutions neutral to coloured reagents it was necessary to use 1½ equivalents of soda to 1 equivalent of phosphoric acid. They do not seem to have examined if the solution neutral to litmus would give a definite crystalline phosphate. The authors have obtained this salt—sesquisodic phosphate. It may be regarded as formed by the combination of 1 mol. monosodium phosphate and 1 mol. disodium phosphate. They have also obtained an analogous arseniate.

Fixation of Hypochlorous Acid upon the Propargylic Compounds.—L. Henry.—The propargylic compounds (ethylic and methylic) combine readily with hypochlorous acid, even in very dilute solutions, forming a heavy oil.

Bulletin de la Société Chimique de Paris. No. 9, May 5, 1881.

Influence of Succinic Acid upon the Fermentation of Cane-Sugar.—U. Gayon.—Succinic acid alone is not capable of producing the inversion of cane-sugar.

Combinations of Phthalic Anhydride with the Hydrocarbons of the Benzol Series.—MM. Friedel and Crafts.—The desired reactions are easily effected on mixing about equal parts of the hydrocarbon, the anhydride, and of aluminium chloride, and heating them in the water-bath for two or three hours. The product of the reaction is poured into water by small portions, and boiled with a large excess of water. All the aluminium chloride and a part of the phthalic acid are thus removed. The acid obtained is dissolved in ammonia and precipitated by hydrochloric acid from the dilute boiling solution.

No. 10, May 20, 1881.

Evaporation-Heat of Sulphuric Anhydride.—M. Berthelot.—The evaporation of SO_3, at about 18°, absorbs 5·9 cals.

Formation-Heat of the Oxides of Sulphur.—M. Berthelot.—Already noticed.

Solubility of Tribasic Alkaline Phosphate in Ammoniacal Salts and in Neutral Alkaline Salts, from an Analytical and Agricultural Point of View.—A. Terreil.—The ammoniacal salts dissolve tricalcic phosphate in proportions varying from 0·309 per cent of the phosphoric acid present, in case of the nitrate, to 7·08 per cent in case of the citrate. Potassium citrate dissolves from 2·02 to 1·78 per cent.

Sterilisation of the most Unstable Animal and Vegetable Liquids in the Cold.—P. Miquel and L. Benoist.—This process will be inserted at length.

Russian Chemical Society.—Session, November 6/18, 1880.—M. A. Krakau.

M. Lubavine described the action of ammonium cyanide upon various anhydrides.

M. Markownikow described the preparation and the properties of itaconic anhydride, and conjointly with M. Krestownikow he made a communication concerning a new acid, the homo-itaconic.

M. Miller announced that, contrary to the statement of Toumsky, phenol-phthaleine may serve as an indicator in alkalimetry.

M. Jagn submitted an apparatus for the automatic washing of precipitates.

M. Zagoumenny gave a full description of the formation and the properties of benzo-pinacone, benzo-pinacoline, tri-phenyl-methan, and tetra-phenyl-ethan.

MM. Maltchewsky and Sokoloff announce that the action of iodine upon sodium bisulphite gives rise to sodium dithionate.

M. Golubeff, on causing nitric acid to react upon desoxybenzoin, has obtained a third isomeric dinitro derivative in yellow crystalline needles melting at 154° to 155°.

M. Bronnikoff described a method for the determination of ammonia and nitric acid by colorimetric procedures.

M. Driguine described a double hydrochlorate of quinine and urea.

M. Boungue gave a communication on the electrolysis of the formic and mellic acids, and remarks on the nature of a gelatinous matter deposited in the manufacture of beet-root sugar.

M. Tanatar sent in a memoir on the structure of the fumaric and maleic acids.

MM. Danilewski and Radenhausen gave an account of researches on the albumenoids of cows' milk, and on the decomposition-products of the albumenoids.

M. Potilitzine described the double decomposition of salts in aqueous solution from a thermo-chemical point of view.

M. Louguinine gave an account of his researches on the combustion-heats of certain alcohols of the allyl series.

MISCELLANEOUS.

London Hospital Medical College.—The eighth Biennial Festival of this College was held on Monday evening, at the "Criterion." Dr. Robert Barnes presided, and was well supported by a large number of members of the Staff and former pupils of the Hospital. The usual loyal toasts having been drunk, Dr. Barnes, in proposing our "Alma Mater," alluded to the great clinical opportunities afforded at the Hospital, and to the increasing prosperity of the School, which has of late been considerably enlarged and improved. Dr. Barnes also made a feeling allusion to the deaths of Dr. Billing and Mr. Luke, who were for very many years on the Staff of the Hospital. Mr. John Henry Buxton, the Chairman of the Hospital, Dr. Andrew Clark, and Mr. Hutchinson also spoke of the well-being of the School, and of the good feeling that existed between the House Committee and the Staff.

King's College, London.—Lessons in Metallurgy.—Under the direction of Prof. A. K. Huntington, the Laboratory for instruction in Metallurgy is open to Students every day from 10 to 4 (except on Saturday, when the College closes at 1); on Friday evenings from 7 to 9. Lectures will be delivered on Mondays and Thursdays at 4 p.m., and on Wednesdays at 7 p.m. Fees (including materials):—Day classes: Lectures only, £3 3s; Laboratory for one month, £6 6s.; two months, £11 11; three months, £15 15s; six months, £27 6s.; nine months, £37 16s. Students attending the Laboratory can attend the Lectures without further charge. Students taking a month's ticket may attend daily during such time as the Laboratory is open, or three days a week for two months, or two days a week for three months. Evening classes:

Lectures only, £1 11s. 6d.; Laboratory only, £2 2s. The course of Lectures is designed for all those who in any way have to do practically with the applications of metals. It treats of the methods by which metals are obtained from their ores, and the means by which they are rendered suitable for the various requirements of the Arts. The following are the principal subjects treated of:—General considerations concerning the principles of Metallurgy. Physical properties of metals. The physical and chemical properties of various kinds of fuel; the selection and economic preparation of fuel to suit the requirements of special processes. Materials used in the construction of furnaces, &c.; fire-bricks, crucibles, &c. The various methods by which iron and steel are produced; the effects caused by the presence of foreign substances. Copper-smelting; alloys of copper, &c. Treatment of zinc ores; means by which it can be rolled into sheets; alloys of zinc, *e.g.*, brass, Muntz's metal, &c. Smeting and desilverisation of lead. Extraction of silver from its ores; its alloys. Methods of extraction of gold, and parting from silver and copper, &c. Smelting of tin ores. Tin-plating, bronze, &c. The means by which antimony, bismuth, nickel, cobalt, mercury, &c., are obtained; their properties and uses will also be discussed. Practical Metallurgy:—The work in the Laboratory is intended to illustrate the principles discussed in the Lectures. The instruction given to each Student is, however, regulated by his special requirements.

NOTES AND QUERIES.

*** Our Notes and Queries column was opened for the purpose of giving and obtaining information likely to be of use to our readers generally. We cannot undertake to let this column be the means of transmitting merely private information, or such trade notices as should legitimately come in the advertising columns.

Chloride of Calcium Process for Refining Sulphur.—Can any of your correspondents give me any information as to the chloride of calcium process for refining sulphur mentioned in a paragraph in the *Times* a few days ago, as having been devised by MM. de la Tour de Breuil? Any information on the point will be interesting.—Brimstone.

A POCKET-BOOK FOR CHEMISTS,

Chemical Manufacturers, Metallurgists, Dyers, Distillers, Brewers, Sugar Refiners, Photographers, Students, &c.

By THOMAS BAYLEY, Assoc. R. C. Sc. Ireland.
Analytical and Consulting Chemist and Assayer.
SECOND EDITION, WITH ADDITIONS.

Synopsis of Contents.

Atomic Weights and Factors—Useful Data—Chemical Calculations—Rules for Indirect Analysis—Weights and Measures—Thermometers and Barometers—Chemical Physics—Boiling-points, &c.—Solubility of Substances, Inorganic and Organic—Specific Gravity: methods of obtaining, conversion of hydrometers, strength of solutions by specific gravity—Analysis: gas analysis, water analysis, qualitative analysis and reactions, volumetric analysis, manipulation—Mineralogy—Assaying—Alcohol, Beer, Sugar—Miscellaneous technological matter relating to Potash, Soda, Sulphuric Acid, Chlorine, Tar Products, Petroleum, Milk, Tallow, Photography, Prices—Formulæ for Alcohol, Beer, Wort, and Correction of Density for Temperature—The Elements arranged according to Mendelejeff's Classification—Table showing strength of solution of ammonia by specific gravity—Table showing the strength of solutions of Glycerine by spefic gravity—Table showing the boiling-points of saturated solutions—Tables for calculating the value of cubic centimetres with different corrections—Dry Reagents, &c.

London: E. and F. N. SPON, 16, Charing Cross.

BERNERS COLLEGE of CHEMISTRY.

Instruction and preparation in CHEMISTRY and the EXPERIMENTAL SCIENCES under the direction of Professor E. V. GARDNER, F.A.S., M.S.A.

The Class Rooms are open from 11 to 5 a.m. and from 7 to 10 p.m daily.

Especial facilities or persons preparing for Government and other examinations.

Private Pupils will find every convenience.

Analyses, Assays, and Practical Investigations connected with Patents, &c., conducted.

Prospectuses and full particulars on application to Prof. Gardner at Berners College, 44, Berners-street W.

Messrs. WATSON, KIPLING, & Co., Limited, Seaham Harbour.

In Liquidation, under the Companies' Acts.

SALE OF CHEMICAL WORKS & BLAST FURNACES.

MR. ARTHUR T. CROW has been commissioned to offer for SALE BY AUCTION, at the Queen's Hotel, Sunderland, in the County of Durham, on WEDNESDAY, 12TH OCTOBER, 1881, at Two for Three o'clock in the afternoon, the extensive

CHEMICAL WORKS

situate at the Port of Seaham Harbour, in the Parish of Dalton-le-Dale, near Sunderland aforesaid, with 8 first-class Workmens' Cottages, comprising an area of 16 a. 2 r. 13 p., or thereabouts, held by Lease from the Marquess of Londonderry to Messrs. Watson, Kipling, and Co., for 99 years from the 1st day of May, 1864, at the Yearly Rental of £200. Also the

IRON WORKS, BLAST FURNACES, COKE OVENS, & LAND

connected therewith, adjoining the Chemical Works, and comprising an area of about 10 a. 1 r. 30 p., held by Lease from the Marquess of Londonderry to Messrs. Watson, Kipling, and Co., for 91 years from the 1st day of January, 1869, at the Yearly Rental of £200.

The Chemical Works comprise Offices, Store House, Burner Shed, containing 64 Burners; Two Sets Sulphuric Acid Chambers 2 Glover's Denitrating Columns, 2 Absorbing Columns.

Decomposing House, with 3 Decomposing Furnaces and 1 Jones's Mechanical Furnace, 5 Condensers.

Furnace House, with 4 Hand Ball Furnaces with Settlers, Ball Tanks and Receivers, and 2 Mechanical Ball Furnaces, 5 Hand Carbonating Furnaces, and 1 Mactear's Carbonating Furnace.

Alkali Sheds, with 4 Pans, Drainers and Settlers.

Dissolving House, with 18 Pans and Settlers.

Crystallising House, with 276 Cones.

2 Chimneys, 159 feet high, and 1 Chimney 59 feet high, and Flues

9 Boilers and 2 Hot Water Boilers.

22 ENGINES, estimated equal to 150 nominal horse-power.

6 Weighing Machines, Tramways, Turntables.

Workshops and Sheds, Cold Water Well 108 by 8.

The Magnesia Process consists of Magnesia and Calcining Houses, with 5 Kilns, Mill, Tank, Cisterns, and Drying Stoves, and the Works are said to be capable of manufacturing 260 Tons of Soda Crystals and 4 Tons of Magnesia per week.

Water and Coal are obtainable from the Lessor, and Magnesian Limestone from his Lordship's Quarry adjoining the blast furnaces, the payments for same being fixed by provisions of the Lease.

Both Leases contain clauses peculiarly advantageous to the Lessees so far as regards Railway Rates, which are remarkably low, the main line of railway running into both Works; and as to importing and exporting goods and merchandise to and from the Port of Seaham Harbour, and also as to the disposal of the refuse left from both Chemical Works and Blast Furnaces.

Until the past few days the Chemical Works have been in active operation, and are now in such a condition as to enable a purchaser forthwith to commence the trade recently carried on. The Blast Furnaces are in excellent order, and may, at comparatively small expense, be placed in good working condition.

There is a large quantity of Loose Material and Plant which may be taken at a valuation at purchaser's option.

Intending purchasers, or their Solicitors, may inspect copies of the Leases and conditions of sale at any of the addresses given below at any time within ten days of the day of sale.

Further particulars, with orders to view, may be had from George C. Pecket, Esq., 2, Park Place East, Sunderland, the Liquidator duly appointed to wind up the Estate; Joseph Heap, Esq., Solicitor, Rochdale; Messrs. Johnson and Weatheralls, Solicitors, 7, King's Bench Walk, Temple, London; Messrs. Norris, Allens, and Carter, Solicitors, 20, Bedford Row, London; from the Auctioneer, Manor House, Sunderland; and from Messrs. Haswell and Marshall, Solicitors, 61, John Street, Sunderland.

BIRKS & CO.,

CARBOLIC ACID MANUFACTURERS, TAR DISTILLERS, &c.

CARBOLIC ACID.

No. 1.—Crys. at 34·35° C.
No. 2.—Crys. at 28·29° C.

Liquid Carbolic, straw-coloured and water-white.

Aurine, Carbolic Disinfecting Powder, 10%, 15%, and 20%. All warranted unadulterated.

Tar Products of all kinds.

WORKS—CLAYTON, NEAR MANCHESTER.

Water-Glass, or Soluble Silicates of Soda and Potash, in large or small quantities, and either solid or in solution, at ROBERT RUMNEYS Ardwick Chemica Works Manchester.

IRISH HILL BAUXITE (Alum Clay).

THE IRISH HILL MINING CO. are now, and always have been, the LARGEST PRODUCERS OF THIS CLAY, of Superior Quality, and supply the Manufacturers of Alum, Sulphate of Alumina, and Alum-Cake, of the United Kingdom, America, and the Continent, almost exclusively.

ANALYSIS BY JOHN PATTINSON, ESQ.

Supplies over 90 % of the Bauxite (Alum Clay) used.

	Dried at 212° F.		
	Gertrude (extra qual.)	1st Quality.	2nd Quality.
Alumina	59·00	53·83	52·00
Peroxide of Iron	0·47	1·57	4·57
Silica	18·00	8·67	12·00
Titanic Acid		5·80	6·20
Lime, Magnesia, Potash, Soda, and Sulphuric Acid	0·23	0·83	1·14
Combined Water	22·30	29·27	24·00
	100·00	99·97	99·91

Supplies over 90 % of the Bauxite (Alum Clay) used.

Our MINES, DRYING KILNS, and GRINDING MILLS are situated very close to the Shipping Ports of BELFAST and LARNE, and adjacent to Railways running alongside both Steamers and Sailing Vessels at both Ports, from either of which shipping is abundant and cheap, therefore we can guarantee Regular Delivery as Buyers require it, and are prepared to quote prices f.o.b. c.i.f., or delivered at any Port, in Bulk or Bags, Lump or Ground.

ON THE PHOTOGRAPHIC SPECTRUM OF COMET "*b*," 1881.*

By WILLIAM HUGGINS, D.L.C., LL.D, F.R.S.

IN the year 1866 and 1868 I applied the spectroscope to the light of comets, and in the latter year I showed that the three bright bands in the visible part of the spectrum agree with the similar bright bands which are seen when an induction spark is taken in olefiant gas.† The same bands are also seen in the flames of many compounds of carbon. I was inclined at that time to consider that these bands were due to the vapour of carbon. Subsequent investigations which have been made on the spectra of the compounds of carbon appear to make it probable that these bands are the spectrum of a compound of carbon with hydrogen. These observations (1868) showed the presence of carbon—probably in combination with hydrogen—in the cometary matter.

Since that time until the present year no comet has appeared sufficiently bright to allow of the observations on its spectrum being extended to the ultra-violet region. The apparatus with which I had successfully photographed the spectra of stars was especially suited to this purpose.‡ It consists essentially of a spectroscope, furnished with a prism of Iceland spar and bases of quartz, placed so that the slit shall be in the principal focus of a mirror eighteen inches in diameter, equatorially mounted, and driven by an electrically-controlled clock.

On the evening of June 24, 1881, I directed this instrument, armed with a very sensitive gelatin plate, to the head of Comet "*b*," so that the nucleus should be upon one-half of the slit. After an exposure of one hour the open half of the slit was closed, the shutter withdrawn from the other half, and the instrument was then directed to Arcturus for fifteen minutes.

After development the plate presented a very distinct spectrum of the comet, together with that of the star, for comparison.

The spectrum of the comet consists of two spectra superposed upon each other:—A continuous spectrum, which extends from about F to a little distance beyond H. In this continuous spectrum can be seen the Fraunhofer lines G, *h*, H, K, and many others. This spectrum is, therefore, due to reflected solar light. The second spectrum consists of two sets of bright lines and a suspicion of the presence of a third set. These lines are obviously to be referred to original light from the comet.

The strongest set consists of two bright lines in the commencement of the ultra-violet region. Measures, made by the aid of the comparison star-spectrum, give for these bright lines the wave-lengths 3883 and 3870. The less refrangible line is much stronger, and a faint luminosity can be traced from it to a little beyond the second line 3870. There can be, therefore, no doubt that these lines represent the brightest end of the ultra-violet group which appears under certain circumstances in the spectra of the compounds of carbon. Professors Liveing and Dewar have found for the strong line at the beginning of the group the wave-length 3882·7, and for the second line 3870·5.

I am also able to see upon the continuous solar spectrum a distinct, though fainter, impression of a group of lines between G and *h*. There can be little doubt that this group is the one for the least-refrangible limit of which the wave-length 4220 is given by Professors Liveing and Dewar.

An increase of brightness in the continuous spectrum is also seen between *h* and H, which may be due to other bright lines; but the photograph is not strong enough to admit of any certain conclusion on this point.

On June 25 a second photograph was obtained with an exposure of an hour and a-half. This photograph, notwithstanding the longer exposure, is fainter, but shows distinctly the bright lines in the ultra-violet and the continuous spectrum.

These photographs confirm the results of my earlier observations on comets—that part of their light is reflected sunlight, and part is original light; and, further, that carbon is present in the cometary matter.

The new bright groups in the comet's spectrum which the photographs have revealed to us are certainly characteristic of substances containing carbon.

In their paper "*On the Spectra of the Compounds of Carbon* (*Proc. Roy. Soc.*, vol. xx., p. 494)," Profs. Liveing and Dewar bring forward evidence to show that these two groups indicate the presence of cyanogen, and are not to be seen in hydrocarbons unless nitrogen is also present. If this be the case, the photograph supplies us with strong evidence of the presence of nitrogen in the comet, in addition to the carbon and hydrogen shown to be there by the bright groups in the visible region of the spectrum. It is of great interest in connection with this result, now that Schiaperlli has shown us the close relationship of meteors and comets, to mention the results of Professor Graham's experiments on the gases occluded from the meteoric iron of Lenarto (*Proc. Roy. Soc.*, vol. xv., p. 502, 1867). This iron gave nearly three times its volume of gas, consisting chiefly of hydrogen, with small quantities of carbonic oxide and nitrogen.

Professor Wright's examination of the stony meteorites shows the oxides of carbon, chiefly the dioxide, to be present in largest quantity; but he obtained also a small percentage of hydrogen and nitrogen (*Amer. Journ. Science*, vol. x., July, 1875).

Other kind of meteors are known which contain hydrocarbons, even in considerable quantity. It is scarcely necessary to add that, under suitable conditions, the spectra of the gases from meteorites will be similar to that observed from the light of comets.

Professors Liveing and Dewar's experiments would seem to show that a high temperature must be present in the comet if the cyanogen is formed there: but if cyanides should be found in meteorites the necessity would not exist.

Whatever the views that may be entertained as to the forms of combination in which the carbon exists, there can be no doubt whatever of the presence of carbon in comets. I should mention that Mr. Lockyer regards the two bright groups seen in the photograph, and the three groups in the visible spectrum, to be due to the vapour of carbon at different heat levels (*Proc. Roy. Soc.*, vol. xxx., 461).

It is of importance to mention the strong intensity in the photograph of the lines 3883 and 3870 as compared with the continuous spectrum, and the faint bright group beginning at 4220. At this part of the spectrum, therefore, the light emitted by the cometary matter exceeded by many times the reflected solar light.

On August 21 I attempted to obtain, with an exposure of one hour, a photograph of the spectrum of a large comet which has appeared since—Comet "*c*," 1881. The evening was not very favourable, and the comet was at a low altitude and not so brilliant as Comet "*b*." I am not able to see on the plate more than a faint trace of the brightest lines (W. C. 3883 and 3870) of the spectrum obtained from the former comet.

Saccharine.—E. Peligot, Prof. Descloiseaux, Dr. v. Lippmann, Prof. Scheibler.—Saccharine has the same percentage composition as cane-sugar, but differs it its properties. It is most readily obtained from lævulose lime. —*Biedermann's Centralblatt*, x., 1.

ON THE

SPECTRUM IMPRESSED ON SILVER CHLORIDE AND ITS BEARING ON SILVER PRINTING IN PHOTOGRAPHY.*

By Capt. W. DE W. ABNEY, R.E., F.R.S.

SILVER chloride is the haloid salt of silver which is most employed in silver printing in photography; but, till quite recently, it has been difficult to develop an image on it except by means of acid development. Even then it is necessary to give a very prolonged exposure, masking much that could be learnt regarding the rays to which it is sensitive, which is not the case when a short exposure can be given to it, and a stronger method of development. When silver chloride is formed as an emulsion in gelatin, plates may be prepared which Dr. Eder and Capt. Pizzighelli have shown can be developed with a neutral organic iron compound, viz., a solution of ferrous citrate in citrate of ammonia, or, as I have shown, by a stronger developer, viz., dissolving ferrous oxalate in a solution of potassium citrate. Dr. Eder has shown that hydrokinone—a developer which I brought to notice a year ago—could also be employed by rendering it alkaline with ammonium carbonate. In my recent investigations all these developers have been employed.

Gelatin plates were prepared containing silver chloride in its ordinary molecular state, as precipitated by a cold solution, and also others with the chloride modified in molecular structure by the aid of heat or by the application of ammonia. These were exposed to the spectrum, and on developing the three kinds of plates no very marked variation in the region to which the silver chloride is sensitive was observable. The place of maximum intensity at the least refrangible part of the spectrum was found to be at H,—that is, at the limit of the visible spectrum,—and the curve of sensitiveness seemed to follow the curve of energy in the ultra violet.

The absorption spectra of the chlorides were next photographed, and in the case of the cold-precipitated chloride a very faint canary-coloured tint was observed, and in the spectrum obtained there was total absorption beyond H, rapidly diminishing towards *h*, and fading off about F. From the modified chloride the slight absorption did not appear to reach beyond F, but started abruptly near H.

It will thus be seen that the absorption spectrum answered to the spectrum impressed on the silver chloride; that is, that where the radiations were absorbed work was done in the molecules of the silver chloride.

My next experiment was to expose to the spectrum silver chloride spread on paper, to which a slight wash of potassium nitrate was given in order to absorb the chlorine evolved by the action of light, which the gelatin did in the first experiments. By careful observation it was found that the maximum intensity, as shown by visible colouration, was situated at the same locality, viz, H, spreading to G, and below; in fact the two spectra, viz., the developed and the printed, agreed perfectly together.

When ordinary sensitised albumenised paper was exposed to the printing action of the spectrum, the H lines and the G lines appeared apparently simultaneously, but there was a marked difference in the colour of the two portions. That part near H was much bluer than near G. Where the spectrum was allowed to fall on pure albuminate of silver the maximum effect was found near G, and G was found to be impressed before H. Now, in albumenised paper we have two factors. We have the albuminate of silver and also the silver chloride, both of which are formed when the albumenised paper of commerce is floated on the silver nitrate bath. We have therefore a ready explanation of the behaviour of the albumenised paper when placed in the spectrum, and the difference in colour about G and H. About H the chloride, and at G the albuminate, of silver give their colour to the print.

There is a practical appreciation of this research in ordinary photographic printing. In the winter time it is well known that silver prints on albumenised paper lack the brilliancy of tone which can be secured in the summer or spring, and that in dull weather the same want is felt. In the winter time the light is deficient in the ultra violet rays, and consequently more proportionate work is done by the albuminate than by the chloride of silver. In other words, the image is more composed of the former than of the latter.

I may point out a remarkable confirmation of this result in position of maximum sensitiveness in the spectrum impressed on silver chloride, as found by Dr. Eder. He found the maximum in the blue, and that for taking negatives the silver chloride had only one-twentieth the rapidity of silver bromide in the same medium. My own experiments were made in July, and the sensitiveness of the chloride for negative work was but little inferior to that of silver bromide, whilst my maximum was found at H. The extra proportion of ultra violet rays evidently gave the increase in apparent sensitiveness, and also the shifting of the least refrangible maximum. I am not aware what prisms Dr. Eder used. If he employed those so often found in Germany, which have a yellowish tint, there would be a sound reason why he found the maximum in the blue. In my own case a diffraction grating with quartz lenses were used, or else very white medium-dense flint-glass prisms. Be this as it may, I have no hesitation in placing the maximum at H. It should be remarked that for the comparison of all silver salts a standard light should be used, and the most convenient that I have found is the crater of the positive pole of the electric light, an image of which is projected on the slit. Since this has always the same temperature, the same proportion of rays are emitted.

The examination thus made also points to the necessary care that must be taken in suiting the quantity of silver chloride to albumen for different states of light in silver printing,—or, at all events, to the length of time of sensitising albumenised paper,—so as to obtain a right proportion of the organic and haloid salts. Into this question I need not enter, since I have treated of it elsewhere. The remarks I then made were based on long-continued practice in silver printing, being unaware, when they were written, as to the theoretical reason for the course to be pursued.

It is a very common idea that the rays which can affect silver chloride, or indeed any other silver haloid, are dependent on the medium in which it is placed. I would point out that this is not the case, so far as regards the haloid. If the medium absorb the rays which can affect the haloid, then we may look for an alteration in effect, and not otherwise. The molecules will always answer to the same undæ if these undæ can have access to them.

It is in the knowledge of photographers that the different colour of the deposit of silver in a negative largely modifies the tone of the print and its capacity for giving brilliant prints. The explanation will be found in what I have brought forward. Thus, in my hands, prints from negatives which are stained of a yellow or brown colour—such as are many gelatin negatives—can never secure that brilliancy of tone that a negative which is colourless can give. There is also an olive-green colour to the deposit of silver in some negatives, which, though very thin to all appearance, gives excellent prints. This particular colour in very moderate thickness cuts off all the ultra violet rays; hence its efficiency. The black deposit of silver which is particularly noticeable in negatives developed by ferrous oxalate cuts off all rays nearly equally; hence the greater facility of judging the right intensity of a negative when this means of development is adopted. My advice to photographers is that at all hazards they should get rid of the brown stain which is so apparent in many gelatin negatives, if they wish to secure the greatest brilliancy in their prints from such negatives.

One more bearing this subject has, viz., on the scientific measurement of the radiation of total daylight by means

* Read before the British Association, York Meeting, Section B.

of silver chloride. Up to the present time I have always been under the impression that we have, by means of Roscoe's actinometer, been measuring all the rays as far as G in their totality. I think it will be seen that we are measuring less than that. For my own part, I would say that I am glad of it; for the more we can isolate any particular parts of the spectrum for measurement the better it is for the value of those measurements. Perhaps by using twin instruments—one fed with silver chloride paper and another with silver bromide—we may get still further advantages than we are already reaping from the continuous observations we are making at South Kensington.

I would here wish to add that Mr. H. Darwin, with the advice of Prof. Roscoe, has now made a form of Roscoe instrument which works perfectly in every way; and I hope that Prof. Roscoe may next meeting be able to criticise the results obtained by our proposed trial of chloride and bromide, and tell us whether he thinks the suggestion now made is worth carrying on.

I need scarcely point out the importance of the methods introduced by Dr. Roscoe of obtaining a record of the effect of certain radiations of daylight; and it appears to me that we are now, by the aid of the new instrument, in a position to make more exhaustive records than has previously been the case.

NOTE ON A NEW METHOD OF MEASURING CERTAIN CHEMICAL AFFINITIES.*

By ALFRED TRIBE.

WHEN a metal is immersed in an electrolytic field (*i.e.*, in an electrolyte in the act of electrolysis), and the electromotive force set up on any part of its surface suffices to overcome the affinities of the radicles of the medium, the positive ion separates on that part of the surface which may be supposed to have received −electrification, and the negative ion on that part which receives +electrification.

When the metal is in the form of a rectangular plate, and placed so that the lines of force are perpendicular to its surface, the maximum electromotive force set up is on the central parts of such a plate, becoming less towards the edges, where, and for some little distance from which, it is insufficient to initiate electro-chemical action.

When the rectangular plate is placed in the electrolytic field, so that the lines of force are parallel with one of its edges, the maximum electromotive force is on the end of the plate, becoming less and less towards the central parts until it no longer suffices to bring about electro-chemical action. This is denoted by the boundaries of the deposit, which in many cases are very sharply defined. A plate, in fact, in the position just named, may be regarded, in so far as electrical power is concerned, as a series of pairs of electrodes, the limit of the electro-deposits representing a pair, the electromotive force of which is just incapable of resolving the electrolyte into its constituent ions (*Proc. Roy. Soc.*, Nos. 209, 214, 1881; *Phil. Mag.*, p. 446, 1881).

The very intimate relation between electromotive force and chemical affinity was a long time ago pointed out by Sir W. Thomson, and recently in an elaborate research by Dr. Wright. It was therefore anticipated that if, in a series of trials, the chemical affinities were altered while other circumstances remained the same, the magnitude of the intermedial space between the boundaries of the electro-deposits would increase along with the force required to overcome the affinities of the ions of the electrolyte.

A series of experiments with molecular solutions of the chloride, bromide, and iodide of zinc with plates (*analysers*) of silver, copper, iron, and zinc, showed that this is the case; *i.e.*, the intermedial space with the chloride was greatest, the bromide less, and the iodide least. Another series with silver analysers, but with molecular solutions of the sulphates of zinc and copper, showed that the intermedial space in the case of the zinc sulphate was much the greater. Again, another series with zinc sulphate showed that a zinc analyser gave the least intermedial space, iron greater, copper greater still, and silver most of all.

This method affords a simple means of demonstrating differences of chemical affinity, but whether it is capable of giving more than approximate measurements will require further investigation to determine. In some cases secondary actions are, of course, set up, so that the intermedial space would represent the initial electromotive force + or − any interfering electromotive forces.

Dulwich College, August, 1881.

CELLULOSE AND COAL.*

By E. J. BEVAN and C. F. CROSS.

IN prosecuting our researches into the constitution of the jute fibre, we subjected it to the action of sulphuric acid, with the object of converting the carbohydrate constituents into dextrin and the aromatic constituents, which we have shown to belong to the tannin group, into the condensation-products characteristic of this group, and thus of effecting their more accurate separation. The fibre was dissolved by the acid at ordinary temperatures to a viscous solution; on diluting a flocculent precipitate of the aromatic bodies was formed, but on washing it passed into solution in proportion as the acid was washed away. On heating the viscous solution to from 60° to 70° for some minutes a copious separation of a black substance took place, and on adding water and filtering we obtained a colourless filtrate from which the whole of the fibre substance appeared to have been removed. This black substance was converted by the action of chlorine into a substitution compound of bright yellow colour, completely soluble in alcohol, and containing, therefore, no free carbon. To the formation of the black substance the cellulose of the fibre had evidently contributed, and we therefore for obvious reasons turned our attention to the action of the acid upon this substance. Taking an acid, of sp. gr. 1·6, and heating the viscous solution of the cellulose (dextrin) to from 70° to 80°, the colour changed from yellow to dark brown; copious effervescence then ensued, and accompanied by the formation of a considerable quantity of acetic acid, a black spongey substance separated out, which was instantly drenched with water. On washing and drying at 100° it passed into a form exactly resembling an ordinary coal; and the resemblance did not end here, the composition proving to be similar as regards C, H, and O, as was also its behaviour on heating. We append analyses of preparations of this body:—

From dextrin	0·2505 gave	0·0935 H_2O and	0·5845 CO_2
,, ,,	0·254 ,,	0·097 ,, ,,	0·594 ,,
From jute	0·159 ,,	0·064 ,, ,,	0·374 ,,

C	63·6	63·7	64·4
H	4·14	4·24	4·4
O	32·26	32·06	31·2
	100·00	100·00	100·0

If the acid be more concentrated, or the mass be rapidly heated, more highly carbonaceous products are obtained, having, moreover, a much denser structure. One of these bodies was found to contain 68·5 per cent C and 4·04 per cent H.†

* Read before the British Association, York Meeting, Section B.

† Compare lignite containing 68 per cent C and 5·8 per cent H (Vaux).

The spongy products are easily converted by the action of a current of chlorine gas at ordinary temperatures in presence of water into orange-coloured substitution derivatives, exactly resembling those obtained by the direct chlorination of lignified fibres, *i.e.*, smelling of tetra-chloroquinon, soluble in alkalies to deep red-brown solutions, which are much deepened in colour by previous treatment with sodium sulphite. The denser products are also convertible into these derivatives, but they require the action of $KClO_3$ and HCl (dil.) at 70°. We append the analysis of one of these derivatives obtained by the latter method and carefully purified.

0·4655 gave 0·464 AgCl and 0·013 Ag

			Calc. $C_{20}H_{16}Cl_4O_{10}$
C ..	43·56	43·6	43·01
H ..	2·82	2·76	2·86
Cl ..		25·58	25·4

Comparing this body with those obtained by us from jute, $C_{19}H_{18}Cl_4O_9$, and esparto, $C_{22}H_{23}Cl_4O_{10}$ (*Journ. Chem. Soc.*, 38, 666), the resemblance is seen to extend to composition. Having, therefore, through the medium of the action of sulphuric acid, passed from carbohydrated to bodies of aromatic structure, identical, moreover, with those directly obtainable from lignified fibres, are we justified in assuming that any such conversion takes place, in the living plants, of cellulose into lignin?

In the first place, working to this hypothesis, we found that the reaction of dextrin with sulphuric acid is very destructive in character. Three determinations of the yield of the (spongey) black substance gave the following percentages: 35·1, 34·8, 34·3. Allowing for the higher percentage of carbon in the product, these members correspond to about 50 per cent of the original carbon, *i.e.*, one half the carbon has been eliminated as carbonic and acetic acids, &c. Without further evidence, therefore, it cannot be inferred that there is anything in the reaction more than a passage from one great group of carbon compounds to another.

On the other hand, in fibres which tend to lignification the percentage of cellulose is always inverse to that of lignin; and the microscopic investigation of the process of lignification has led to the conclusion that it is the result of an intrinsic modification of the substance of the cell wall (cellulose), and not to the infiltrating of substances from the cavity of the cell.

In jute there is evidence of the existence of a constituent intermediate between these two groups—a body which by special treatment may be converted into cellulose, but in the ordinary processes of estimating cellulose is degraded by oxidation into bodies of the humus group. Thus, in our method of estimating cellulose, if the chlorination of the fibre is followed by some hours' contact with sulphurous acid, previously to the alkaline treatment, the result is an increase in the yield of cellulose to the extent of 2 to 5 per cent. An investigation of the formation of hippuric acid in the process of digestion (herbivorous) led to the conclusion by Meissner and Shepard ("Die Hippursäure," Hannover, 1866) of the presence of a particular constituent in ordinary fodder (hay), containing a benzoic residue, the withdrawal of which causes the disappearance of the acid from the urine; this constituent they regard *as a particular form of cellulose*. Our own investigation of hay led to the identification therein of the aromatic constituents characteristic of bast fibres; and we have, therefore, in the above conclusion, a further probability of the conversion of cellulose into aromatic bodies as the result of plant life, and therefore of the existence of intermediate products. We have previously (*loc. cit.*) spoken of a peculiar degradation of the jute fibre, the result of a species of fermentation which takes place when masses of the fibre are allowed to lie in the damp state. The most noticeable features of this decomposition are the destruction of cellulose (20 to 30 per cent) and the formation of a soluble astringent, aromatic substance, belonging to the tannin group. When these facts are considered in connection with the homogeneity of the jute fibre,* and with the fact that although *resolvable* into cellulose and aromatic bodies, the association of its constituents in the natural fibre is of the most intimate character, the conclusion of a close structural connection is almost inevitable. The whole chemistry of the astringent substances, their almost invariable association with carbohydrates, their evident formation at the expense of the constituents of normal plant structures (pathological tannins), and the long held but recently controverted view of tannic acid as being a *glucoside* of gallic acid, shows the intimate connection in nature of these bodies with the carbohydrates.

We have now to say a few words on the subject of coal, to a consideration of which our experiments obviously lead. It is sufficiently expressive of the comparative looseness of views upon this subject to find that the authors of our most modern handbook do not hesitate to speak of coal "*as a form of carbon* less pure than wood charcoal."† Balzer has recently given expression to the more reasonable hypothesis that it is made up of a series of compounds of C, O, N, and H, genetically if not homologously related. We have found that a cannel coal when treated with chlorine in presence of water is converted into substitution-products of a brown colour, which when treated with potash swell up like starch and are then dissolved to a deep brown solution, without residue. On neutralising with an acid a copious flocculent precipitate is obtained which shrinks enormously on drying, and ultimately yields a black jet-like substance of high lustre. The same coal reacts also vigorously with bromine and with nitric acid, being likewise converted into soluble products. As, however, the carbon hypothesis of the composition of coal has never held any place as a substantive theory, it scarcely needed to be dislodged by experiment. These facts, however, and the formation of similar coal-like bodies from cellulose by the action of sulphuric acid, make it at least probable that cellulose, lignin, peat, lignite, cannel coal, and anthracite, are terms of a vast series of compounds, differentiated under natural conditions difficult of elucidation and impossible to reproduce.

* Compare also Erdmann's researches on glycodrupose (*Ann. Chem Pharm.* 138, 1), which we find closely similar in composition.

LONDON WATER SUPPLY.

REPORT ON THE COMPOSITION AND QUALITY OF DAILY SAMPLES OF THE WATER SUPPLIED TO LONDON, FOR THE MONTH ENDING SEPTEMBER 30TH, 1881.

By WILLIAM CROOKES, F.R.S.
WILLIAM ODLING, M.B., F.R.S., F.R.C.P.,
Professor of Chemistry at the University of Oxford;
and C. MEYMOTT TIDY, M.B., F.C.S.,
Professor of Chemistry and of Forensic Medicine at the London Hospital; Medical Officer of Health for Islington.

To the RIGHT HONOURABLE THE PRESIDENT OF THE LOCAL GOVERNMENT BOARD.

October 3rd, 1881.

SIR,—We beg to lay before you the results of our daily examinations of the water delivered, for the month ending the 30th of September, by the seven London water companies taking their supply from the Thames and the Lea. The samples are taken by a man in our service at places and times which we ourselves appoint.

In 12 only of the 182 samples taken during the month were we able to detect by examining the water in large bulk

with the naked eye the minutest trace of matter in suspension. The turbidity in six of these samples occurred in the supply of the East London Company.

In Table I. we have recorded the analyses in detail of samples, one taken daily from September 1st to September 30th inclusive. The purity of the water in respect of organic matter has been determined by the Oxygen and the Combustion processes, and the results of our analyses by these methods are stated in columns XIV. to XVIII.

We have recorded in Table II. the tint of the several samples of water as determined by the colour-meter we have described in a previous report.

Of the 26 samples supplied by the New River Company, the whole, without exception, were found to be well filtered, clear, and bright.

Of the 26 samples from the mains of the East London Company, six were recorded as "very slightly turbid," the remainder being well filtered, clear, and bright.

Of the 26 samples from the mains of the Chelsea Water Company, all (excepting one) were found to be well filtered, clear, and bright.

Of the 26 samples from the mains of the West Middlesex Company, the whole, excepting one sample which was "very slightly turbid," were found to be well filtered, clear, and bright.

Of the 26 samples from the mains of the Lambeth Water Company, the whole excepting one which was "very slightly turbid," were found to be well filtered, clear, and bright.

Of the 26 samples from the mains of the Grand Junction Company, the whole excepting two which were "very slightly turbid," were found to be well filtered, clear, and bright.

Of the 26 samples from the mains of the Southwark and Vauxhall Company, one was noted as "very slightly turbid." The rest were well filtered, clear, and bright.

In Table III. we have recorded the oxygen required to oxidise the organic matter, and the quantities of free oxygen present in the whole of the samples collected.

Altogether, the water supplied by the Companies during the month of September continues to be of excellent quality, though no longer presenting that exceptional freedom from other than blue colour, by which it was characterised during the summer months.

We remain, Sir,

Your obedient Servants,

WILLIAM CROOKES,
WILLIAM ODLING,
C. MEYMOTT TIDY.

SOME DOUBLE AND TRIPLE OXALATES CONTAINING CHROMIUM.

By F. W. CLARKE.

CHROMIC oxalate unites with other oxalates to form two well-known series of double salts. One series is represented by the blue potassio-chromic oxalate, $Cr_2K_6C_{12}O_{24}6H_2O$. The other is typified by the red salt, $Cr_2K_2C_8O_{16}8H_2O$. The compounds described in this paper belong to the higher series.

The barium, strontium, and calcium salts of this series were discovered by Rees-Reece.* By mixing solutions of the ammonium salt with the chlorides of barium, strontium, and calcium, he obtained precipitates of dark violet silky needles, having the following formulæ:—

1. $Cr_2Ba_3C_{12}O_{24}.12H_2O$.
2. $Cr_2Ba_3C_{12}O_{24}.18H_2O$.
3. $Cr_2Sr_3C_{12}O_{24}.18H_2O$.
4. $Cr_2Ca_3C_{12}O_{24}.36H_2O$.

By a different process, Berlin† prepared a calcium salt with 18 aq., a lead salt with 15 aq., and a silver salt with 9 aq.; besides other compounds which need no mention here.

About a year ago, I requested Mr. E. A. Kebler to reprepare the barium salts described by Rees-Reece. The only variation from the method of the latter chemist was in using the potassium salt instead of the ammonium salt for the precipitant. Masses of very dark green silky needles were thrown down, and these were easily re-crystallisable from boiling water. Two hydrates of the desired salt were thus obtained, one agreeing with the twelve molecule salt of Rees-Reece, while the other, lighter coloured, contained but seven molecules of water. For the latter, the subjoined analytical data were found:—

	Found.	Theory.
Cr	8·94	8·90
Ba	34·96	35·16
H_2O	10·91	10·77

The formation of this new hydrate naturally led to experiments aimed at the discovery of the conditions under which different degrees of hydration were produced. Although this point was not definitely settled, interesting results were secured. Four samples of the double oxalate were precipitated, two from dilute and two from concentrated solutions. Two were thrown down in the cold, and two were precipitated boiling. All the precipitates were in the form of green silky needles, which were carefully air dried. In these several preparations the following percentages of water were obtained:—

						Mean.
Precip. concent'd, cold	9·50	9·78	9·19			9·49
Precip. concent'd, hot	9·39	9·31				9·35
Precip. dilute, cold	9·98	9·90	9·43	10·10	10·72	10·03
Precip. dilute, hot	12·07	12·13	11·12			11·77

Theory for 6 molecules of water	9·38
" " 7 " "	10·77
" " 8 " "	12·13

It will be seen that the two salts precipitated from concentrated solutions are definitely hexhydrated; the third salt gave doubtful results; while the last agrees fairly with the percentage for eight molecules of water. Evidently the six molecule salt is definite and typical; doubtless the twelve and eighteen molecule salts of Rees-Reece are definite also; all the other hydrates may be but mixtures of the lowest with one of the higher compounds. This point remains to be settled. The colour is always darker, the higher the hydration; but, though green under ordinary circumstances, all the salts described in this paper become dull violet by gaslight. Specific gravities were found as follows:—

$Cr_2Ba_3C_{12}O_{24}$	Anhydrous	2·570 at 6·8°
"	$6H_2O$.	2·445 at 13·9°
"	$12H_2O$.	2·372 at 27°

Here the second salt is nearly a mean between the other two.

The strontium salts were also prepared by Mr. Kebler, under varying conditions of temperature and dilution. These too came down as pale green satiny needles of considerable beauty, and easily re-crystallisable from hot water. From cold dilute solutions the salt $Cr_2Sr_3C_{12}O_{24}.12H_2O$ was precipitated.

	Found.	Theory.
Cr	9·36	9·37
Sr	23·59	23·64
H_2O	19·29	19·45

From the mother-liquor and washings of this salt a somewhat lower hydrate was deposited, possibly a mixture, corresponding in hydration to $10\frac{1}{2}$ molecules of

* *Comptes Rendus*, xxi., 1116.
† *Berzelius' Jahresbericht*, xxiv., 244.

water. Specific gravity 2·148 at 8·8°. From hot concentrated solutions of the precipitants a deca-hydrated salt was obtained. Calling these salts A and B respectively, we have the following analytical data:—

	Found.		Theory 10½ aq.	Theory 10 aq.
	A.	B.	A.	B.
Cr ..	9·55	9·52	9·59	9·67
Sr ..	24·14	24·31	24·22	24·45
H_2O..	17·36	16·87	17·40	16·75

I am inclined to look upon these preparations as mixtures of the twelve molecule salt with small quantities of a hexhydrated salt yet to be discovered.

The mother-liquors from all these strontium precipitates were united and concentrated. Upon standing, a very dark green, almost black, crystalline crust was deposited. This, which had a specific gravity of 2·155 at 12·8°, proved to be a new triple oxalate having the formula—

$$Cr_2Sr_2K_2C_{12}O_{24},$$

with either eleven or twelve molecules of water.

	Found.	Theory, 11 aq.	Theory, 12 aq.
Cr	9·51	9·60	9·44
Sr	16·15	16·15	15·89
K	7·26	7·22	7·10
H_2O ..	18·33	18·28	19·61

I suspect that the twelve molecule formula is the true one, and that the salt as analysed by Mr. Kebler may have been slightly effloresced. Still, the analytical agreement with the lower formula is wonderfully close.

The discovery of this new triple salt led to a search for the corresponding barium compound. The ordinary bario-chromic oxalate was accordingly dissolved with an equivalent quantity of the potassium salt in boiling water, and the mixture was then heated with barium carbonate in order to remove a little free oxalic acid which happened to be present as an impurity. Upon filtering, dull bluish green needles were deposited, having the composition $Cr_2Ba_2K_2C_{12}O_{24}$, with five or six molecules of water.

	Found.	Theory, 5 aq.	Theory, 6 aq.
Cr	9·86	9·68	9·53
Ba	24·25	25·51	25·09
K	7·41	7·28	7·14
H_2O ..	8·65	8·38	9·89

Since the salts which yield this triple salt each contained six molecules of water, I am inclined to consider that as the true degree of hydration for the compound now in question. In fact, throughout this series of complex oxalates, the hydration is almost uniformly six molecular, or represented by some even mutiple of six. The chief exceptions are the lead and silver salts of Berlin, with 15 aq. and 9 aq. respectively; values which are regular submultiples of six.

The process by which these barium and strontium salts are prepared from the potassium salt is suggestive of their constitution. We may fairly regard the chromic oxalate itself as a weak acid, having the subjoined structural formula:—

$$\left.\begin{matrix}H.C_2O_4\\H.C_2O_4\\H.C_2O_4\end{matrix}\right\}Cr—Cr\left\{\begin{matrix}C_2O_4.H.\\C_2O_4.H.\\C_2O_4.H.\end{matrix}\right.$$

These six atoms of hydrogen are replaceable by six potassium atoms, by three barium atoms, or by two of each, and so on with all the other salts of the series. If chromium be regarded as trivalent, the formulæ should of course be halved.

We attempted to prepare the sexbasic acid here suggested, but did not attain to final results. The barium salt was decomposed by an exactly equivalent quantity of sulphuric acid. Upon filtering, an acid liquid was obtained, strongly dichroic, and dark violet red by transmitted light. Probably this was the acid in question, but actual proof is yet wanting.

Mr. Kebler also tried to prepare several other salts of the series under discussion, but unsuccessfully. No calcium salt like that of Rees-Reece could be obtained. Calcium oxalate, slightly discoloured by chromium, was thrown down every time. With salts of cadmium, cobalt, ferrous iron, zinc, copper, lead, and stannous tin, the blue potassio-chromic oxalate gives either no precipitate, or else, after some time, a precipitate of the ordinary oxalates of the metals in question. The filtrates from these oxalates afterwards deposit crystals, too impure for analysis, which appear to be the potassio-chromic salt of the red series. The plan of heating bario-chromic oxalate with the sulphates of cadmium, cobalt, copper, iron, and zinc was also tried. In each case an ordinary oxalate was formed, mixed with barium sulphate.—*American Chemical Journal.*

NOTES OF WORK BY STUDENTS OF PRACTICAL CHEMISTRY IN THE LABORATORY OF THE UNIVERSITY OF VIRGINIA.

No. X.

Communicated by J. W. MALLET,
Professor of General and Applied Chemistry in the University.

(64.) *On Iod-ammonium Iodide, the Product of the Action of Dry Gaseous Ammonia upon Iodine.* By W. H. Seamon, of Wheeling, West Virginia.

In 1814 Colin* examined the action of dry ammonia gas upon dry iodine, and observed the production of a viscid liquid, which had a somewhat metallic lustre, was non-explosive, and took up an excess of ammonia, forming a less viscid, very dark red-brown liquid, also without explosive character, the union of the two substances being attended with rise of temperature, but no evolution of gas. He considered that simple "protiodure" and "deutiodure d'ammoniaque" had been formed, but gave no quantitative results.

In 1838 Bineau† exposed a known amount of iodine in a recurved gas jar to the action of gaseous ammonia, and determined the volume absorbed of the latter. Reducing volume to weight, he found in two experiments that 100 parts of iodine took up 20·7 and 20·4 parts respectively of ammonia. Hence he deduced the formula $N_3H_9I_2$, and suggested that either the compound is simply an "iodide of ammonia," as imagined by Colin, or may be viewed as containing nitrogen iodide, and represented as—

$$3(NH_3.HI)+NI_3+5NH_3, \text{ or as}$$
$$3\left\{(NH_3)_2.HI\right\}+(NH_3)_2.NI_3.$$

In the same year Millon‡ published the results of his experiments upon the second (more fluid) of the compounds produced by Colin, which alone he considered to be definite in character, the viscid liquid containing in addition variable amounts of free iodine. Millon found that at +10° C. 100 parts of iodine absorbed 8·3 parts of ammonia, when the tube was surrounded by snow the gain of weight was 9·0 parts, and when surrounded by a mixture of snow and salt 9·4 parts. He stated that it was impossible to produce complete saturation, since after a time a continuous current of ammonia carried off some of the product, and accurate weighing of the residue was prevented. He concluded that the substance actually produced contained I_3 for $(NH_3)_2$, but may be represented by the formula $3(NH_3.HI)+(NH_3)_2.NI_3$, with an excess of iodine due to incomplete saturation, this formula

* *Annales de Chimie*, 91, 262.
† *Annales de Chimie et de Physique* (II.), 67, 226.
‡ *Annales de Chimie et de Physique* (II.), 69, 84.

agreeing with his supposed production of the same substance by the action of ammonium iodide on so-called iodide of nitrogen containing hydrogen.

Mr. Seamon made a number of experiments with a view to ascertaining precisely what compound or compounds can be produced by the absorption at various temperatures of dry gaseous ammonia by pure solid iodine. The results were indefinite and unsatisfactory until the following plan was adopted. The ammonia was expelled by heat from its aqueous solution, and dried by passage through a cool empty bulb, a U-shaped tube of lime, and finally two tubes of solid potassium hydrate, making together 1 metre in length. The iodine was placed in a long-necked flask, fitted with two tubes, one, reaching nearly to the bottom, serving to introduce the gas, while the other carried off such of it as was not absorbed. The flask was immersed in a bath of melting ice crushed to small fragments. The flow of gas was kept up as long as any was absorbed. The greater part of the liquid product from the bottom of the flask was then transferred to a previously weighed, dry, wide-mouthed, glass stoppered, little bottle, which was at once placed (without the stopper) inside a jar admitting of being tightly closed, the same jar also containing a second open, wide-mouthed bottle of concentrated sulphuric acid. The jar was closed, surrounded by melting ice, and allowed to stand for ten days, with renewal of the ice as it melted. The acid kept the interior of the jar dry and absorbed all surplus ammonia, of which a considerable quantity was given off by the iodine compound. At the end of this time, it having been ascertained by occasionally inserting the stopper in the weighing bottle and determining its weight that no further loss of ammonia would take place, the bottle was removed, and its weight accurately taken. The contents were washed out with a solution of sodium sulphite, and in separate portions of the liquid the iodine was determined as silver iodide, and the ammonia by distillation with sodium hydrate, absorption in standard sulphuric acid, and titration with standard soda.

The results of analysis were definite and consistent. In one experiment, in which about 12 grms. of the iodine compound had been formed, Mr. Seamon obtained—

		Calc. for NH_3I_3.
I	93·745	93·702
NH_3	6·190	6·298
	99·935	100·000

It is obvious, therefore, that the compound in question, prepared under these definite conditions, is identical with the iod-ammonium iodide, which may be written—

$$N\left\{\begin{matrix}H_3\\I\end{matrix}\right\}I,$$

prepared by Guthrie* by treating a saturated solution of very soluble ammonium salt (nitrate or carbonate) with about one-third of an equivalent of potassium hydrate, and adding finely powdered iodine in small portions, avoiding excess.

The general properties of the material agree with Guthrie's description. It is in mass a black, lustrous liquid, in thin layers of dark red-brown colour by transmitted light. Sp. gr. = 2·46 at about 15° C. Solidifies at −8° C. to a reddish black solid, which melts again at −2°. Is slowly decomposed by keeping at a temperature a little above 15°; more rapidly, without boiling, at 70°. It is readily soluble in glacial acetic acid, anhydrous glycerin, absolute alcohol, and dry ether: less soluble in benzene and carbon disulphide.

No definite substance could be obtained correspoding to the formula of either Millon or Bineau.

(65.) *On an Interesting Specimen of Native Gold from Montgomery Co., Virginia.* By SAMUEL PORCHER, of Hanover Court-House, Virginia.

The specimen in question represents the product of gold-washing, which has for the last year or two been carried on with some profit in Montgomery Co., in this State. The metal is in small rounded grains, which have almost exactly the colour of fine gold and full metallic lustre; but the specific gravity is low (15·46), and on cutting the grains, or scraping them with a knife, it becomes apparent that the colour first observed is superficial only, the metal in the interior being almost white. Mr. Porcher's analysis gave—

Gold (by cupellation and parting)	65·31
Silver (by cupellation and difference) ..	34·01
Copper	0·14
Iron	0·20
Quartz	0·34
	100·00

The atomic ratio of gold to silver is 100·0 : 94·9. Hence, allowing for the partial removal of silver which the surface has experienced, this alloy seems in all probability to consist of single atoms of the two precious metals, or may be represented as AgAu. The like proportion is recorded for a native gold from Transylvania, and one from Santa Rosa, New Grenada, both analysed by Boussingault,* and one from Schlangenberg, in the Altai, analysed by Klaproth.†

(66.) *On the Temperatures at which Mercuric Oxide is formed, by Direct Union of its Elements, and Decomposed, respectively.* By W. H. ECHOLS, jun., of Huntsville, Alabama.

It was known as early as the days of Geber that metallic mercury moderately heated in the air becomes converted into a red solid substance, and that a stronger heat prevents this or reproduces the metal with its original properties, and these changes have acquired historic importance as furnishing the means to Lavoisier for the analysis of air. No statement is, however, on record, so far as I am aware, as to the exact points of temperature at which the two opposite changes occur, most of the text-books merely saying that the metal heated to about its boiling-point is converted into mercuric oxide, and that this oxide at something like a red heat is resolved again into mercury and oxygen.

Mr. Echols made some experiments on the temperature required for the two changes in question, using Carnelly's method‡ of comparison with the fusing-points of various salts heated under similar conditions. A piece of hard glass combustion tubing, open at both ends, was bent to an obtuse angle in the middle; pure mercury was placed in the bend, which was immersed in a bath of melted lead, heated by a large gas burner. A very slow stream of dry oxygen was passed through the tube. A precisely similar tube placed beside this contained at the bend a small quantity of each of the comparison salts taken separately in succession. The temperature was very gradually raised. The red oxide began to be formed at a temperature between the fusing-points of—

ZnI_2..	446° C. (Carnelly) and
AgCl	451 ,, ,,

The red mercuric oxide (crystalline) was then placed in the bent tube, and the temperature gradually raised until the first faint deposit of metallic mercury was seen to form on the cool part of the glass. This occurred between the fusing-points of—

NaI	628° C. (Carnelly) and
KI	634 ,, ,,

The experiments were repeated with dry air passing through the tube instead of oxygen. No difference was observable, except that the temperature at which the oxide was formed seemed to be if anything a little nearer

* *Chem. Soc. Jour.*, July, 1863, 239.

* *Annales de Chimie et de Physique*, 24, 408.
† *Beiträger*, iv., 1.
‡ *Chem. Soc. Jour.*, July, 1878, 273.

the melting-point of the silver chloride than that of the zinc iodide.

Hence it may be stated that mercuric oxide is first formed by direct union of mercury and oxygen at about 450° C., and that mercuric oxide begins to be decomposed at about 630°. All the experiments were made under ordinary atmospheric pressure, about 740 to 745 m.m.

(67.) *On the Production of Hydrated Crystals of Barium Nitrate in Isomorphous Admixture with Strontium Nitrate.* By R. A. Berry, of Marion, South Carolina.

It is remarkable, in view of the isomorphous relations of barium and strontium salts, that no hydrated nitrate of barium has been obtained with composition analogous to that of the strontium salt, $Sr(NO_3)_2.4H_2O$. Indeed, the only substance in which water of crystallisation is reported as taken up by the salt of the former metal is that of an experiment by Hirzel,* in which a solution cooled to between 12° and 0° is said to have once yielded a product containing *two* molecules of water.

Mr. Berry made numerous attempts to obtain hydrated crystals of barium nitrate by evaporation of the solution under various conditions of temperature and rate of evaporation, including an air-pump vacuum over sulphuric acid in a receiver surrounded by ice, but in every case the common octahedral anhydrous crystals were alone obtained.

He then attempted to crystallise a mixed solution of the nitrates of barium and strontium at such low temperatures as would lead to the formation of hydrated crystals of the latter; but these were found to be free from barium, and the barium nitrate separated out in anhydrous octahedra.

At last, however, it was found that by saturating the same portion of water with both nitrates, introducing a well-formed crystal of hydrated strontium nitrate to serve as a nucleus, and evaporating *in vacuo* over sulphuric acid at a temperature kept close to 0° C., crystals identical in form with the nucleus could be grown, and these on analysis proved to contain the two nitrates in amorphous admixture. The water was determined by careful heating below the temperature of decomposition of either nitrate; the barium was separated as chromate by the method of Frerichs,† with attention to the suggestions in the paper by Morse‡—the method being also tested by comparative experiments here, and found to give satisfactory results—and the strontium was found by difference. Two analyses of different specimens, using in each case large *single* crystals only, gave§—

§ Not quite free from flaws or little internal cavities, hence doubtless the small excess of water.

NOTICES OF BOOKS.

A Report on the Teaching of Chemistry and Physics in the United States. By Frank Wigglesworth Clarke, S.B., Professor of Chemistry and Physics in the University of Cincinnati. Washington: Government Printing Office. 1881.

This report gives a very complete account of the manner in which chemistry and physics are taught in the United States. It is compiled principally from the answers given by the various professors and schoolmasters to certain questions asked. These questions, sent out by the Commissioner of Education towards the close of the year 1878, were very comprehensive, covering the ground from the most elementary work of the common schools up to the highest courses of the Universities. The history of instruction in chemistry and physics, the present courses of study, the text-books used, the value of apparatus, the laboratory facilities, the character of examinations, and the cultivation of original research, were all made subjects of enquiry.

Gradually answers came in: some questions were answered fully, others vaguely. One set of answers has been left almost entirely out of consideration, namely, those relative to examinations: they were full enough in many cases, but resting on no common basis they could not be fairly compared.

The object of the report is twofold—first, to state the facts; secondly, to point out the defects and remedies. The bulk of the work is occupied by text descriptive of single institutions, and by statistics of a general character.

The teachers are divided in opinion as to whether book work and laboratory practice should be carried on at the same time. The writer of this report holds strongly (and we think with good reason) to the opinion that both should go on together.

The comparison of the work done in chemistry and physics at schools and colleges is very interesting. In most cases the latter teach chemistry and physics to the same extent, and in the same manner as the former. It is obvious that the colleges ought to do higher work than the schools; the present duplication of studies is clearly a waste of time. In some few cases this rule is not followed, higher work being done than in the schools.

The chapter giving an historical sketch of the growth of chemistry in America is very interesting. Fifty years ago no college would have given chemistry an equal rank with Greek, but now choice is permitted between the two subjects in many institutions.

The University of Pennsylvania Medical School in 1768, the Medical School of Harvard College in 1782, and the Dartmouth School in 1798, are among the places where chemical science was first taught. Between 1800 and 1845 the study of science grew slowly but surely into favour; here and there at home professors opened laboratories for the use of the more scientifically-inclined students. One thing, however, was wanting, namely, the recognition of the importance of original research.

Among reports from over one hundred and seventy cities only a few show that there is *no* scientific training. In some schools the pupils begin laboratory work at a very early age. The following letter, written by a teacher in New York to the Commissioner of Education, will show what can be done for the advancement of scientific knowledge:—

"Dear Sir,—Twenty years ago I was in the habit of having a teacher lecture on chemistry and physics in my school. I asked him what he would charge to sit still and not touch anything, but give directions and advice while a small class of boys handled what was necessary and made their own experiments. He said, 'They will break things.' I said, 'Yes, you must take that into account.' After thinking about it he said, 'I should have to charge five dollars an hour.' This was rather

dear, but I concluded to try it. The first trial convinced me that I was on the right track. They were soon taught to handle acids, to bend glass tubes, as well as to make hydrogen and oxygen; and I saw small boys in my own school learn more of useful chemistry in three months than I learned in three years in college. Towards the close of the school year one of the boys came to me and asked for one of my visiting cards. On asking what for, I was told that their teacher of chemistry had informed them that there was a metal used in enamelling the cards, and they were directed to find it out. They did so. Two years ago I had in my school my son of nine years. On asking my teacher of chemistry whether he thought so young a boy could learn chemistry in this way, he said 'Certainly.' Joining two others of that age with him, I was quite surprised at the end of two weeks to see them making their own hydrogen and oxygen, and performing for themselves experiments that I used to look at with wonder when done by others while I was in college. I have pursued this practical system of teaching ever since, and always with success. My only difficulty has been to persuade parents to allow their children to be taught in this way. I have taken the liberty of writing to you at length about this matter, because it seems to me very important, and perhaps some one else may be encouraged to pursue the same course. I have been amazed at the general apathy displayed about these studies, and am delighted at your trying to arouse the public to a proper sense of their importance."

Many schoolmasters think that chemistry and physics cannot be taught practically without a quantity of expensive apparatus, but this is a mistake. A country school teacher was awarded a special prize at the Paris Exhibition for a set of apparatus made by himself out of the commonest materials (glass bottles and the like).

In the chapter on institutions for the superior instruction of women we read the following:—"One of the questions sent out in the circular issued by the Bureau of Education, preparatory to this report, was as follows.—'Are pupils permitted to do extra laboratory work?' To this the President of one of the female Colleges answers, 'Being girls, no.' This answer typifies a widespread sentiment and a common misapprehension as to the object of scientific teaching. It may represent the assumption that girls are in some mysterious way unfit to undertake laboratory practice, or the belief that such instruction would be useless to them. Neither view is correct, as the experience of many teachers of science can testify."

In the chapter on Universities, Colleges, and Schools of Science, a single rule is followed. With few exceptions, only those institutions are described in which laboratory work is done by students and carried as far as a course in qualitative analysis. The other colleges are duly treated of in the statistical tables.

There are about one hundred and twenty pages describing the various methods of teaching science in the Colleges and Universities, and then a list of text-books used. From the tables of statistics at the end we gather that, taking it all in all, chemistry and physics are very well taught in the United States. There are numbers of institutions which are well known and looked upon as first class colleges, while in England the number of such places is very few.

CORRESPONDENCE.

ACTINIUM.

To the Editor of the Chemical News.

Sir,—My experiments on the new metal Actinium have been interrupted in various ways, and by the fact that, for the sake of my health, I have been compelled to leave London for a short time. The metal has been isolated by means of magnesium, which precipitates it rapidly from its ammoniacal solution, with evolution of abundance of hydrogen and considerable production of heat. Zinc does not precipitate it either in the neutral, ammoniacal, or slightly acid solutions, either cold or hot. Precipitated by magnesium it forms a light grey deposit, which, by compression, becomes white like silver and extremely brilliant; it oxidises slowly in ordinary water and saline solutions, but can be preserved under alcohol. As the only method which I have yet discovered of separating oxide of actinium from oxide of zinc is by means of caustic soda, I am not certain that I have, hitherto, obtained the process perfectly exempt from oxide of zinc, even after four or five treatments at boiling heat. Hence, I hesitate for the present to describe its reactions and salts. However, I may state that the sulphate crystallises in magnificent modified octahedra. The sulphide in the state of hydrate oxidises somewhat by contact with the air, and in this state possesses the property of displacing ferrous oxide from the sulphate of iron. The action of light upon the partially oxidised sulphide is more rapid in contact with a little pyrogallic acid, ferrous sulphate, or yellow sulphide of ammonium. I hope to be able to continue these experiments in a few weeks.—I am, &c.,

T. L. Phipson.

Southsea, October 7, 1881.

CHEMICAL NOTICES FROM FOREIGN SOURCES.

Note.—All degrees of temperature are Centigrade, unless otherwise expressed.

Comptes Rendus Hebdomadaires des Séances, de l'Académie des Sciences. No. 9, August 29, 1881.

Dioptric Studies.—Ch. V. Zenger.—A mathematical paper, not capable of useful abridgment.

Certain New Cases of Equipotential Figures realised Electro-chemically.—A. Guébhard.—This memoir does not admit of abstraction.

Absorption of the Ultra-violet Rays by Certain Media.—M. de Chardonnet.—The juices of vegetables all appear greedy of the chemical rays. The sap of the vine in spring is very active, as are also tincture of arnica, and white and red wine, even when very dilute. Fluorescence does not seem to be in direct relation with the intensity of actinic absorption. With animal fluids the results are more varied. Blood, even much diluted, is an energetic absorbent. The aqueous humour of the eye and the white of a hen's egg have no action upon the chemical rays. Distilled water, alcohol, ether, collodion, and solution of cane-sugar are without action.

Figures Produced by the Fall of a Drop of Water holding Red-Lead in Suspension.—C. Decharme.—Regular figures have been obtained formed of red-lead arranged in rays and concentric rings.

Composition of Buck-Wheat.—G. Lechartier.—The proportion of mineral matter in the straw increases along with its weight. The straw may, indeed, become richer in phosphoric acid than the grain, differing thus completely from that of the cereals. The straw of a crop of buck-wheat may contain much more mineral matter than does the grain. The sum of the principal fertilisers removed from the soil by an entire crop is much more considerable than for a crop of wheat containing the same quantity of grain.

Hydrosulphurous Acid.—Aug. Bernthsen.—A reply to the papers of M. Schützenberger (*Comptes Rendus*, xcii., p. 875, and xciii., pp. 47 and 151).

Solution of Silver in Presence of Alkaline Iodides.—A. Ditte.—If a plate of silver is placed in a solution of

potassium iodide containing 5 per cent, and the whole is left exposed to the air, the metal becomes covered with brilliant crystals of silver iodide. The action is quickest at the surface where the access of the air is free. In very concentrated solutions there is no formation of crystals, as the silver iodide dissolves in the potassium iodide.

Constitution of Glyceric Ether and Transformation of Epichlorhydrin into Normal Propylic Alcohol.—R. D. Silva.—The author having prepared allylic alcohol by the method of Tollens and Henninger slightly modified, obtained the glyceric ether of Gegerfelt, the etheric character of which has not been established by any decided reaction.

Pyruvic Alcohol and its Derivatives.—L. Henry.—Dipropargyl yields, by double decomposition, hexylic diacetyl.

Action of Tri-ethyl-amin upon Epichlor-hydrin. Compounds of Oxallyl-tri-ethyl-ammonium.—E. Reboul.—Epichlor-hydrin and tri-ethyl-amin, if mixed in equal volumes, act upon each other below 100°, yielding ultimately oxallyl-tri-ethyl-ammonium chloride.

Observations on a New Enunciation of Gay-Lussac's Second Law on the Combinations of Gases.—M. Garcia de la Cruz.—M. Verschaffel (*Comptes Rendus*, xcii., p. 476) announced the following proposition:—The space occupied by a gaseous compound is always double the space occupied by that one of its components which enters into the compound with a smaller volume. This law comprises the rules of contraction in the cases where the volumes are equal or are in the ratio of 1 : 2. The author points out some of the numerous exceptions, such as phosphamin, arsenamin, ethylene bichloride, phosphorus trichloride, arsenious anhydride. The theoretic density of many substances in the gaseous state, as deduced from their formulæ, does not agree with the law announced, *e.g.*, nitrous, nitric, and chlorous anhydrides.

Biedermann's Central-Blatt für Agrikultur-Chemie, Vol. x., No. 1.

The Proportion of Carbonic Acid in the Atmosphere.—An abstract from the *Comptes Rendus*, the *Chem. Central-Blatt*, and the *Proceedings of the Royal Society*.

Determination of Rainfall.—M. Chrimes and F. E. Nipher.—The authors have measured the rainfall at different heights. They observed the same decrease of quantity in the 4 feet between 1 and 5 feet above the surface of the ground as in the 15 feet between 5 and 20. They find the decrease greater in exposed than in sheltered places, and ascribe it to the action of the wind.

Clover-Sickness of the Soil.—Dr. S. Linde.—As in the case of turnip-sickness this affection of the soil is due not to the exhaustion of certain constituents of the soil, but to the increase of animal and vegetable parasites. Hence a change of crop is more useful than manuring.

African Guano.—Dr. A. Petermann.—The guano in question is imported from the South African islands, Halifax, Pomona, Possession, and Ichaboe, and contains a total of 13·77 per cent nitrogen, and 8·8 per cent phosphoric acid. It is consequently superior to Peruvian guano as a source of nitrogen.

Phosphorites of Southern France.—L. L'Hote.—From the *Comptes Rendus*.

Manuring with Potassium Salts.—Adolf Mayer.—The author observes that the ashes of plants are uniformly basic; that fruitful arable soils present to the crops a suitable mixture of mineral food, but that by the copious use of mineral manures, and especially of Stassfurt salts, the proportions of this mixture are modified. Arable soils have a slightly alkaline, nearly neutral reaction, and only in such a medium can the roots of plants retain their health. All mineral manures may be arranged in three groups—the physiologically neutral, where acid and base are absorbed by the plant simultaneously; the physiologically basic, where the acid is absorbed more readily than the base; and the physiologically acid, where the base is assimilated more readily than the acid. The third class are in comparison with their amount of nutritive matter bad manures. They include the chlorides of ammonium, potassium, and magnesium, the sulphates of magnesia and potassa, the Stassfurt salts in general, and potash superphosphate. He recommends the addition of lime to Stassfurt salts, and a compost of peat-earth with potassium chloride and quicklime.

Comparative Experiments on the Action of Soluble, Reverted, and Precipitated Phosphoric Acid in Light Sandy Soils.—Dr. C. Müller and W. C. Müller-Scheessel.—Soluble phosphoric acid gave a better result than phosphoric acid soluble in ammonium citrate. The reverted acid had a decided influence on the yield, and a partial substitution of the latter for soluble acid had a remarkably favourable action.

Composition of Protoplasm.—Dr. Rodewald and Prof. J. Reinke.—The authors were able to obtain protoplasm in a state of purity from the fructification of *Æthalium septicum*, a fungus developed in heaps of tan. In its more solid portions the authors have identified the following bodies:—Vitelline, myosine, pepton, peptonoid, pepsin, nucleine, lecithine, guanine, sarkine, xanthine, ammonium carbonate, para-cholesterine, cholesterine, æthalium resin, a yellow pigment, glycoses, sugar (non-reductive), oleic, stearic, palmitic, butyric, carbonic acid, glycerides, and para-cholesterides of the fatty acids, calcium stearate, palmitate, oleate, lactate, oxalate, acetate, formiate, phosphate, carbonate, sulphate, magnesium and potassium phosphate, sodium chloride, and iron in an unknown state of combination. The albumenoids scarcely form 30 per cent of the entire weight.

The Injurious Action of Potato-Sugar.—Prof. Kedzie, Nessler, Barth, Fleck, and Schmitz.—Potato-sugar contains impurities of sulphuric acid, iron sulphate, and lime. Its most dangerous ingredient is a bitter matter remaining after the sugar has passed into fermentation, and which occasions cold sweats, oppression on the chest, headache, &c. Wines "gallised" with potato-sugar are consequently *pro tanto* poisonous, and the use of such sugars in brewing becomes a matter of questionable permissibility.

Examination of American Preserved Meats.—Prof. A. Mayer.—The author shows the presence in the cans of lead derived from the solder.

Influence of the Addition of Ammonia in Determining Bibasic Calcium Phosphate according to Petermann's Process.—Dr. A. König.—The author shows experimentally that the large addition of ammonia to the solution of citrate, as recommended by Petermann, is not justified, and causes the result to fall too low.

Vol. x., No. 2.

Relations between the Distribution of Atmospheric Pressure and the Distribution of the Rainfall.—J. Hann.—From observations made at more than 260 stations in Austria-Hungary, Switzerland, and Saxony, the author concludes that a relation between variation of the barometer and the rainfall cannot be shown; the fall of the barometer does not depend mainly on the rainfall, and is not notably affected by the latter. He mentions that the extremely violent rains of August 15 to 18, 1874, actually fell within the scope of a barometer maximum.

Humoid Matters Extracted from the Soil of Alkalies.—Dr. Otto Pitsch.—In most soils, phosphoric acid, if present in the form of iron or aluminium phosphate, is soluble in ammonium humate. The author considers that humus is of great importance for arable soils, not merely by improving their physical condition, but by its chemical action on the soil and its influence on the absorptive power of the latter.

Irrigation with the Drainage of Dunghills.—Prof. A. Müller.—The sandy soil operated collected little of the ingredients of the drainage, with the exception, perhaps, of phosphoric acid.

Application of Potassium Salts in Agriculture.—Prof. M. Maercker.—The failures on record in the use of potassium salts are often due to the fact that artificial manurial matters are sometimes applied without the simultaneous use of nitrogenous and phosphatic bodies. It is not to be expected that potassium salts can act advantageously on all soils and in all methods of cultivation, by the direct efficacy of their potash. As all potassium salts are converted in the soil into silicates, it is indifferent in case of a deficiency of potash whether it is supplied as sulphate or chloride. Potatoes, beetroot, and tobacco form exceptions, and are injuriously affected by potassium chloride. The magnesium chloride present in crude Stassfurt salts is, in dilute solutions, not more hurtful than equivalent quantities of potassium or sodium chloride.

Influence of Light upon the Transformation of Matter in Animals.—J. Moleschott, S. Fubini, and C Speck.—Moleschott and Fubini conclude that the elimination of carbonic acid increases under the influence of light, and that light acts not merely through the eyes, but upon the whole surface.

Researches on Splenic Fever.—L. Pasteur.—From the *Comptes Rendus*.

Scheibler's Process for the Determination of Sugar in Beets.—Prof. B. Tollens.—The author concludes that the results of this process approximate very closely to the truth.

Influence of Oxygen upon Fermentation.—A. Mayer, H. Hayduck, and M. Delbrück.—A. Mayer infers from his experiments that organic salts, such as potassium sodium tartrate, have a decided influence in promoting fermentation.

Archives Neerlandaises des Sciences Exactes et Naturelles. Tome xvi., Livraison 1me.

The Equations of the Movement of Gases, and the Propagation of Sound according to the Kinetic Theory of Gases.—H. A. Lorentz.—A mathematical paper, not susceptible of useful abridgment.

Crystallisation of the Diamond.—E. H. von Baumhauer.—A comparative crystallographic examination of the true diamond, of bort, and of supposed amorphous carbon. The difference is merely one of more or less perfect crystallisation, the three forms passing into each other by insensible gradations.

Tome xvi., Livraison 2me.

The Products of the Action of Phosphorus Pentachloride upon Acroleine.—P. van Ramburgh.—In this very elaborate paper the author takes as his point of departure certain researches of Hübner and Geuther (*Ann. Chem. Pharm.*, cxiv., 36). He examines acroleine chloride, the product boiling at 110°; the action of chlorine upon acroleine chloride, and upon the product boiling at 110°; the preparation of Hartenstein's tetrachloride, which boils not at 171°, but at 180°; the action of bromine upon acroleine chloride, and upon β-chlorated allyl chloride; and, finally, the accessory products boiling at higher temperatures.

MISCELLANEOUS.

University College Chemical and Physical Society.—At a public meeting to be held on Friday, October 21, at 7 p.m., Prof. Alex. W. Williamson, Ph.D., LL.D., F.R.S., will deliver an address on "An Error in the Commonly Accepted Theory of Chemistry."

JUST PUBLISHED,
Royal 32mo., Roan, gilt edges7, 43 pages with diagrams, price 5s.

A POCKET-BOOK FOR CHEMISTS,

Chemical Manufacturers, Metallurgists, Dyers, Distillers, Brewers, Sugar Refiners, Photographers, Students, &c.

By THOMAS BAYLEY, Assoc. R. C. Sc. IRELAND.
Analytical and Consulting Chemist and Assayer.
SECOND EDITION, WITH ADDITIONS.

SYNOPSIS OF CONTENTS.

Atomic Weights and Factors—Useful Data—Chemical Calculations—Rules for Indirect Analysis—Weights and Measures—Thermometers and Barometers—Chemical Physics—Boiling-points, &c.—Solubility of Substances, Inorganic and Organic—Specific Gravity: methods of obtaining, conversion of hydrometers, strength of solutions by specific gravity—Analysis: gas analysis, water analysis, qualitative analysis and reactions, volumetric analysis, manipulation—Mineralogy—Assaying—Alcohol, Beer, Sugar—Miscellaneous technological matter relating to Potash, Soda, Sulphuric Acid, Chlorine, Tar Products, Petroleum, Milk, Tallow, Photography, Prices—Formulæ for Alcohol, Beer, Wort, and Correction of Density for Temperature—The Elements arranged according to Mendelejeff's Classification—Table showing strength of solution of ammonia by specific gravity—Table showing the strength of solut'ons of Glycerine by spefic gravity—Table showing the boiling-points of saturated solutions—Tables for calculating the value of cubic centimetres with different corrections—Dry Reagents, &c.

London: E. and F. N. SPON, 16, Charing Cross.

BERNERS COLLEGE of CHEMISTRY.

Instruction and preparation in CHEMISTRY and the EXPERIMENTAL SCIENCES under the direction of Professor E. V. GARDNER, F.A.S., M.S.A.

The Class Rooms are open from 11 to 5 a.m. and from 7 to 10 p.m daily.

Especial facilities or persons preparing for Government and other examinations.

Private Pupils will find every convenience.

Analyses, Assays, and Practical Investigations connected with Patents, &c., conducted.

Prospectuses and full particulars on application to Prof. Gardner at Berners College, 44, Berners-street W.

HENRY WIGGIN & CO.,
NICKEL AND COBALT REFINERS,
BIRMINGHAM.

Patentees and Manufacturers of Rolled Nickel Anodes for Electro-Nickel-Plating.

Malleable Nickel Sheets, Grain and Cube Nickel, German Silver, and other Nickel Alloys, Oxides of Cobalt, &c.

BIRKS & CO.,
CARBOLIC ACID MANUFACTURERS, TAR DISTILLERS, &c.

CARBOLIC ACID.
No. 1.—Crys. at 34·35° C.
No. 2.—Crys. at 28·29° C.

Liquid Carbolic, straw-coloured and water-white.
Aurine, Carbolic Disinfecting Powder, 10%, 15%, and 20%. All warranted unadulterated.
Tar Products of all kinds.

WORKS—CLAYTON, NEAR MANCHESTER.

FOR SALE, a bargain.—3 Vats, each 4500 gallons. All perfectly clean, and equal to new vats. Almost any price would be taken, as the space they occupy is wanted.—Apply to E. Beanes and Co., Falcon Works, Hackney Wick, E.

IRISH HILL BAUXITE (Alum Clay).

THE IRISH HILL MINING CO. are now, and always have been, the LARGEST PRODUCERS OF THIS CLAY, of Superior Quality, and supply the Manufacturers of Alum, Sulphate of Alumina, and Alum-Cake, of the United Kingdom, America, and the Continent, almost exclusively.

ANALYSIS BY JOHN PATTINSON, ESQ.

Supplies over 90 % of the Bauxite (Alum Clay) used.

	Dried at 212° F.		
	Gertrude (extra qual.)	1st Quality.	2nd Quality.
Alumina	59·00	53·83	52·00
Peroxide of Iron	0·47	1·57	4·57
Silica	18·00	8·67	12·00
Titanic Acid		5·80	6·20
Lime, Magnesia, Potash, Soda, and Sulphuric Acid	0·23	0·83	1·14
Combined Water	22·30	29·27	24·00
	100·00	99·97	99·91

Supplies over 90 % of the Bauxite (Alum Clay) used.

Our MINES, DRYING KILNS, and GRINDING MILLS are situated very close to the Shipping Ports of BELFAST and LARNE, and adjacent to Railways running alongside both Steamers and Sailing Vessels at both Ports, from either of which shipping is abundant and cheap, therefore we can guarantee Regular Delivery as Buyers require it, and are prepared to quote prices f.o.b. c.i.f., or delivered at any Port, in Bulk or Bags, Lump or Ground.

AFFINITY AND VALENCY.

By FRED. D. BROWN.

Those chemists who were present at the recent meeting of the British Association must have been struck with the unanimity which prevailed in the Chemical Section with regard to that important property of the elements which we term valency or atomicity. Professors Williamson, Odling, Roscoe, and others, successively declared that it was impossible to attribute a constant combining power to the atoms, while it was more than once argued that if the idea of valency be retained in the science at all, it must be understood to refer to a property of the atoms which is subject to variations of unlimited extent.

This question has much occupied my attention during the present year, and I have gradually come to the conclusion that the force of affinity with which an atom tends to combine with another is unaltered, or but little altered, by such combination: in other words, if a force of attraction F be exerted between two atoms A and B, this force will remain the same whether A be combined with one or more atoms, C, D, &c., whether it be combined with a second atom A, or whether it lead for the time being an independent existence.

Many arguments in support of this hypothesis have from time to time occurred to me. Some of these are contained in a paper published in the October number of the *Philosophical Magazine*, but none, in my opinion, is more cogent than that derived from the very existence of chemical reactions. It is frequently said that the atoms forming the molecules of most chemical substances "have their affinities satisfied," and it is, I think, generally supposed that the chemical energy or affinity of the atoms is neutralised, such neutralisation being regarded as in some respects similar to that which takes place when a conductor charged with positive electricity is brought into contact with another which has received a negative charge. Yet, on reflection, it is evident that if this were the case it would not be possible for the molecule in question to exert any influence upon another, or, *a fortiori*, to enter into any chemical reaction. This argument will be better understood by applying it to some simple reaction, such, for example, as the formation of hydrochloric acid from hydrogen and chlorine, which we are accustomed to express by the equation—

$$H_2 + Cl_2 = 2HCl.$$

The molecule H_2 is supposed to be made up of two atoms of hydrogen united together by the force of chemical affinity in precisely the same manner as an atom of hydrogen is joined to an atom of chlorine in hydrochloric acid. Now, if neutralisation takes place at all between these two atoms it must be complete, for they are identical, and therefore neither of them can have a surplus of the attractive force available after the rest has been employed in neutralising that of the other; but if the neutralisation be complete, neither atom is in a position to combine with an atom of chlorine or to attract it in any way; hence the reaction cannot take place as long as the atoms of hydrogen are united together. That they remain thus united when left alone is proved by the fact that hydrogen gas obeys Avogadro's law. Since the reaction does take place we are bound to assume that in the molecule H_2 the affinity of the hydrogen atoms is not neutralised.

If we are forced to this conclusion in this particular case of hydrogen, we are equally so in the case of most other elements, but with compound bodies the argument is more complicated. Take, for instance, the case of water. We wish to show that the atoms of hydrogen and oxygen which form its molecule retain their original attractive forces when they are thus combined together. Now we can imagine (1) that the attractive forces are entirely neutralised; (2) that the hydrogen is only sufficient to neutralise a part of the affinity of the oxygen, leaving the rest free to act upon any other atom; (3) that the oxygen is only sufficient to neutralise a part of the affinity of the hydrogen atoms, leaving the rest free to act upon other atoms; (4) that the affinities are not neutralised at all.

We have already seen that the first supposition is inadmissible, since the molecule of water reacts upon other molecules. As regards the second view, that the attractive force of the hydrogen alone is entirely neutralised, it is discountenanced by the fact that chlorine acts upon the hydrogen of water, forming hydrochloric acid, and setting free the oxygen. It is true that this reaction is not one of everyday occurrence, but there is no doubt that under suitable conditions it really takes place. The third hypothesis, that the attraction of the oxygen is entirely neutralised, is disproved by numberless reactions in which the oxygen is attacked by atoms belonging to other molecules, while the hydrogen is liberated. We are, therefore, in this case also driven to the only other possible supposition, viz., that no neutralisation takes place.

It would not be difficult to apply the same line of reasoning to most other compound bodies, and thus to show that *in any molecule every atom retains the same affinity or power of attraction which it possesses when it is uncombined with any other.*

If this statement be true, it follows that as far as the force of affinity is concerned an atom may combine with any number of other atoms, or, in other words, that its valency must be unlimited. The number of atoms which can remain sufficiently close to it to be retained within the sphere of attraction is, however, necessarily very limited. Thus we may imagine an atom of nitrogen surrounded by a considerable number of atoms of hydrogen, each of which is moving with great velocity, and some few of these may come so close to the nitrogen as to be unable to get away again; but as soon as these hydrogen atoms, which remain constantly vibrating in the immediate neighbourhood of the nitrogen atom, have reached a certain number it will become impossible for any others to approach sufficiently near to be retained permanently. We may therefore reasonably ascribe the phenomena of valency to the conditions of space and motion under which the atoms are placed. By so doing, and admitting that the attractive forces exerted by the atoms remain unaltered, we are enabled to overcome most of the difficulties connected with the subject, and to account to ourselves in a fairly satisfactory manner for the variation of combining power and the existence of molecular compounds. Thus, with respect to the first point, it is clear that the valency of an atom must be dependent not only on the form, size, motion, &c., of the atom itself, but also on the same attributes of the atoms which tend to combine with it. The valency, therefore, might be expected to differ with the nature of these latter bodies.

With regard to substances such as NH_4Cl, H_2SiF_6, $BaCl_2 + 2H_2O$, which many are accustomed to regard as molecular compounds, the hypothesis that the affinity of the atoms is undiminished by combination renders it impossible to draw any distinction between them and the so-called atomic compounds of chemistry.

Solution of Chlorine in Water.—M. Berthelot.—At 12° one litre of pure water dissolves at the ordinary pressure 4 grms. of pure chlorine. In concentrated solutions of alkaline chlorides, chlorine is less soluble than in water, its solubility increasing with the dilution. In presence of hydrochloric acid chlorine dissolves more abundantly in water.—*Bull. de la Soc. Chim. de Paris.*

ON THE FORMATION OF SODIUM HYDRATE FROM THE SULPHATE.

By E. J. BEVAN and C. F. CROSS.

THE problem of the production of sodium hydrate from the sulphate is full of interest, both from its technical and theoretical bearings. As a possible method for the more economical preparation of alkali on the large scale, it has received the attention of several chemists, whose labours, however, being directed rather towards the result than the causes which determine it, have established little beyond the fact that the limit of conversion is so low as to be a veto upon its application as a manufacturing process. The object of our investigation was to test the accuracy of the statements which have been made concerning this limit, and to give a precise expression to the influence of its several factors.

Before proceeding to the statement of our results it will be necessary to glance briefly at the historical evidence on the subject. Of the earlier chemists, Delius, Achard, Scheele, Klaproth, and Westrumb, have treated of the preparation of alkali by this method. (Lunge's "Alkali," ii., 325). In 1840 Anthon showed the partial character of the decomposition; in 1852 it was made the subject of an English patent by Claussen, but proved economically a failure. In 1865 Hunter introduced the condition of excessive pressure. He employed solutions of sodium and of potassium sulphate of sp. gr. 1·1, and excess of lime, the pressure to which the solutions were subjected being 40 to 50 lbs. per square inch in the former and 80 to 90 lbs. in the latter case (*Jahresber.*, 1866, 846). This process likewise appears to have failed commercially. Hill investigated the reaction under various pressures, but the yield of hydrate proved in all cases very meagre (CHEMICAL NEWS, xxviii., 165). In reference to the reaction under the atmospheric pressure with lime and sodium sulphate he says—"In experiments upon this I never succeeded in getting 1 per cent of soda in the sulphate as caustic soda." Under a pressure of 3 atm the decomposition reached 6 per cent, and under 13 atm., continued for several hours, 13 per cent was converted into hydrate. As, however, it is not stated that the solutions were filtered under pressure, a precaution adopted by Hunter to obviate reverse decomposition, these numbers probably do not represent the maxima actually obtained. According to Tessié du Motay (*Berl. Ber.*, v. 741), 75 to 80 per cent of the sodium sulphate is causticised in twelve hours by lime, under the joint conditions of high pressure (2 to 20 atm.) and low temperature (0° to −20°), but we cannot find that these results have been realised on the large scale. More recently C. E. Davis has investigated the reaction, and kindly communicated his results to us. They are as follows:—

Sp. Gr. Solution.	Duration of Heating.	Pressure.	Decomposition p.ct.
1·03	24 hours	Atmospheric	1·8
1·02	12 ,,	5 lbs. per sq. in.	2·3
1·01	12 ,,	5 ,, ,, ,,	3·0
1·005	12 ,,	5 ,, ,, ,,	8·0
1·005	12 ,,	10 ,, ,, ,,	17·8
1·005	12 ,,	75 ,, ,, ,,	23·0

Still more recently Lunge has instituted experiments upon this same problem, and the publication of his results (*Dingl. Polyt. Jour.*, 238, 69) has taken place during the course of our investigation. The numbers arrived at are comprised in the following table, (A) being the results obtained by boiling under the ordinary atmospheric pressure in flasks attached to upright condensers, (B) by heating for ten to twelve hours in sealed glass tubes.

From this it appears that the evidence of previous researches is remarkably conflicting.

As the first step in our investigation it was necessary to clear up a few points in connection with the solubilities of the reagents. The saturated solution of calcium sulphate

Proportions by Weight. Na_2SO_4 : CaO : H_2O.	Amount of Decomposition.
(A.)	
* 1 : 1 : 15	6·55 per cent
1 : 1·1 : 30	9·64 ,,
1 : 1·1 : 90	20·93 ,,
1 : 1 : 90	19·88 ,,
1 : 1 : 180	28·82 ,,

Temperature.	Pressure.	Proportion. Na_2SO_4 : CaO : H_2O.			Amount of Decompstn.
(B.)					
130—140°	2—3 atm.	1	1	6	3·13
130—145	2—3·5	1	1	10	11·2

150	5	1	1	50	23·49
150	5	1	2	50	23·91
140—150	4—5	1	1·1	10	13·88

* See Table III.

(at 15°) is variously stated to contain from 1-250th to 1-500th its weight.*

The wide discrepancies between the results of the different observers must be accounted for by differences in the state of the salt operated upon. We made some observations on this point, using a preparation precipitated by sulphuric acid from a solution of the chloride and well washed. The quantity dissolved (anhydrous) at 9° C. we found in three instances to be 1 in 493, 1 in 498, and 1 in 500: we also found that the quantity was not increased by prolonged contact. In the case of calcium hydrate, on the other hand, we found that time is a very important factor of the result. Thus, in a solution filtered after one hour's contact, we found 1 part CaO in 628 of solution; and after twenty-four hours' contact, 1 part in 575. In another instance, 1 in 824, as against 1 in 598, after twenty-four hours' contact. A number of similar determinations established the constancy of this result, but at the same time showed the phenomenon to be in other respects extremely irregular. The solubility in a saturated solution of calcium sulphate was found to be the same as in pure water, and in the same way to vary with the duration of contact. The most probable explanation of the influence of time is that solution is preceded by further hydration of the di-hydrate, and that the variations in the quantity dissolved in a given time are caused by corresponding variations in fineness of division, and other conditions affecting hydration.

We next determined the influence of caustic soda upon the solubility of calcium hydrate, having the *a priori* ground for regarding it as a precipitant, afforded by the absence of lime in the commercial preparations of caustic soda.

We found, in effect, that after ten minutes' contact with a solution of 2·8 per cent (Na_2O) not a trace of CaO had been taken up. After one hour's contact a small quantity had been dissolved, and that practically, therefore, lime is insoluble in a 3 per cent solution of caustic soda. Not only so, but also that a solution prepared directly from sodium, with exclusion of carbonic acid, gave a precipitate with lime-water.

We append the results of a series of observations upon the solubility of lime in soda solution.†

* The following statements are given by Storer ("Dic. Sol.") respecting the solubility of calcium sulphate:—1 part in 450 of boiling and 1 in 500 cold saturated solution (Bergmann); 1 in 250 to 300 (Dumas); 1 in 500 hot or cold (Fourcroix); 1 in 380 cold (Poggiale), and a maximum, at 35° C., of 1 in 400, as against minima of 1 in 500 at 0° C. and the boiling-point. To test the accuracy of this statement conjointly with its probable influence on the decomposition under investigation, we carried out an experiment uniform with Series D, with a dilution of 350 c.c., and duration of one week, and obtained at the temperature of 35° a decomposition of 25·2 per cent, as against 35 per cent at the ordinary temperature.

† The precipitating action of caustic soda upon solutions of lime throws some light upon the formation, during the preparation of the former by the ordinary method, of a curious compound of the two hydrates which is not decomposed by washing.

Per cent Na_2O.	Eqt. Na_2SO_4 in 150 c.c.	Per cent CaO dissolved. After 3 hours. (a)	(b)	After 24 hours.
1·16	4 grms.	1 in 8772	1 in 8770	1 in 4000
0·87	3 ,,	1 8333	1 8330	1 3400
0·58	2 ,,	1 5000	1 5000	1 3000
0·23	0·8 ,,	1 1530	—	1 1240
0·12	0·4 ,,	1 1210	—	1 986
0·06	0·2 ,,	1 920	—	1 533

These numbers afford additional proof of the influence of time.

We now turn our attention to the more special subject of our investigation. Confining ourselves throughout to the relative weights required by the equation—

$$Na_2SO_4 + Ca(OH)_2 = 2NaOH + CaSO_4,$$

and using uniformly 5 grms. Na_2SO_4 and 2 grms. CaO, our first experiments were directed towards the question of the influence of the partial solubility of the calcium sulphate. That this is of first importance follows from the fact that general considerations based on the laws of energy give us no ground for assigning a limit to the decomposition; and that such a limit occurs in the case of the sulphate, but not with the carbonate, phosphate, or silicate of sodium, is therefore referable to differences in the solubilities of the resulting calcium salts.

A. *Effect of Varying the Solubility of the Calcium Sulphate by Addition of Alcohol.* (1) Time constant (one week). Temperature 13° to 16° C.*

Vol. of Solution.	Percentage Composition by Vol. Water.	Alcohol.	Per cent Na_2SO_4 Decomposed.
(a) 400	100	—	33·8
(b) 400	77·5	22·5	54·8
(c) 400	33	67	25·3
(d) 350	100	—	35·0
(e) 300	30	70	44·6
(f) 300	40	60	21·6
(g) 300	100	—	30·0
(h) 250	64	36	29·1
(k) 250	100	—	28·1
(l) 200	55	45	19·8
(m) 200	100	—	26·3

(In *c*, *f*, *h*, *l*, no Ca was present in the filtered solutions; in *b*, *e* traces were found dissolved.)

The influence of the addition of alcohol upon the yield of alkali is very marked; that the maximum occurs when the percentage of spirit is comparatively low is due to the fact that the solubilities of the original reagents are likewise affected.†

(2) Time constant (4 hours). Temperature 85° C. Volume kept constant by means of an upright condenser.

Volume of Solution.	Percentage Alcohol by Volume.	Per cent Na_2SO_4 Decomposed.
200	45	29·2
200	—	8·5

* The method employed for determining the quantity of alkali in solution was as follows:—The solutions were filtered through dry filters, and at the temperature of the experiment. An aliquot portion of the filtrate was treated with carbonic acid gas until any carbonate precipitated was re-dissolved: the solution was then boiled, filtered, and titrated. The error due to reverse decomposition of the calcium sulphate by the sodium carbonate we neglected for the reasons—(1) That the amount of the sulphate dissolved was always much less than that indicated by its solubility, and even in experiments where the quantity formed was insufficient to saturate the volume of water it was for the most part precipitated; (2) that our numbers have a relative rather than an absolute value; and (3) the alternative method of throwing out the sulphate by addition of alcohol involved an error due to the removal of sodium hydrate by the precipitate.

† From the following table of the solubility of sodium sulphate in dilute alcohol it will be seen that in three of the above experiments the original reagents were insoluble in the liquid employed:—

Sp. Gr. Solution.	Containing Alcohol Per cent.	Contains saturated at 15°.
1·00	0	25·6
0·976	10	14·3
0·952	20	5·6
0·939	40	1·3

B. *Effect of Varying the Solubility of the Lime by Addition of Sugar.* Time constant (4 hours). Temperature (100°) and volume constant (boiled in flasks attached to upright condensers).

Vol. of Water.	Sugar added.	P.ct. Na_2SO_4 decomp.
350 c.c.	5 grms.	20·0
350	0·0	11·42

C. *Effect of Increasing the Solubility of the Calcium Sulphate by Addition of Sodium Chloride.* Conditions, otherwise, as above.

		P.ct. Na_2SO_4 decomp.
350 c.c.	5 grms. NaCl.	7·10

In the above experiments we have arrived at a more exact knowledge of the influence of the solubilities of the reagents, which it is seen are very powerful in affecting the limit of the reaction.

The next category of conditions affecting the results are the duration of the experiment, together with the temperature and volume of the solution, and those which, to use the language of molecular science, affect the number of collisions of the reacting molecules.

D. *Effect of Dilution.* (α) Time, 7 days; temperature 13·16°; the solutions were placed in stoppered bottles and agitated from time to time. (β) Time, 4 hours; solutions boiled in flasks attached to upright condensers.

Volume of Solution.	Percentage Na_2SO_4 Decomposed. (α)	(β)
100 c.c.	12·0	6·25
150	24·5	7·73
200	26·3	8·51
250	28·0	9·7
300	30·3	10·1
* 350	35·0	11·4
400	33·8	10·8
450	33·12	—
500	31·8	10·3
600	30·2	9·98
700	20·1	9·6
800	20·1	—

The maximum decomposition took place, in each series, when the volume of the solution reached 350 c.c., *i.e.*, when the molecular ratio $Na_2SO_4 : H_2O = 1 : 550$.

E. *Effect of Time.*—(α) vol. constant (350 c.c.); boiled in flasks attached to upright condensers. (β) vol. constant (250 c.c.); temp. 13° to 16°, solutions placed in stoppered bottles and agitated from time to time.

(α) Time.	Na_2SO_4 Decomp.	(β) Time.	Na_2SO_4 Decomp.
4 hours	11·42	4 hours	12·9
20 ,,	10·8	40 ,,	23·5
35 ,,	19·6	7 days (1)	28·0
96 ,,	25·2	7 ,, (2)	28·7
7 days	25·3	14 ,,	28·8

The attainment of the maximum is therefore a work of considerable time, both at the ordinary and boiling temperatures.

F. *Effect of Rest or Motion of the Liquid.*—Volume constant (350 c.c.); temperature 13° to 16°; time 7 days; size and shape of containing vessel constant.

	Yield P.ct.	Special Condition of the Experiment.
(a)	34·8	Perfect rest.
(b)	35·0	Occasional agitation.
(c)	34·7	Constant agitation; the vessel was attached to the fly-wheel of an engine in constant motion.
(d)	34·5	As in (c), with addition of asbestos to secure the maximum distribution of insoluble substances.

The absence of difference is remarkable.

* At 35° C., but under otherwise identical conditions, the decomposition reached only 25·2 per cent of the theoretical.

G. *Effect of Height of Liquid Column.*—Volume 350 c.c ; temperature 13° to 16° ; time 7 days ; liquid at rest.

Height of Column.	Decomposition per cent.
4 inches	34·6
24 ,,	24·3

The effect of the remaining limiting condition, viz., the decomposition of calcium sulphate by sodium hydrate, has also been investigated. In our experiments on this point we employed cold solutions of the hydrate, free from carbonate, which were placed in contact with excess of calcium sulphate for a period of twenty-four hours. The subjoined table embodies the first series of results:—

H.

	Vol. of Solution.	C.c. NaOH Soln. taken.	Eqt. to Na_2SO_4.	C.c. NaOH recovered.
(*a*)	150	1	0·2	0·98
(*b*)	150	2	0·4	2·00
(*c*)	150	3	0·6	2·98
(*d*)	150	4	0·8	3·95
(*e*)	150	5	1·0	4·95

The last column gives the result of titrating the filtered solution. These numbers were controlled by determinations of Ca and SO_4 in aliquot portions. From 50 c.c. of (*a*) we obtained 0·0587 CaO and 0·2412 $BaSO_4$: these, when converted into their equivalents of $CaSO_4$, furnish identical numbers. From 50 c.c. of (*e*) we obtained 0·0763 CaO (eqt. 0·185 $CaSO_4$) and 0·3372 $BaSO_4$ (eqt. 0·196 $CaSO_4$), and therefore evidence of incipient decomposition.

Having fixed this point we continued the observations with stronger solutions of the hydrate.

	Vol. of Solution.	C.c. NaOH Solution.	Eqt. Na_2SO_4.	C.c. NaOH recovered. (*a*)	C.c. NaOH recovered. (*β*)
(*f*)	150	5	1 grm.	0 95	0·98
(*g*)	150	10	2 ,,	1·19	1·2
(*h*)	150	15	3 ,,	1·74	1·69
(*i*)	150	20	4 ,,	2·59	—
(*k*)	150	25	5 ,,	3·3	2·98

In series (*a*) we made determinations of the ratio CaO : SO_3 in solution.† 50 c.c. of (*f*) gave 0·0672 CaO (eqt. 0·163 $CaSO_4$) and 0·3187 $BaSO_4$ (eqt. 0·18 $CaSO_4$). Here, as before, we observe a slight disturbance of the equivalents indicating the commencement of decomposition.

50 c.c. of (*k*) yielded 0·0302 CaO and 0·6405 $BaSO_4$. Assuming the CaO to be present entirely as sulphate, the calculated quantity of Na_2SO_4 present is 1·6 grms., as against 1·7 observed by the alkalimetric test.

It will be seen from these observations that in none of the previous experiments at the ordinary temperature was sufficient caustic soda formed to reach the limiting strength, and no reverse decomposition could therefore have taken place.

In conclusion we would call attention to the more remarkable facts which have come to light in the course of our investigations: (1.) That, even employing the reagents in the theoretical ratio of single molecules, the limit of the decomposition is much higher than the numbers previously assigned. (2.) By the addition of alcohol, the limit has been raised to 55 per cent of the theoretical yield. (3.) The most important factors of the limit are time and the degree of insolubility of the calcium sulphate in the menstruum employed; of lesser influence are temperature and the solubilities of the original reagents; and the decomposition is comparatively independent of the *visible* rest or motion of the system. (4.) The occurrence of reverse decomposition has been obviated by the extent of dilution of our solutions, but is shown to be fatal to the economical realisation of the reaction on the large scale.

* It will be seen on reference to our determinations of the solubility of lime in solutions of caustic soda, that traces only could be dissolved in the experiments of this series, and therefore the loss of alkalimetric strength measures the decomposition which has taken place, without sensible error.

† The solutions were diluted to 250 c.c. before estimating.

THE HYDROMETALLURGY OF COPPER, AND ITS SEPARATION FROM THE PRECIOUS METALS.*

By T. STERRY HUNT, LL.D., F.R.S., Montreal, Canada.

WET processes for the extraction of copper from its ores have of late attracted much attention, especially in Europe, where the use of cupriferous iron pyrites as a source of sulphur prevails. These processes present an additional interest, when, as is often the case, the copper ores to be treated contain one or both of the precious metals, since the complete separation of these from copper, either in the dry or the moist way, is, as is well known, one of the difficult problems of metallurgy. The principal wet processes hitherto in use for the extraction of copper from its ores may be included under three classes:—

I. Those in which the copper in sulphuretted ores is rendered soluble in water by calcining them, after a preliminary roasting which removes the greater part of their sulphur, with a portion of common salt, by which the copper is converted into a chloride (Longmaid and Henderson) or with sulphate of soda by which sulphate of copper is formed (Monnier). Allied to these is the method by which a portion of the copper is got as soluble sulphate by roasting without addition, a process which is sometimes modified and rendered more complete by re-roasting the lixiviated residues with the addition of a portion of raw sulphuretted ore (Bankart).

II. Those methods in which free chlorhydric or sulphuric acid is used to dissolve the copper from oxidised or roasted ores. These, while simple and efficient, are too costly, except in certain localities where chlorhydric acid is a waste product. Related to them is the plan which consists in exposing the oxidised and moistened ores to the slow action of sulphurous acid mixed with air, by which a soluble sulphate of copper is formed. It has been proposed to decompose the solutions of sulphate or chloride of copper by sulpuretted hydrogen, thus separating the copper as sulphide, and using the liberated acid to dissolve fresh portions of oxidised copper. It is, however, the almost universal practice to throw down the copper from its solutions, however obtained, in the metallic state by the use of iron, either scrap-iron or iron-sponge, although in some instances milk of lime has been used as a precipitant, by which oxide of copper is produced.

III. The method in which a hot solution of ferrous chloride, with common salt, is used to chloridise the oxidised copper and convert it into a mixture of cupric and cuprous chlorides, which latter, though nearly insoluble in water, is dissolved by help of the chloride of sodium. From this solution the copper is precipitated by metallic iron, thereby reproducing the ferrous chloride, and regenerating the solvent, an advantage which this process possesses over any other which gives the copper in the metallic form. This, which is known as the Hunt and Douglass method, may, in many cases, be used with advantage for the treatment of low-grade copper ores, and, as the neutral solvent does not dissolve either arsenic or antimony, enables fine copper to be got directly from ores holding these impurities.†

When, however, it is applied to the treatment of copper ores containing silver, the use of the bath of ferrous chloride and chloride of sodium has, in common with the method of roasting with salt, the disadvantage that it converts the silver into a chloride which is soluble in a strong solution

* A paper read before the American Institute of Mining Engineers at the Meeting at Staunton, Va., June, 1881. From the *Engineering and Mining Journal*.

† The hydrous silicate of copper (chrysocolla) is, like the carbonates of copper, completely decomposed by a hot solution of ferrous chloride with common salt. An account of the application of this method to the treatment of a crystalline hydrous silicate of alumina, magnesia, and copper (which is essentially a copper-chlorite, and has been described by the writer as a new species under the name of venerite), will be found in the *Transactions of the American Institute of Mining Engineers*, vol. iv., p. 328.

of chloride of sodium and is then with difficulty separated from the chlorides of copper. The separation of silver and copper when dissolved together in the state of chlorides has greatly exercised the ingenuity of metallurgical chemists from its importance in connection with the treatment of Spanish and Portuguese pyrites, now so extensively used in Great Britain as a source of sulphur, where their consumption in 1877 amounted to 600,000 tons. These ores contain on an average about forty-nine per cent of sulphur and two or three per cent of copper, with a little silver, equal, according to Claudet, to from twenty to twenty-eight grms. to the ton of ore, and traces of gold. The residues after calcination still retain three or four per cent of sulphur and about four per cent of copper, with sixty per cent or more of iron, chiefly as peroxide. This material, after having been again calcined for some hours at a low heat in a reverberatory with about fifteen per cent of common salt (or, as at Oker, in Germany, with crude chloride of potassium), gives up to water acidulated with a little chlorhydric acid its sulphur as sulphate of soda, and its copper and silver as chlorides, together with a considerable excess of common salt, leaving behind a nearly pure peroxide of iron with not over two thousandths of copper. A minute portion of gold, which was converted into aurous chloride during the roasting, is also present in the solution.* The lixivium, in an example given by Claudet, had a specific gravity of 1·24, and held in a meter-cube, besides 144·0 kilogrms. of sulphate of soda, 64·0 of chloride of sodium, and 52·8 of copper as protochloride, besides small portions of zinc and iron, with a little lead, and 44 grms. of silver. The above details of the self-roasting process, which have often been published, are here repeated, in order to bring more clearly before us the problem of separating the silver from the copper.

Various plans have been suggested for extracting from such solutions as the above the dissolved silver before throwing down the copper by metallic iron. It has been proposed to precipitate the silver by finely-divided metallic copper, as is done in the Augustin process from solutions of chloride of sodium holding only dissolved silver-chloride; but, since metallic copper at once converts protochloride into dichloride of copper, it becomes necessary, as a preliminary to the precipitation of the silver by this means, that the whole of the copper in the solution should first be brought into the latter condition. This may be effected by treating the hot solution with sulphurous acid, or by filtering it at a temperature near the boiling-point through a layer of coarsely-ground copper matte, or of vitreous or purple copper ore, from which, as I have found, a second equivalent of copper is taken up. From solutions holding the whole of the copper of dichloride, the silver may be readily thrown down in the metallic state by filtering them through a layer of finely-divided metallic copper; but, inasmuch as the dichloride requires to hold it in solution a great volume of hot concentrated brine,† this method of separating silver from solutions containing a considerable amount of copper is not in all cases practicable.

Among the plans which have been proposed for the separation of the silver from these saline solutions are those based on fractional precipitation. This is effected as at Oker, by the use of sulphide of sodium; or better, by diluted sulphuretted hydrogen gas, as got by the action of air mixed with carbonic acid on the waste calcium-sulphide from Leblanc's soda-process. In the latter case, the whole of the silver is, according to Gibbs, carried down with the first six per cent of the copper. Snelus blows finely divided metallic iron into the solution, and finds the first twenty per cent of copper thus precipitated holds four-fifths of the silver. For the extraction of the silver from the mixed sulphides, it suffices to convert the silver into a sulphate, as in the Ziervogel process. For the separation of silver from precipitated copper, J. A. Phillips, by a process patented in 1877, makes the material into a paste with water and a mixture of common salt and carbonate of soda; and, after calcination in a reverberatory, gets the silver in the form of chloride, which is dissolved out by brine from the oxidised copper.

The solvent power of solutions of chloride of sodium for chloride of silver is diminished by dilution, and upon this fact, apparently, is based a process for the separation of silver, patented in 1877 in Great Britain by Jardine and Chadwick, which consists in diluting the strong lixivium from the salt-roasted ore to about sp. gr. 1·10—1·12, and adding thereto, in the form of a dilute-solution, about half a pound of acetate of lead to the ton of liquid. The precipitate, which after a time separates, consisting, in large part, of sulphate of lead, carries with it a portion of chloride of silver, and, it is said, a trace of gold.

The most elegant method for the separation of silver from these mixed solutions is, however, that patented by Claudet, and extensively applied in Great Britain. It depends on the almost complete insolubility of iodide of silver in solutions of chloride of sodium, and consists in adding to the lixivium, in which the proportion of dissolved silver has previously been determined, a dilute solution of a soluble iodide just sufficient in amount to convert the whole of the silver into iodide of silver. The precipitate, which separates after forty-eight hours of repose, is washed with dilute chlorhydric acid, to remove adherent copper-salts, and then consists chiefly of a mixture of sulphate of lead with iodide of silver, which is reduced by metallic zinc, the iodine being thus recovered for further use. Treated in this manner, the calcined Spanish ores yield to the ton 20 grms. of silver containing 1·3 per cent of gold, amounting, according to Lunge, to about two-thirds the entire amount of precious metals contained in the ore. The presence of dichloride of copper in the solution interferes, by the production of a cuprous iodide, with the separation of the silver as iodide; and hence the calcination of the ores with salt must be so conducted as to give the copper in the condition of protochloride.*

The extraction of copper from its ores by roasting with salt is limited to pyritous ores poor in copper, which yield, by their previous calcination, a large proportion of peroxide of iron; the presence of this being necessary to the effectual chloridising of the copper in the furnace. When applied to richer ores, this method fails to render the whole of the copper soluble, for reasons which are made apparent by the investigations of Mr. Thomas Macfarlane, described by him in 1865. He found that while copper ores, such as chalcopyrite and bornite, when calcined with salt, either alone or with an admixture of pulverised quartz, yield but a small portion of their copper in the form of soluble chloride, such a mixture of ore and salt, with twice its weight of peroxide of iron, and a little pyrites to furnish additional sulphur, if calcined at a low temperature, and without stirring, gave up nearly all its copper to water as a soluble chloride. It was made evident, from these and other experiments described by Macfarlane, that the mass of heated peroxide of iron, in the presence of air, favours the conversion of the sulphur into a sulphate, through which the

* Plattner, as is well known, showed that gold, like silver, is chloridised when pyritous ores containing it are roasted at a low red heat with common salt; an aurous chloride being apparently found, which, in the presence of chloride of sodium, has a considerable degree of stability, though it is decomposed at higher temperatures. This chloride of gold is insoluble in water, and unlike chloride of silver, is not decomposed by mercury. It is but slightly soluble in brine, though readily dissolved by a solution of hyposulphite of soda or lime. A process proposed by Kiss for the simultaneous extraction of silver and gold from pyritous ores is based on these reactions.

† 100 c.c. of a solution holding 15·0 grms. of chloride of sodium, dissolve at 90° C., 10·0 grms; at 40, 6·0; and at 14°, 3·5 grms. of cuprous chloride; while 100 c.c. of a solution holding 5·0 grms. of chloride of sodium, dissolve at 90°, 2·6 grms, and at 50°, 1·4 grms. of cuprous chloride. This substance, contrary to the received statements, is not quite insoluble in water. When the cuprous chloride is boiled with distilled water, an amount equal to about 1·35 grms. to a litre passes into a solution, and is in part thrown down on cooling in a white crystalline form; the solution, at 14° C., still retaining about 0·90 grms. to the litre. The above numbers are only approximations.

* For an excellent account of wet processes for the extraction of copper see Friedr. Bode in *Dingler's Polytechnisches Journal* for January-March, 1877, vol. ccxxxi., pp. 254, 357, 428

decomposition of the common salt and the chloridising of the copper are effected.*

These conditions are most fully realised when a material like the calcined residue of Spanish pyrites, containing in 100 parts about 4 parts each of copper and sulphur, and 80 parts or more of peroxide of iron, is calcined with a sufficient amount of common salt, in which case, as we have seen, the chloridising of copper is nearly complete. Ignorance of these conditions has more than once led to failure in attempts to apply this process of copper-extraction.

Unlike the method of chloridising by roasting with salt, that depending on the use of a solution of ferrous chloride with salt is a general one, applicable to all naturally or artificially oxidised copper ores, which may be readily and cheaply chloridised by its aid.† When applied to copper ores containing silver, however, this shares with the salt-roasting process the disadvantage that the silver is at the same time chloridised, and if not present in too large an amount, is dissolved, while the dichloride of copper formed by the reaction between the oxide of copper and the ferrous chloride precludes the use of Claudet's method of precipitating the dissolved silver by a soluble iodide.

There is a large class of copper-bearing ores and furnace-products containing, besides silver, and in some cases gold, portions of antimony and arsenic, often accompanied by lead, the treatment of which, either by the wet or the dry way, offers many difficulties. A simple and economical general method, which will effect a complete separation of copper from silver and gold on the one hand, and from arsenic, antimony, and lead on the other, has hitherto been a desideratum in metallurgy. From the want of such a process, considerable quantities of refined copper extracted from Western ores and mattes, and carrying from 40 to 50 ounces of silver per ton, have of late years been sold in our markets.

With my friend, Mr. James Douglas, Jr., of Phœnixville, Pa., I have devoted much time to the metallurgical problem thus presented, and as the result of our joint labours have now to bring before the Institute of Mining Engineers a novel wet process for the extraction of copper from its ores, which will, I think, be found to meet the required conditions. The new method is based upon the reaction described by Wöhler between sulphurous acid and a solution of protochloride of copper, which gives rise to insoluble dichloride with the elimination of one-half the chlorine in the form of chlorhydric acid, and the simultaneous formation of sulphuric acid, as simply expressed in the old notation by the formula—

$$2CuCl + SO + HO = Cu_2Cl + HCl + SO_3.$$

The resulting acid solution, when brought in contact with cupric oxide, will take up as much copper as it originally held, which may, in its turn, be thrown down by sulphurous acid. In this way, the solution of copper from an oxidised ore, and its precipitation as dichloride, may be repeated indefinitely, provided chlorine be supplied each time by the addition of a sufficient amount of some soluble chloride.

The reaction between sulphurous acid and a solution of protochloride of copper goes on slowly at ordinary temperatures, but is very rapid between 80° and 90° C. Solutions of sulphate of copper mixed with an equivalent of chloride of sodium, and holding 8·0 per cent of copper, after being treated at 90° C. with an excess of sulphurous acid gas, retain less 1·0 per cent of dissolved copper; while in the presence of an excess of sulphate of copper and sulphurous acid the precipitation of the chlorine from chloride of sodium is nearly complete; sulphate of soda and sulphuric acid remaining in solution in accordance with the equation—

$$2CuO,SO_3 + NaCl + SO_2 = Cu_2Cl + Na,SO_3 + 2SO_3$$

The sulphurous acid gas for effecting this reaction on a large scale is readily got in sufficient purity from the burning of iron pyrites in the ordinary kilns used by the makers of sulphuric acid, care being taken that an excess of air be avoided. A Knowles pump, constructed for the purpose, has proved an efficient means of injecting the heated gas into the liquid. By this reaction, we have found it easy, in repeated trials with a small experimental plant, to throw down in three hours' time 125 pounds of copper from an 8 per cent solution, the liquid still retaining about 1 per cent of copper dissolved.

The acid liquors, when the reaction with sulphurous acid is complete, have exchanged their bright blue colour for a pale green, and now contain in solution an excess of sulphurous acid, which must be got rid of before using them to dissolve a fresh portion of copper. This may be effected by keeping back a small portion of the chloridised copper solution, and, after the action of the gas is complete, as may be known by the changed colour and the sulphurous odour of the liquid, adding the reserved portion thereto, by which means the excess of sulphurous acid will be oxidised. The chief part of the dichloride of copper separates during the passage of the gas, but a further portion is deposited on the cooling of the solution.

The excess of sulphurous acid may also be got rid of by blowing a current of hot air through the liquid after it has been withdrawn from the precipitated dichloride, and best while the process of saturating it with oxide of copper is going on. This, when got by the calcination of sulphuretted ores, contains more or less suboxide of copper,* which, with chlorhydric acid, forms a portion of cuprous chloride, and the separation of this, under these circumstances, may be prevented by the action of atmospheric oxygen.

Cuprous chloride is quickly transformed into cupric oxychloride by atmospheric oxygen, and, when dissolved or suspended in an acid liquid, is by this means readily converted into a cupric salt, which may be again reduced to cuprous chloride by the action of sulphurous acid. In this way, like the nitric oxide in the leaden chamber, the cuprous chloride acts a medium through which sulphurous acid and oxygen are made to combine and to form sulphuric acid. The two reactions of oxidation and reduction just described may go on alternately or simultaneously in the liquid, and thus it happens that when an excess of air enters the pyrites-kiln, so that considerable free oxygen passes with the sulphurous acid into the copper solution, the dichloride is either separated slowly or not at all, while at the same time much sulphuric acid is formed. By taking advantage of these reactions between oxygen, sulphurous acid, and chloride of copper, we may at will increase the solvent power of our acid bath.

In applying this new process of copper extraction to a roasted sulphuretted ore or matte, which we will suppose to contain a portion of silver, we begin by dissolving therefrom by water the sulphate, which, with proper care in roasting, should contain not less than one-third of the copper of the ore; taking care to add to the water enough of some soluble chloride to chloridise and render insoluble any sulphate of silver which may be present. From the clear lixivium thus obtained, after adding the requisite amount of chloride of sodium, the copper is precipitated, as already described, by the action of sulphurous acid gas. The resulting acid liquid, freed from the excess of sulphurous acid by the addition of a reserved portion of the original solution containing copper chloride, and still retaining more or less copper, is now used to dissolve the oxide of copper from a portion of the lixiviated ore; the process being aided by heat, and, if the formation of dichloride of copper is to be feared, by the injection of a current of air, which may be made the means of heating

* *Canadian Naturalist*, Second Series, vol. ii., pp. 219, 231, and vol. iii, p. 457.

† A process of copper-extraction, based on this principle, is the subject of United States letters-patent, granted to T. Sterry Hunt and James Douglas, Jr., February 9th, 1869.

* I have found calcined sulphuretted copper ores to contain, in addition to soluble cupric sulphate and insoluble oxides of copper, a small portion of a cuprous compound, which, though insoluble in water, is dissolved by a hot and strong solution of common salt, and is probably a cuprous sulphate or sulphite.

and agitating the mixture. If the ore contains silver, either in the form of metal or unoxidised sulphide, we have in the chloride of copper which is formed the best agent for bringing it to the condition of chloride of silver. This will be found in the residue after the extraction of the copper, together with any gold which may be present, lead as sulphate, oxides of antimony and iron, and earthy matters. Cobalt, nickel, and zinc, if present, will, however, be dissolved, and, not being precipitated by sulphurous acid, will, by successive operations, accumulate in the solution, and may afterward be extracted.* From the residues thus deprived of copper we have found the silver to be readily dissolved by brine,† after which, if gold be present, it may be removed by chlorination, or the two precious metals may be extracted together from the residues by amalgamation. When, as in the case of certain mattes from Utah, for example, the residues contain a large amount of lead as sulphate, this may be recovered by smelting, and a base bullion got containing the precious metals. The same result may also be attained by smelting the residues with an admixture of a lead ore.

Chloride of silver is soluble to some extent in solution of cupric chloride, and is then in part carried down with the cuprous chloride in the precipitation of the latter. The formation of cupric chloride may be avoided by adding to the solution of sulphate of copper little more than the amount of chloride of sodium necessary for the conversion of the copper into dichloride. In this case, as we have seen, the acid liquid after precipitation by sulphurous acid will contain chiefly sulphuric acid, though still holding sufficient cupric chloride to effect the chloridising of any silver which may be present in the ore.

The dichloride of copper, as obtained by precipitation, is a white, coarsely crystalline powder, having a specific gravity of 3·376 (Playfair and Joule), and, as we have seen (second note, column 1, p. 199) is nearly insoluble in cold water. After being washed from the acid liquid, it may be readily reduced by placing metallic iron in the moist dichloride, which should be covered with water to exclude the air. The action spreads rapidly through the precipitate, so that a single mass of iron will, in a few hours, change a considerable volume of dichloride around it into pure spongy metallic copper. The reduction of copper from solutions obtained in those wet processes where the copper exists as protochloride, often accompanied by salts of iron, entails a considerable loss of metallic iron, and gives a copper which is impure from the presence of basic iron salts. The reduction of the solid dichloride, however, presents none of these disadvantages. Forty-five parts of iron suffice to reduce 100 parts of copper; the precise ratio being as 28·0 : 63·4. The ferrous chloride which remains in solution may with advantage be used instead of chloride of sodium for chloridising subsequent solutions of sulphate of copper, ferrous sulphate being formed, which, as it accumulates, may be separated by crystallisation from the acid liquid. The ferrous dichloride required to chloridise 20 parts of copper would equal about 61 parts of hydrated ferrous sulphate.

Another mode of treating the dichloride, which may in some cases be resorted to, consists in decomposing it, best at a boiling-heat, with a slight excess of milk of lime. The dichloride is by this means converted into a dense orange-red suboxide of copper, which, after being washed from chloride of calcium, in a filter-press or otherwise, and dried, may be readily reduced to metallic copper in a reverberatory furnace. For this reaction 28 parts of pure quicklime are required for 63·4 parts of copper, and the resulting chloride of calcium may be used instead of chloride of sodium or chloride of iron for chloridising solutions of sulphate of copper. In this case there will be formed an insoluble sulphate of lime or gypsum, while the free sulphuric acid of the solution is replaced by chlorhydric acid. The use of the chloride of calcium would, however, require an additional operation, since, to avoid the presence of the precipitated gypsum either with the dichloride or the undissolved residue of the copper ore, it would be necessary to add the chloride of calcium to the clear copper solution, and, after allowing time for the gypsum to subside, to transfer the liquid to the vats in which the copper is to be precipitated by sulphurous acid. There may, however, be localities in which the cost both of metallic iron and of common salt is such as to render advantageous the decomposition of the dichloride of copper by lime, provided there is no silver to be extracted.

We have heretofore considered only the case in which the acid liquor got by precipitating the copper from neutral solutions in the form of dichloride is used to dissolve successive portions of oxide of copper alone. This can be done in the case of pure ores free from other strongly basic oxides, if without loss, yet without any gain of acid save what comes incidentally from the portion of sulphuric anhydride which is given off in the calcination of pyrites, or from the reaction between sulphurous acid and oxygen in the presence of chloride of copper, as already explained. If, however, as is more often the case, we are treating artificially oxidised sulphuretted ores or mattes, which yield by roasting a mixture of oxide and sulphate of copper, it will be apparent that by the repeated use of the present process there must result a constantly augmenting proportion of free acid in the liquid.

This may be made clearer by examples. Let us suppose a solution holding in a cubic foot (equal 1000 ounces of water) 63·4 ounces or two equivalents of copper in the form of sulphate. To convert this into protochloride would require two equivalents, or 117 ounces of chloride of sodium; but for the production of the dichloride, as we have seen, one equivalent, or a little more, will suffice, or, in place thereof, a corresponding amount of ferrous or calcic chloride. When, by the action of sulphurous acid, the whole of the copper is reduced to the cuprous condition, and in a great part thrown down as dichloride, the previously neutral solution will contain two equivalents or 98 ounces of sulphuric acid* (oil of vitriol), which, if a larger amount of chloride had been added, would be in part replaced by chlorhydric acid. These two equivalents of acid are capable of taking up two equivalents, or 79·4 ounces, of oxide of copper, after which the solution will contain, as at first, 63·4 ounces of copper. If, however, we add to this acid solution, instead of simple oxide of copper, a calcined ore or matte in which one-third of the copper is present as soluble sulphate, and two-thirds as oxide, it is clear that when the acid is saturated we shall have in the liquid, besides the 63·4 ounces of copper from the oxide, one-half as much more, or 31·7 ounces of copper which were already present as sulphate in the roasted ore; making in all three equivalents, or 95·1 ounces, of dissolved copper, which are, in their turn, to be converted into dichloride. Now, as the amount of acid set free in this reaction is equal to that originally combined with the copper, it follows that the liquid after the precipitation of the dichloride will contain three equivalents of acid, instead of two as before. If to this we add, a second time, enough of the mixture of two-thirds oxide and one-third sulphate of copper to neutralise these three equivalents, we shall have four and a half equivalents of dissolved copper, from which, by a third repetition of the process of precipitation by sulphurous acid, four and a half equivalents of sulphuric acid would be set free; so that in place of 98 ounces we should have 220½ ounces in the solution,—an amount which a fourth repetition of the process of saturation and precipitation would raise to six and three-quarter equivalents, or 330 ounces of oil of vitriol.

* For observations on the association of nickel and cobalt with certain copper ores, see Appendix I.

† For notes on the solubility of chloride of silver in solutions of common salt and other chlorides, see Appendix II.

* While we recognise the dyad nature of copper, oxygen, and sulphur, and the bibasicity of sulphuric acid, it is simpler and more convenient for the calculations of the manufacturing chemist and the metallurgist to use, as we have done in the present paper, the older notation, and to speak of 31·7 parts of copper, 8 parts of oxygen, 40 parts of sulphuric oxide, 49 parts of oil of vitriol, 36·5 parts of chlorhydric acid, and 58·5 parts of chloride of sodium as equivalents.

If, instead of a mixture containing one-third of its copper as sulphate, we have one in which only one-fourth is sulphate and three-fourths are oxide, we should get, by saturating with this a solution containing two equivalents of acid, and subsequent precipitation with sulphurous acid, a liquid holding 2·66 equivalents of free acid, which by a third repetition of the process would yield 3·55, and by a fourth 4·73, equivalents of free acid, in place of the two equivalents which were present after the first precipitation.

The above calculations are founded on the supposition that the roasted ore or matte contains, besides the oxide of copper, no base that would be attacked by dilute acids. In fact, however, oxides of lead, zinc, and, more rarely, nickel and cobalt, may accompany the copper oxide, and give rise the first to an insoluble and the others to soluble sulphates, consuming more or less acid. Ores containing more or less carbonate of lime (often with carbonate of magnesia) are also of frequent occurrence, and here is seen a great advantage which this mode of copper extraction possesses over all the other wet processes; for since lime and magnesia, and their carbonates, not only neutralise free acids, but throw down copper from its solutions, the treatment, by these processes, of ores containing any considerable proportion of calcareous matter, is impracticable. With the process here proposed, which generates an abundance of free acid, the extraction of copper from ores which do not contain an excessive amount of calcareous matter presents no difficulty except such as arises from the mechanical obstacle created by the formation of gypsum in the solutions. The accumulation of acid in the bath is, indeed, so rapid in many cases that it will become unnecessarily strong, and may be diluted with water; while that portion not needed, after being deprived of the last portions of copper by the action of metallic iron, may be rejected unless it retains in solution other metals of value.

It will be seen, from the foregoing description, that the new process here described resembles those which, at the beginning of this paper, we have placed in Class II., inasmuch as the oxidised copper is separated from foreign metals by dissolving it in sulphuric and chlorhydric acids, with the difference, however, that the acids for this purpose are generated in the process itself, by the action of sulphurous acid, while the copper is separated from its solutions in the form of dichloride; the reduction of which to pure copper is readily effected by the consumption of a minimum amount of metallic iron. At the same time, any silver or gold which may be present in the ore is left undissolved, and in the best condition for subsequent extraction by well-known methods, while the saving of cobalt and nickel, of lead, or of antimony, should these be present in quantities of economic importance, may be subsequently effected by very simple processes.

The apparatus for this new general method of copper extraction is simple and inexpensive. The chlorine required in the precipitation of the copper being recovered for further use, the only reagent consumed, except the sulphurous acid,—which is a waste product from the roasting of sulphurous ores,—is an amount of iron which is equal to less than one-half the weight of the copper, and may be recovered in the form of sulphate of iron, or, instead thereof, the same quantity of caustic lime.*

Appendix I.

The presence of small portions of cobalt and nickel in cupriferous pyrites is not uncommon, and mixed earthy oxides of copper, nickel, and cobalt have been found in considerable quantities in Missouri. A greenish, translucent, amorphous mineral, with black stains, resembling chrysocolla in appearance, from some place in Western Nevada, where it was said to have been abundant, and to have been mined for the manufacture of sulphate of copper, was brought to me in 1876, and found to contain considerable quantities of both cobalt and nickel. One of two closely agreeing analyses by my former pupil, Mr. Hardman, made at the Massachusetts Institute of Technology in 1877, gave for this mineral as follows:—Oxide of copper, 9·63; oxide of nickel, 3·23; oxide of cobalt, 3·88; peroxide of iron, 3·08; peroxide of manganese, 2·40; lime, 1·04; magnesia, 0·10; alumina, 13·01; silica, 42·97; water, 18·38 = 97·72. The cobalt and nickel were separated by Rose's method. Another analysis, in which these metals were separated by the method of Fischer, with nitrite of potassium, gave of oxide of cobalt, 4·11. Such an ore, if abundant, would be a valuable source of both nickel and cobalt.

This aluminous mineral, like chrysocolla (see second note, col. 2, p. 198), is attacked by a solution of ferrous chloride and common salt, by which the oxides of cobalt and nickel are indirectly dissolved; since, although they have not the power of decomposing ferrous chloride, they decompose the cupric chloride which is formed by its reaction with cuprous oxide.

Appendix II.

As regards the solubility of chloride of silver in solutions of chloride of sodium, Vogel found that 1 litre of a saturated solution, at ordinary temperatures, held dissolved 0·950 grm. of chloride of silver, while, according to Hahn, a litre at 19·6° C. holds 1·269 grms. Becquerel found at ordinary temperatures for a similar solution 0·800 grm. to the litre: 100 parts of water, saturated at 100° C., holds 26·61 parts, and at 15·6° C. 26·34 parts, of chloride of sodium, the densities of the solutions being respectively 1206·93 and 1204·03. Hence 1 litre of a saturated solution at 15·6° holds 316 grms. of common salt, 1000 parts of which solution under these conditions dissolve, according to Hahn, at 15·6° C., 3·0 parts of chloride of silver; while, according to the observations of Vogel and of Becquerel, at "ordinary temperatures," not defined, 1000 parts in saturated solution dissolve respectively 4 parts and 2·53 parts of chloride of silver. The latter figure approximates to that given by Pelouze and Frémy, according to whom 1000 parts of salt at 18° C. hold dissolved 2·40 parts of chloride of silver. The solvent power, according to these chemists, varies greatly with the temperature, the amount dissolved being equal to 1·70 parts at 10° C., and not less than 6·80 at 100° C., while at 0° C. but traces of chloride of silver are dissolved. Differences of temperature may suffice to explain the discrepancies between the results of Vogel, Hahn, and Becquerel, but not those of Pelouze and Frémy at 18·0° C., a temperature above that mentioned by Hahn. It is possible that these chemists may not have employed solutions saturated with chloride of sodium, to which the observations of the others refer. Fresenius, speaking of the solubility of chloride of silver in hot concentrated solutions of the chlorides of sodium, potassium, ammonium, calcium, zinc, &c., says:—"On sufficient dilution with cold water, the dissolved portion separates so completely that the filtrate is not coloured by sulphuretted hydrogen."*

As to the solubility of chloride of silver in some other chlorides, Hahn found that a litre holding 30·70 per cent of ferrous chloride, and having a specific gravity of 1·419 dissolves, at 20° C., 2·385 grms. of chloride of silver; while a solution holding 44·48 per cent of cupric chloride, and having a specific gravity of 1·5723, dissolves at 30° C., for 1 litre, 0·836 grm. of chloride of silver. For further observations on the solubility of chloride of silver in other chlorides, see Percy, *Metallurgy of Silver and Gold*, Pt. I., p. 58, and also Hahn, *Transactions American Institute Mining Engineers*, vol. ii., p. 99.

On Caryophylline.—E. Hjelt.—Caryophylline has the formula $C_{40}H_{64}O_4$. Its isomerism with camphor appears accidental.—*Berichte der Deutschen.*

NOTES OF WORK BY STUDENTS OF PRACTICAL CHEMISTRY IN THE LABORATORY OF THE UNIVERSITY OF VIRGINIA.

No. X.

Communicated by J. W. MALLET,
Professor of General and Applied Chemistry in the University.

(Continued from p. 190.)

(68.) *Analysis of Wulfenite from Ruby Hill, Eureka Co., Nevada.* By C. L. ALLEN, of Charleston, South Carolina.

Among a number of specimens of crystallised wulfenite sent me from the above locality in Nevada there were some which there was reason to suppose might contain calcium molybdate in considerable proportion. An analysis of the mineral was made by Mr. Allen in order to determine this point. The material, formerly found in quite large quantity, is well crystallised, of a bright orange-yellow colour, and of sp. gr. = 6·701. The molybdenum was precipitated from a solution of ammonium sulphomolybdate, and a definite portion of the precipitate reduced to disulphide by cautious ignition in hydrogen. The results of the analysis were—

MoO_3	39·33
PbO	61·11
CaO	1·04
Fe_2O_3	0·38
	101·86

Not very accurate work, but sufficient to show that there is no large amount of calcium present, and that the mineral from this locality—of which I believe no analysis has hitherto been published—has no marked peculiarity of composition.

(69.) *On the Possibility of Artificially Preparing Amorphous Elementary Carbon Free from the Gaseous Elements, Hydrogen, Oxygen, and Nitrogen.* By SAMUEL PORCHER, of Hanover Court-House, Virginia.

It is well known that black amorphous carbon prepared from any form of organic matter as a residue from destructive distillation or imperfect combustion retains obstinately small quantities of hydrogen, oxygen, and (if nitrogenous matter be used) nitrogen, which cannot be driven off by exposure to any attainable temperature. It is an interesting question whether these gaseous impurities exist in chemical union with the carbon or are retained by surface attraction only, such surface condensation undoubtedly occurring to a large extent on exposure to the atmosphere, though much, if not all, of the gaseous matter so condensed *may* be driven off again by heat. With a view to obtain some light on this question it was proposed that carbon should be prepared from materials altogether free from the elements in question, that its weight should be determined; it should then be exposed to the atmosphere, heated again, and the product after cooling examined as to the presence of any of the three other elements named, hydrogen if found being of course attributable to vapour of water. These experiments were undertaken by Mr. Porcher, and some progress made with them, when they were unfortunately interrupted by his serious illness, which prevented their completion before the end of the College year. The following partial results, however, may be worth recording.

The carbon was prepared by passing the vapour of carbon tetrachloride over metallic sodium, very carefully freed from any traces of naphtha, in a hard glass tube, taking care to expel all air before heating the metal. To protect the glass, a layer of pure, well-burned lime was placed on the lower side of the tube, and on this, well pressed down, the sodium rested. In spite, however, of this precaution, the energy of the reaction caused the volatilisation of some of the metal, and the upper part of the glass was attacked, introducing silicon into the product. To avoid this, the lime was in the later experiments placed in a loose inner tube of copper-foil. Platinum was tried, but was itself extensively attacked. Some of the carbon left could be mechanically detached from the upper face of the lime, but up to the time when the experiments were broken off none had been directly obtained free from calcium and copper, which had to be removed by prolonged treatment with nitric and hydrochloric acids and washing with water. The amount of ash left from the combustion of the products first obtained was quite large, but finally a specimen was obtained which was almost perfectly free from fixed impurities.

After being heated to a temperature not much below that at which it would have begun to burn, and then burned in a little platinum boat in a stream of very carefully purified and well dried oxygen, the products of combustion collected as in ordinary organic analysis, one specimen gave absolutely no water, thus indicating the absence of either condensed aqueous vapour or combined hydrogen, while a minute loss on the weight of the original material was probably attributable to the carbon not being completely burned, traces being retained in the ash, which was in this case present in considerable amount.

(70.) *On the Absorption of Chlorine by Arsenious Chloride, and the Amount Retained at Various Temperatures.* By B. E. SLOAN, of Charleston, South Carolina.

Notwithstanding the failure which has hitherto attended all attempts to produce a pentachloride of arsenic, it seemed worth while to examine the effect of exposing the trichloride to gaseous chlorine at low temperatures, observing to what extent the gas was absorbed, and whether any indications could be obtained of true chemical combination.

Pure arsenic trichloride was prepared by the direct action of chlorine on the metal, and the product was carefully rectified from a second retort, access of atmospheric moisture to the receiver being guarded against by a sulphuric acid tube, and the surplus chlorine carried off into a large jar of slaked lime. This trichloride was now placed in a long-necked flask, immersed in a properly protected bath of crushed ice and hydrochloric acid, and chlorine gas, well dried and previously cooled, was slowly bubbled through for eight hours, maintaining throughout a temperature of $-23°$ C., under ordinary pressure, about 745 m.m. At the end of this time a sample, about 20 c.c. of the liquid was drawn off into another cooled flask using a special arrangement of tubes to prevent any gaseous chlorine being brought with it, and to obviate any general contact with the atmosphere. The liquid was received in a short dry test-tube, supported in a vertical position by freezing some water round it in the bottom of the flask, while a second test-tube contained a sufficient amount of a strong solution of sodium hydrate for the complete decomposition of the chloride. This receiving flask with its appurtenances, including a stopper, which had been accurately weighed beforehand, was now allowed to stand for some hours to acquire the temperature of the laboratory, was then again weighed, so that the exact amount of the chloride introduced was known; the mixture of the latter with the soda solution was gradually made complete, the mixed solution was diluted to a definite volume, and in separate portions of this the chlorine and arsenic were separately determined. The results showed 4·447 atoms of chlorine for 1·0 of arsenic. As a lower temperature could hardly have been used without risk of simply liquefying the chlorine itself, and as other experiments showed that the time employed was much more than sufficient to allow of all the gas being taken up that would dissolve, it was obvious that a pentachloride had not been formed.

The stability of the liquid formed at −23° was then examined by exposing separate samples of it to various higher temperatures for considerable lengths of time, and analysing the residual products. During the exposure of each sample, simple evaporation was guarded against by closing the mouth of the little containing flask with a stopper through which passed a tube, open at both ends, containing solid sodium hydrate, which was washed out of the tube afterwards, and chlorine and any arsenic in the solution determined. The results obtained as to the composition of the liquid were—

			Atoms Cl for 1 at. As.
After 2 hrs. 30 mins. at	−23° to −19° C.*	..	4·324
,, 1 hr.	,, −19 − 6	..	4·292
,, 10 hrs.	,, − 6 +15	..	4·233
,, 8 hrs. 30 mins.	,, 15 24	..	4·080

The rate of loss of surplus chlorine being slower than might have been expected on the supposition of its existing merely in a state of physical solution, and the apparent tendency of the above figures to a ratio of 4 atoms chlorine for 1 atom of arsenic suggested the possible existence of a compound, As_2Cl_8, in which arsenic would appear as a pentad. Another specimen, however, of the liquid product obtained as above, the first supply having been exhausted, was exposed to a still higher temperature—viz., 37° C.—and was afterwards found to contain but 3·33 atoms of Cl for 1 of As. This specimen was *prepared* at a much higher temperature than the former, the advance of the season having made it very difficult to work with freezing mixtures for any considerable time, and this fact, coupled with the rather abrupt change of composition observed between the specimens exposed to 24° and 37° respectively, makes it still conceivable, though perhaps not very probable, that an unstable compound, As_2Cl_8, may exist.

(To be continued.)

CHEMICAL NOTICES FROM FOREIGN SOURCES.

Note.—All degrees of temperature are Centigrade, unless otherwise expressed.

Comptes Rendus Hebdomadaires des Séances, de l'Académie des Sciences. No. 10, September 5, 1881.

Carbonated Ferruginous Waters.—J. Ville.—Alkaline and alkaline earthy bicarbonates do not affect ferruginous waters. Chlorides and sulphates retard in a marked manner the decomposition of such water on exposure to the air.

No. 11, September 12, 1881.

Comparative Qualities of the Waters of the Isère and the Durance for the Purposes of Irrigation.—M. de Gaspardin.—The author gives a comparative analysis of the two waters. The results are of merely local interest.

New Process of Working Mines of Sulphur.—MM. de la Tour du Breuil.—The authors boil out the sulphur from its gangue in a solution of chloride of calcium containing 66 per cent of the solid salt and having its ebullition-point at 120°. This solution attacks neither the sulphur nor the gangue. In this manner the sulphur is extracted in a state of great purity, at the cost of 5 francs per ton, and without the production of any nuisance.

Radiophony Produced by Lamp-black.—E. Mercadier.—Lamp-black is not merely pre-eminently the thermophonic agent, but it may, like selenium, act as an electric photophone. The author referring to the double coil receivers, which he described *Comptes Rendus*, xcii., p. 789, states that, instead of selenising one of their surfaces, it may be blackened by exposure to the smoke of an oil lamp, taking care not to carbonise the parchment paper, which isolates the metallic coils from each other.

Explanation of a Contrast in Circular Double Refraction.—M. Croullebois.—A mathematical paper, not susceptible of useful abstraction.

Magnetic Metals.—M. Gaiffe.—Cobalt is much more strongly magnetic than nickel.

Metaldehyd.—MM. Hanriot and Œconomides.—Metaldehyd is insoluble in water, almost insoluble in alcohol, tolerably soluble in aldehyd. Its best solvents are chloroform and benzol. It has been heated to 200° in sealed tubes for four hours without being converted into aldehyd to the extent of more than one-half.

Berichte der Deutschen Chemischen Gesellschaft zu Berlin Vol. 13, No. 7.

Certain Compounds of the Leuko-base from Cuminol and Dimethyl-aniline.—J. Ziegler.—The base is obtained according to Otto Fischer's process. The author describes the hydrochlorate, picrate, iodmethylate, the platinum double salt, and the action of nitric acid. By oxidising the base, colouring-matters are obtained almost identical with benzol green.

The Ureides.—J. M. A. Kramps.—The author has examined the action of chlorine and bromine upon sulphydantoin.

Problem to Determine the Number of Isomeric Paraffins of the Formula C_nH_{2n+2}.—F. Hermann.—The numbers of the possible isomeric paraffins of the formulæ $C_{12}H_{26}$ and $C_{13}H_{28}$ are respectively 355 and 802.

Action of Sodium upon Turpentine Hydrochlorate.—E. A. Letts.—When all the chlorine has been removed from the hydrochlorate the product yields on distillation a white solid, which boils at about 157°. In addition to this main product there passes over at about 330°, a yellowish white liquid.

Action of Ammonia upon the Ethyl-esters of Camphoronic Acid.—E. Hjelt.—On passing dry ammoniacal gas into an alcoholic solution of the mono-ester, there was obtained the corresponding mono-amide. A more permanent amide was obtained by a similar process from the diethyl-camphoronate.

Colouring-Matters Obtained by the Action of Naphthol upon Diazo-azobenzol.—R. Nietzki.—The author points out certain inaccuracies in the memoir of W. v. Miller (*Berichte*, xiii., p. 542).

Sequel to a Notice on New Colours.—W. v. Miller.—The author admits the priority of H. H. Caro and Schraube as regards certain points advanced in his memoir (*Berichte*, xiii., p. 542).

Composition of Barium Dioxide Hydrate.—Em. Schœne.—The author maintains his formula for this compound, $BaO_2,8H_2O$, against Berthelot, who ascribes to it ten molecules of water.

Condensation-Products of Tertiary Aromatic Bases.—Otto Fischer.—The author has studied the behaviour of the three isomeric dimethyl-toluidines with benzaldehyd. The para- compound does not react in presence of zinc chloride, even at 120° to 130°. The ortho-compound reacts, but with much more difficulty than dimethyl-aniline. The base was obtained in very small quantities, and its homology with tetra-methyl-diamido-triphenyl-methan is undecided. The meta- compound reacts as easily as dimethyl-aniline.

A Product of the Action of Aqua Regia upon Orcine.—S. Reyman.—The result of the reaction is a chlorine substitution-product of the colouring-matter obtained by Liebermann by the action of nitrous acid upon orcine.

* The temperature was allowed to rise gradually, but was most of the time at the higher point named.

Volatile Chlorides.—V. Meyer and H. Züblin.—Tin chloride seems to exist in the gaseous state in two modifications. In lower temperatures it is Sn_2Cl_4. but at higher temperatures it is resolved into molecules of $SnCl_2$.

Meta-para-dinitro-benzoic Acid Obtained by the Nitration of Para-nitro-benzoic Acid.—A. Claus and W. Halberstadt.—The author has obtained a new—the fifth—dinitro-benzoic acid by the nitration of para-nitro-benzoic acid.

History of Phenyl-acetamide.—Aug. Bernthsen.—Phenyl-acetamide was obtained in quantity from benzyl-cyanide, and described in 1873 by Weddige, and in 1876 by the author.

Bulletin de la Société Chimique de Paris.
No. 10, May 20, 1881.

Volumetric Liquid for the Determination of Super-oxygenised Compounds or such as Act as Oxidisers. A. Terreil.—The composition of the liquid is—

Ferrous sulphate .. .. 100 grms.
Concentrated sulphuric acid .. 200 ,,

The iron sulphate is dissolved in about half a litre of water, the sulphuric acid is then added and water enough to make up 1 litre when the mixture is cold. The solution is then titrated with a standard solution of potassium permanganate. Natural manganese ores, if finely powdered, may be determined in a few minutes. If lead or barium is present in the ore a few c.c. of hydrochloric acid should be added.

No. 11, June 5, 1881.

Action of Nitric Acid and the Metals.—E. J. Maumené.—If tin and nitric acid could be brought to act upon each other in infinitely thin strata, the result would be simply stannous oxide and ammonia.

Explosive Qualities of Mercury Fulminate.—MM. Berthelot and Vieille.—Already noticed.

No. 12, June 20, 1881.

Preparation of Chlorine.—M. Berthelot.—Already noticed.

Russian Chemical Society.—Session of Dec. 5/17, 1880.—A. Krakau.

M. Lebedinsky presented a communication on allyl-di-iso-propyl-carbinol and on the di-iso-propyl-ethyleno-lactic acid derived from this alcohol.

A note was presented by M. Chirokoff on the transformation of oxy-valeric acid into iso-propyl-acetic acid, and on iodo valeric acids.

M. Beketoff gave a communication on the reciprocal displacements of the halogens.

M. Diaconoff described an apparatus for drying gases.

M. Andreeff exhibited an automatic apparatus for washing precip tates, acting in a periodic manner.

M. Melikoff submitted a memoir on the derivatives of acrylic acid.

M. Kowalewsky has undertaken a study of the electrolysis of aqueous solutions of zinc sulphate.

M. Potilitzine explained the continuation of his researches on the speeds of reactions and on the law of distribution.

MISCELLANEOUS.

The Royal Institution.—The Session will commence with a course of six lectures on Astronomy, adapted to a juvenile audience, by Prof. R. S. Ball, F.R.S., Astronomer Royal in Ireland. Dr. Wm. Huggins will give a discourse on Comets at the first Friday Evening Meeting, January 20th, 1882.

King's College Science Society.—This Society, which is open to all past and present students of King's College, London (the annual subscription being 5s, and the entrance-fee 2s. 6d.), will hold its first meeting this Session on Tuesday, the 25th inst., in the Physical Lecture Theatre, when Prof. W. G. Adams, M.A., F.R.S., will give a lecture on "Grove's, Planté's, and Faure's Secondary Batteries. The chair will be taken at 8 p.m. Admission by ticket only. Applications should be made to the Secretary of the Science Society, King's College, Strand, W.C.

Strontianite.—Since it has been shown by Professor Scheibler, of Berlin, that strontium is the most powerful medium of extraction in sugar refinery, owing to its capacity of combining with 3 parts of saccharate, the idea suggests itself that the same medium might be successfully employed in the Arts, and form a not uninteresting subject of speculation for the chemist. Hitherto native strontianite—that is, the 90 to 95 per cent pure carbonate of strontia (not the cœlestine which frequently is mistaken by the term Strontianite)—has not been worked systematically in mines; but what used to be brought to the market was an inferior stone collected in various parts of Germany, chiefly in Westphalia, where it is found on the surface of the fields. Little also has been collected in this manner, and necessarily the quality was subject to the greatest fluctuations. By Dr. Scheibler's important discovery a new era has begun in the matter of strontianite. Deposits of considerable importance have been opened in the Westphalian districts at a very great depth, and the supply of several ten thousand tons per annum seems to be secured, whereas only a short time ago it was not thought possible that more than a few hundred tons could in all be provided. The interests in the various mines are, as it appears, amalgamated, and a syndicate has been formed which is represented in London by Messrs. Zimmermann.

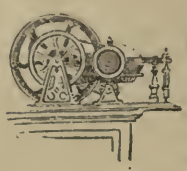
LANCASHIRE

Carr's Patent Paint and Drug Mill.

Approved by some of the most eminent Chemists, and awarded the Silver Prize Medals of the Manchester and Liverpool, and the Middleton Agricultural Shows.



From Messrs. E. H. SMYTH & Co., 21 Duke Street, Edinburgh, and 69, Coleman Street, City, London.—The small Levigator Mill we recently got from you works most efficiently, and is a great economiser of time.

The chief feature in this machine is, that although it can be turned with ease by a boy, it has immense frictional power for levigating purposes. This is caused by the runner being driven at a much greater speed, but in the same direction, than the bowl. The surfaces being Minton ware, they are clean, smooth, and durable.

Testimonials on application.

£11 nett cash, delivered in Manchester.

The diameter of the bowl is 18 ins., and it and the runners are made of Minton ware. It is useful for Painters, Chemists, Grocers, and Cooks, for triturating and mixing Medicines, Vegetable Powders, Ointments, Paints, Sugar, Salt, Spices, Herbs, Meat for Potting, and will grind the COARSEST EMERY INTO A NEARLY IMPALPABLE POWDER in a few seconds. The pan can be tilted for emptying, as shown in the dotted lines; it can be worked by hand or power.

NOTES OF WORK BY STUDENTS OF PRACTICAL CHEMISTRY IN THE LABORATORY OF THE UNIVERSITY OF VIRGINIA.

No. X.

Communicated by J. W. MALLET,
Professor of General and Applied Chemistry in the University.

(Concluded from p. 204.)

(71.) *Analysis of Felspar accompanying Microlite, in Amelia Co., Virginia.* By B. E. SLOAN, of Charleston, South Carolina.

In the vein of coarse granite, about a mile from Amelia Court-House, in this State, from which large sheets of mica are obtained for commercial purposes, and in which the rare mineral microlite has been found,* along with brilliantly phosphorescent fluorspar, columbite, and great crystals of beryl, there occur crystalline masses of a beautiful felspar, nearly white, with a faint bluish green tinge, highly cleavable, with a brilliant vitreous, slightly pearly lustre on the principal cleavage faces; sp. gr. = 2·501. The general appearance is that of oligoclase from some localities, but Mr. Sloan's analysis shows that the mineral is orthoclase. He found—

		Atomic Ratios.	
SiO_2	65·37		1·0895—5·96
Al_2O_3 ..	18·74	0·1837	0·1845—1·01
Fe_2O_3 ..	0·13	0·0008	
CaO	0·27	0·0048	
K_2O	12·98	0·1378	0·1828—1·00
Na_2O ..	2·49	0·0402	
	99·98		

Agreeing closely with the normal tri-silicate formula.

(72.) *On a Zinc-bearing Clay from the Neighbourhood of the Bertha Zinc Mine, Pulaski Co., Virginia.* By B. H. HEYWARD, of Charleston, South Carolina.

This compact, lithomarge-like clay occurs at the locality named, in a seam of several inches thickness, overlying the deposit of calamine. It is light reddish yellow in colour, cuts under the knife like meerschaum, and on a cut surface exhibits a grained texture like that of wood. With water it forms a plastic mass, which is quite tenacious, becomes rigid on drying, and becomes pretty hard in the fire. It is partially decomposed by strong hydrochloric acid, and more completely by concentrated sulphuric acid on heating. Analysis gave—

SiO_2	37·38	
Al_2O_3	24·67	
Fe_2O_3	6·34	
ZnO	12·10	
MgO	0·27	
K_2O	0·47	
Na_2O	0·27	
H_2O (expelled on ignition over blast-lamp)	10·35	17·04
Do. (lost at 100° C.)	6·69	
	98·54	

* *Amer. Chem. Jour.*, May, 1881, 130.

On digestion with acetic acid the zinc, or at any rate a large proportion of it, was found to be soluble, perhaps existing in the clay as hydrate, though more probably as silicate (calamine), in a state of fine subdivision, and uniformly mixed with the aluminous silicate of the clay.

(73.) *Examination for Iodine of the Mother-Liquors from Salt Brines of West Virginia.* By A. L. BAKER, of Baltimore, Maryland.

A few years ago the remarkable statement was published* that the "bitterns" left from the manufacture of salt by boiling the natural brines of West Virginia and eastern Ohio, which have furnished very large quantities of bromine, contain, in addition to this element, about one-third its weight of iodine. This assertion seemed very improbable, but as no direct refutation of it was to be found in the shape of accurate determinations of the presence or absence of iodine in these mother-liquors, and of its amount if present, it was desirable that such an examination of these should be made. I am indebted to Dr. J. P. Hale, of Charleston, West Virginia, for four samples of "bittern," viz.—

No. 1.—Snow Hill furnace, Kanawha Co., W. Va.
No. 2.—Daniel Boom furnace, Kanawha Co., W. Va.
No. 3.—Newcastle furnace, Mason Co., W. Va.
No. 4.—Hartford City furnace, Mason Co., W. Va.

He informs me that, while these mother-liquors vary somewhat in strength from time to time at the same and at different salt-boiling furnaces, the variation is not very great, and that usually from 5 to 7 per cent of the brine as it comes from the wells is left as bittern, of which bittern 20 to 30 gallons will yield 1 pound of bromine.

These specimens all consisted essentially of very strong solutions of calcium, magnesium, and sodium chlorides, the first largely predominating, with enough free hydrochloric acid to give a distinct acid reaction with litmus paper. The specific gravities at 15° C. were—

No. 1.—Snow Hill	1·305
No. 2.—Daniel Boom..	1·270
No. 3.—Newcastle	1·300
No. 4.—Hartford City	1·285

It was found that part of the iodine—in one specimen all of it—existed in the free state, and could be collected directly by agitation with carbon disulphide. It was remarkable, however, that on dilution with water the amount that could be thus collected diminished. A good deal of difficulty was encountered in determining correctly the combined iodine, the other substances present sensibly interfering with its separation. The results obtained were only accepted as satisfactory after they had been checked by comparative experiments made with an artificial brine of the same general composition as the natural, but originally free from iodine, to which known amounts of standard dilute potassium iodide solution were added. It was found that potassium nitrite and *citric* acid answered best for the liberation of the iodine from iodides present; it was then taken up by carbon disulphide, and the amount determined by decolouration with a standard solution of sodium thio-sulphate. No difference in the quantity obtained was produced by the previous addition of arsenious acid; hence iodates were absent.

A number of experiments proved the following amounts of iodine to be present:—(See Table next column.)

Taking the mean of the above results, and calculating on the basis of the returns of West Virginia salt production in 1876, and Dr. Hale's statements as to the ratio of bittern to salt turned out, it appears that about 6287 lbs. of iodine go to waste annually in this region, worth at present about 22,000 dols., or £4500. It seems very doubtful, however, whether the extraction of this from such a mass of bittern can be made profitable. It might be worth while to try Bechi's plan, liberating the iodine

by exactly the right amount of nitrous acid or of chlorine, and collecting it by filtration through animal charcoal. Judging from experiments on the small scale, the precipitation as cuprous iodide seems to be incomplete. The acid condition of these bitterns suggests the probability of extensive loss of iodine by decomposition of magnesium iodide during the later stages of the boiling, and it would be interesting to ascertain what effect upon the amount left in the mother-liquor would be produced by keeping the brine just neutralised with sodium carbonate.

(74.) *Analysis of Epidote from near Greenwood, Albemarle Co., Virginia.* By T. P. Lippit, of Charlestown, West Virginia.

A large lot of railway ballast was laid down some months ago upon the line of the Chesapeake and Ohio Railway, near the University of Virginia, consisting of highly metamorphosed schist passing into felsite, from the above-named locality, and through this epidote was extensively distributed, for the most part intimately mixed with the other components of the rock, but often presenting good specimens in the form of distinct crystalline nodules, sometimes enclosing a nucleus of quartz, and often penetrated by little needles of the same. The mineral is of clear, characteristic, pistachio green colour; sp. gr. =3·39. A careful preliminary examination proved that the iron is altogether in the ferric condition, and that but a trace of alkali is present. After drying at a temperature not over 100° C. analysis gave—

		Atomic Ratios.	
SiO_2	39·74	0·6623	=9
Al_2O_3..	21·55	0·2113	0·3069=4·17
Fe_2O_3	15·29	0·0956	
CaO	22·75	0·4062	0·4214=5·73
MgO	0·61	0·0152	
	99·94		

Agreeing pretty fairly with the normal ortho-silicate formula, $M_6''R_8'''Si_3O_{36}$— about two-thirds aluminium epidote and one-third iron epidote.

(75.) *On the Presence of Ammonia in Human Saliva.* By B. H. Heyward, of Charleston, South Carolina.

A year or two ago I happened to observe the fact that the usual evidence of the presence of ammonia was obtained with human saliva on the addition of the Nessler reagent. So far as I am aware, ammonia has not hitherto been recorded as present in this secretion. Mr. Heyward undertook to examine the point somewhat more fully, and to ascertain whether the reaction is normal by testing the saliva of a number of persons in health, and by examining the secretion of the same person at different times.

In evidence that ammonia is really present, at any rate that the Nessler reaction is not due to any non-volatile or but slightly volatile organic base, a small quantity of saliva was placed at the bottom of a perfectly clean and dry test-tube, a little recently hea ed oxide of magnesium was added, a slip of white filtering paper moistened with the Nessler reagent was suspended in the upper part of the tube, and this was corked and exposed to a temperature of about 30° C. In a few minutes the paper was rendered distinctly orange, while in a blank experiment, conducted under the same conditions, but omitting the saliva, this was not the case.

In all of nineteen different cases examined—all young men in good health—the ammonia reaction was obtained. For ten of these the amount in the mixed saliva was approximately determined by comparison of the colour produced with that due to the use of various determinate dilutions of a very weak standard solution of ammonium chloride. The results were—

1st person, about 100 milligrms. per litre.				
2nd	,,	,,	40 and 80 ditto	(on two occasions).
3rd	,,	,,	80 and 60 ditto	,, ,,
4th	,,	,,	50 and 30 ditto	,, ,,
5th	,,	,,	100 and 50 ditto	,, ,,
6th	,,	,,	60 and 100 ditto	,, ,,
7th	,,	,,	40 and 30 ditto	,, ,,
8th	,,	,,	40 and 30 ditto	,, ,,
9th	,,	,,	50 and 50 ditto	,, ,,
10th	,,	,,	50 and 80 ditto	,, ,,

The mixed saliva of a single person—Mr. Heyward himself—varied as follows on seven successive days :—

1st day—About 40 milligrms. per litre.				
2nd	,,	,,	60	,, ,,
3rd	,,	,,	40	,, ,,
4th	,,	,,	40	,, ,,
5th	,,	,,	40	,, ,,
6th	,,	,,	50	,, ,,
7th	,,	,,	60	,, ,,

To get some idea whether the ammonia is present equally in the pure secretions of the different salivary glands, Mr. Heyward had both of Wharton's ducts closed by a single fine small clamp applied (by Dr. J. S. Davis, Professor of Anatomy in the University) across the frænum of the tongue, and, on examining the saliva collected with the sub-maxillary secretion thus cut off, about 10 m.grms. per litre was the result. Next, these ducts from the sub-maxillary glands were re-opened, and Steno's ducts on both sides were closed by two of the same delicate clamps: with the parotid saliva thus excluded the remaining mixed secretion indicated about 30 m.grms. per litre. The natural saliva on the same morning, none of its components being excluded, showed about 40 m.grms. per litre. Of course the conclusion is that most, if not all, of the ammonia came from the two principal pairs of glands, the parotid and sub-maxillary, and that of these the latter furnished notably the larger share. These results also indicate that the source of ammonia—at any rate the sole or chief source—is not to be found as the free gas in the expired products of respiration, merely condensed in aqueous solution in the mouth.

The main interest attaching to these observations is the establishment of a little point of general physiology; but the practical deduction for chemists may be made, that in delicate analytical determinations with the Nessler reagent a conceivable source of error might arise from small quantities of saliva allowed carelessly to remain upon pipettes or the tubes of washing bottles which have been held in the mouth.

The fact now noted perhaps connects itself with the observation of Schönbein,* that mixed saliva usually, though not always, contains a nitrite or nitrites. Since Mr. Heyward's experiments were made, I have tried the very delicate test of Griess—sulphanilic acid followed by naphthylamin hydrochlorate—upon two or three specimens of saliva, and found the nitrite reaction distinct, although the colour was but slight in each instance.

HYDRATION OF SALTS AND OXIDES.*

By C. F. CROSS.

The hydration of substances, considered as a statical problem, has necessarily received much attention, but its dynamic aspects, especially as presented in the phenomena of dehydration and rehydration, have been very little noticed.

Messrs. Hannay and Ramsay have devised a method for the study of the former, by means of which they obtained a number of interesting and important results (*Chem. Soc. Journ.*, 35, 456 *et seq.*), and in consideration of the value of such constants as they establish, it is to be hoped that they will greatly add to their number. The inverse phenomenon of rehydration must also occupy an important place in future molecular science, and it is with the object of bringing it within the scope of quantitative investigation, of aiding the advance towards a complete knowledge of the relations of matter generally to water, that I have entered upon my researches. The apparatus which I have adopted has been exhibited in a neighbouring building, and sufficiently described in a recent communication to the Chemical News (vol. xliv., p. 101). A number of my numerical results are also expressed in the accompanying diagrams, but my desire, in laying this subject before the Section, is to bring out certain of the more general results of the work already done, and, therefore, with as little reference as possible to particulars. How far the method adopted is to be considered rigorous is the first point for our consideration.

A substance, *e.g.*, $CuSO_4$, with a powerful attraction for water, is exposed under a bell jar to an atmosphere saturated with aqueous vapour. The question that at once arises is this: Seeing that the confined volume of air is very small (2000 c.c.), and the weight of watery *vapour* present also very small in relation to the quantity required by the sulphate (about 1 grm. $CuSO_4$) for saturation, will not the rate of combination of the salt with water rather represent the velocity with which water can be evaporated from below and supplied as vapour than measure the "chemical" attraction of the salt for water? In solution of this, four sets of experiments were made: (1.) It was found that the rate of hydration, *i.e*, the quantities taken up in successive hours and the velocity of attainment of the limiting hydration ($5H_2O$), were strictly proportionate to the ratio of the area over which the salt was distributed to its weight. This held good up to a limit of 1·25 grms. distributed over a circular area of 60 m.m. diameter. With quantities less than this, therefore, copper sulphate does not, in uniting with water, overtake such a supply of water molecules as that conditioned by a volume of 2000 c.c. confined over a surface of water. (2.) A stream of air (*a*), after passing through the water in the trough (*b*), previously saturated by passing over moist cotton-wool, was aspirated through the apparatus by means of a tube passing through the cork of the bell jar; and (*c*), saturated as in the preceding, was aspirated from below, *i.e.*, was caused to descend vertically upon the substance; and in no case was the rate of hydration sensibly affected. (3.) The evaporating surface was several times multiplied by filling the space between the inner glass and the sides of the bell jar with prepared flax, kept moist by capillary absorption of the water in the trough; but the rate of hydration was but very slightly affected. (4.) A large case of glass with a wooden framework, 3 feet in the side, was placed, with its open side downwards, in a trough of water. In this large "bell jar" the salts were confined, by means of an air-tight arrangement: a series of observations showed that the hydration was not sensibly affected by this modification. Within the limits of temperature, therefore, which obtained in the above experiments, 12° to 25° C., we may regard the method of observation as affording strictly accurate results, *i.e.*, in so far as the accuracy desired is of the relative order. And, indeed, an *absolute* measure of the rate of hydration of a salt is in the first instance somewhat difficult of *definition*, and as a quantity to be determined with precision may, without apology, be left to the science of the future.

There occurs in the next place the question of the influence of temperature. This of course is a powerful one, as may be seen from the following table of observations upon $CuSO_4.H_2O$, the quantity of salt being in each case about ½ grm. mol., and the numbers representing the extension of the spirals from the o point.

It is remarkable that the rate of hydration in Expt. 3, *i.e.*, at a temperature below 0° C., is much higher than that which is deducible from the ratio of the tension of aqueous vapour at this, to that at the higher temperatures which obtained in the other experiments, showing consequently that the hydration is by no means a simple function of the number of water molecules in the unit of space.

At a temperature of 50°, in ordinary air, I have observed that the pentahydrated salt loses 4 mols. H_2O, though with such difficulty that it requires 10 to 14 days to complete the dehydration.

Between 0° and 50° on the side of temperature, and complete saturation with and entire absence of water, in respect of the atmosphere surrounding the salt, these varying singly and jointly, we may safely predict the existence of a number of *critical* points for each of these 4 molecules of H_2O. Hence the importance of being able to secure any temperature, and that constant, in all experiments on rehydration. The difficulties to be encountered have hitherto prevented my realising that condition satisfactorily, but the problem will, I hope, be solved before long.

The next question to be dealt with is that of the gain of weight, how far is it due to water only, and how far is it due to water combined with the salt in the manner in which it has been assumed to be? On this latter point

* Read before the British Association, York Meeting, Section B.

we have conclusive evidence. Chromium oxide which had been exposed to a saturated atmosphere for 101 days was ignited before and after strong pressure between blotting-paper: in the former case the loss was 60·3 per cent, in the latter 59·82; it contained no precipitated moisture therefore. The sharply "molecular" character of the hydration of copper sulphate, the constancy of the indications of the balances when a limit has been attained, and the microscopic examination of the hydrated salts, all tend to negative the suspicion of the presence of precipitated moisture. Of the probability of the absorption of atmospheric gases, in addition to water, the former objection, there is no need to treat here; it is doubtless considerable as regards relative volume, and has a part to play in affecting hydration, but the former may be neglected as regards weight, and on the latter we can offer nothing but conjecture.

Having subjected the method of investigating this complex problem of rehydration to a critical examination, it remains to bring before you some of the more important facts which it has established.

General Characteristics of the (Re)hydration of Salts.—These have been, so far as the investigation has gone, numerically and diagrammatically represented in the curves accompanying the balances. They present the following features: *Copper Sulphate* combines with decreasing velocity with $5H_2O$, at which point it remains constant for some time; it then proceeds to take up additional water, though with much less velocity, and, in fact, *deliquesces*. This second phenomenon takes many days to complete. Its occurrence, requiring the more "artificial" condition of a saturated atmosphere, has hitherto been overlooked; it is important as showing that from hydration to solution there is an actual and unbroken series of combinations with water. *Sodium Sulphate*, as well as *Potassium* and *Magnesium Sulphates*, pass through hydration to deliquescence without break, and, indeed, any very marked variation in the rate of combination, such as to indicate a distinction between the phenomena. *Potassium Dichromate* gives us a third type of hydration, inasmuch as, under the conditions of exposure described, and also at the ordinary temperature of the air, it "condenses" water to the molecular limit of 3·5 H_2O (becoming $2K_2Cr_2O_7,7H_2O$), none of which water would be said to be combined with the salt, as it is entirely removed by pressure between blotting-paper, or by a short exposure to ordinary air. Precipitated *Ferric Oxide*, dry at 100°, and containing 1 mol. H_2O, hydrates rapidly at first, but after taking up 1 mol. water the combination proceeds very slowly.

In the following table the hydration of this oxide is compared with cupric sulphate ($CuSO_4.H_2O$) under the same conditions:—

Duration of Exposure.	$CuSO_4.H_2O$.		$Fe_2O_3.H_2O$.	
0 hrs.	89		89	
1	96		95	
2	103		96	
3	110		97	
4	113·5		98	$Fe_2O_3.2H_2O$
5	118		99	
6	122·5		101	
7	125	$CuSO_4.5H_2O$	—	
8	126·5		—	
9	127		—	
20	129		106	
26			108	$Fe_2O_3.3H_2O$
74			114	
76			116	
78			116	$Fe_2O_3.4H_2O$
140			119	
203			126	$Fe_2O_3.5H_2O$
260			127	
386			129	

At this point the bell jar was removed and the oxide exposed to the air. The following observations of dehydration were made:—

2 hrs.	109	
3	108	
4	108	
21	108	$Fe_2O_3.3H_2O$

The stability of the trihydrate had been previously observed (*Chem. Soc. Journ.*, 35, 796). The above instances are typical of the entire series of observations, and I do not therefore think it necessary to multiply examples. There are one or two cases in which a remarkable saltus has been observed, but these need confirmation.

In conclusion I take the opportunity of correcting certain statements of previous observers as to the dehydration of copper sulphate, $CuSO_4H_2O$, by absolute alcohol.

Thorpe and Watts state (*Chem. Soc. Journ.*, 37, 103), on the authority of Playfair, that three of the 5 mols. H_2O are eliminated by the action of boiling absolute alcohol. Two preparations which were boiled repeatedly with successive quantities of absolute alcohol I found to contain, after drying over sulphuric acid, 10·9 per cent and 10·6 per cent H_2O respectively, these numbers corresponding to the monohydrate. The necessity of this is an *a fortiori* inference from the observation, previously mentioned, of the elimination of 4 mols. H_2O by prolonged exposure to a temperature of 50° C. In another case, after boiling for 24 hours with repeated change of the alcohol, the product contained only 8·9 per cent, and after a further 16 hours, 7·54 per cent H_2O, which must be taken as tantamount to the complete dehydration of the (whole of the) salt. There are probably many other cases in which the limiting dehydration by means of boiling alcohol has not been attained.

I take this opportunity of thanking Messrs. E. Richards and Geo. Birkbeck, of the Barrow Steel Works Laboratory, for much assistance in carrying out the above experiments.

UPON THE

DIRECT CONVERSION OF THE AROMATIC AMIDES INTO THEIR CORRESPONDING AZO-COMPOUNDS.

By ALBERT R. LEEDS.

I HAVE already published in another place (*Journ. Amer. Chem. Soc.*, 3, 16,) the results obtained by the action of hydrogen peroxide upon benzene. The latter is gradually converted into phenol-oxalic acid, and a small amount of a yellow colouring matter being formed at the same time.

Phenol itself is but slightly acted upon by hydrogen peroxide in the cold, but at the boiling point undergoes conversion into a tarry substance.

Naphthalen, when digested with hydrogen peroxide, yields a small amount of naphthol. Naphthol itself is not affected to any notable extent by hydrogen peroxide in the cold, but at the boiling point is changed to a tar.

When anthracen is dissolved in glacial acetic acid, and the precipitate obtained on the addition of solution of hydrogen peroxide is digested with excess of the latter reagent the anthracen is slowly converted into anthraquinon. Three grms. of anthracen, boiled for three days with hydrogen peroxide, in a flask attached to a return-cooler, were changed almost entirely into anthraquinon, the brown colouring matter formed at the same time being too small in amount to permit of its being experimented upon successfully.

Benzene-sulphonic acid was slightly acted upon, a brown colour being imparted to its solution after boiling for a number of hours with hydrogen peroxide, and the acid crystallising out from the liquid in small colourless crystals,

identical in appearance with the original body before its treatment with peroxide.

The preceding results show that in certain cases hydrogen peroxide operates upon organic bodies by the substitution of hydroxyl; in other cases, by direct oxidation, and in the third place, by both actions combined.

The experiments were therefore extended to the aromatic amides with the hope that hydroxylated derivatives of these compounds might be obtained. The amide was converted into the acetate, or when this not possible, it was dissolved in excess of glacial acetic acid, and a solution of hydrogen peroxide, containing 1·2 per cent of peroxide, added in successive portions. Heating of the liquid had to be avoided, the amide in every instance being changed to a tarry substance. This result indeed happened in most instances, even when the experiment was conducted at common temperatures or with gentle warming. The following is a brief summary of the results obtained with the compounds thus far operated upon:—

Diphenylamin yielded a large amount of a black liquid and a black tar.

Dimethylanilin gave a very dark red liquid with a black residue soluble in alcohol.

Xylidin formed a claret-coloured liquid with a blackish residue dissolving in alcohol to a dark purple solution.

Naphthylamin gave a rose-coloured liquid with a brownish-black residue.

Similar results were obtained with orthotoluidine, the solution acquiring a ruby colour, and a blackish tarry residue soluble in alcohol being formed.

Failing to obtain by careful sublimation, or by treatment with ligroine, alcohol, and other solvents, any crystalline bodies from the above products, their further study was abandoned.

Aniline and paratoluidine acted differently. The solutions of their acetates in hydrogen peroxide quickly threw down, on gentle warming, copious precipitates of a brownish crystalline appearance. At higher temperatures there was a formation of tar. The precipitates came down principally on the first treatment with the peroxide. On filtering them off and adding an amount of the peroxide in excess of the calculated quantity, the second crop of crystals was small, and the larger portion of the aniline or paratoluidine acetate remained behind in the solution.

The precipitates, after washing and drying, were sublimed very slowly, since the small amounts of accompanying tarry matter interfered seriously with the operation when the temperature was not carefully regulated at the lowest practicable point. The sublimate from the paratoluidine formed yellow needles, some of them exceeding two inches in length. They were repeatedly crystallised from alcohol, in which they are not very readily soluble, and were finally obtained as magnificent orange needles. Their melting-point was 143-144°.

0·2806 grm. of the substance yielded on combustion 0·8123 grm. carbonic acid and 0·1763 grm. of water. These results agree with those calculated on the supposition that the body is azotoluol, $C_{14}H_{14}N_2$:—

	Calculated.	Found.
Carbon	80·00	79·28
Hydrogen	6·66	6·98
Nitrogen	13·34	13·51

The same body has recently been obtained by Barsilowsky* by the action of very dilute potassium permanganate solution upon toluidine sulphate. This reaction yielded a very small product, and Barsilowsky afterwards used a solution of potassium ferricyanide and caustic potash with better results. The orange crystals thus obtained melted at 144°, and were identical in their physical properties both with the parazotoluene, derived by Petrieff from the reduction of nitrotoluene, and with the substance described by the author. By the action of hydrogen peroxide, therefore, upon paratoluidine it is converted directly into parazotoluene.

* *Ann. der Chem.*, 207, 102.

The sublimate from the aniline product yielded large red crystals, together with some accompanying yellow oil. This sublimate had a melting-point of 66°, showing that the body was azotoluene (m.-pt., 66·5°).—*Journal of the American Chemical Society.*

ON CRYSTALS PRODUCED BY THE ACTION OF METALS SEALED UP IN CARBON DISULPHIDE.*

By PHILIP BRAHAM, F.C.S.

FIFTEEN different metals were sealed up in carbon disulphide on June 20, 1879. The tubes were carefully examined from time to time under the microscope. On June 20, 1880, appearances of incessant crystallisation were observed. On May 20, 1881, transparent crystals were found in those tubes which contained gold, antimony, and bismuth. The experiment is being continued.

A new micro-goniometer was exhibited.

PROCEEDINGS OF SOCIETIES.

MANCHESTER LITERARY AND PHILOSOPHICAL SOCIETY.

Ordinary Meeting, October 4, 1881.

J. P. JOULE, D.C.L., LL.D., F.R.S., &c., President, in the Chair.

"*On Drops Floating on the Surface of Water*," by Professor OSBORNE REYNOLDS, F.R.S.

It is well known that under certain circumstances drops of water may be seen floating on the surface for some seconds before they disappear. Sometimes during a shower of rain these drops are seen on the surface of a pond; they are also often seen at the bows of a boat when travelling sufficiently fast to throw up a spray. Attempts have been made to explain this phenomenon, but I am not aware of any experiments to determine the circumstances under which these drops are suspended. Having been deeply engaged in the experimental study of the phenomena of the surface tension of water and the effect of the scum formed by oil or other substances, it occurred to me that the comparative rarity of these floating drops would be explained if it could be shown that they required a pure surface, a surface free from scum of any kind. For, owing to the high surface tension of pure water, its surface is rarely free from scum. The surface of stagnant water is practically never free except when the scum is driven off by wind. But almost any disturbance in the water, such as the motion of the point of a stick round and round in the water, or water splashed on the surface, will serve to drive back the scum for a certain distance. This may be shown by scattering some flowers of sulphur on the surface. This powder is insoluble and produces no scum, and hence it serves admirably to show the motion of the surface and whatever scum there may be upon it. If, when the surface is so dusted a splash be made by a stick so as to throw drops on to the sulphured surface, at the first splash no floating drops are produced; but after two or three splashes in rapid succession it will be seen that the sulphured scum has been driven back by the falling water, leaving a patch of clear surface, and on this drops will float in large numbers and of all sizes. These drops are entirely confined to that portion of the surface which is clear. The drops, either by their initial motion or by

* Read before the British Association, York Meeting, Section B.

the current of air, glide rapidly over the surface from the point at which they are formed. When, however, they reach the edge of the scum they disappear, apparently somewhat gradually. I have this summer made the experiment on several ponds and on various days, and I have never found any difference. Any scum, however transparent, prevented the drops, and they always floated in large numbers when the scum was driven back in the manner described, by the wind or any other way.

This result points to the conclusion that whatever may be the cause of this suspension, it depends only on the surface of the water being pure, and not at all on the temperature or condition of the air.

"*On the Mean Intensity of Light that has passed through Absorbing Media*," by James Bottomley, D.Sc., F.C.S.

"*Note on the Colour Relations of Nickel, Cobalt, and Copper*," by James Bottomley, D.Sc., F.C.S.

In a paper read before the Physical and Mathematical Section, April 13th, 1880, I referred to some experiments I had made to obtain a soluble black, and showed the advantages of such a solution in photometry, also its application to the determination of the law of absorption of light. The mixture used consisted of nickel, cobalt, and copper sulphates in acidulated water. In a paper read before the Chemical Society, May 19th, 1881, Mr. Thomas Bayley gives the results of some similar investigations. He also finds a mixture of nickel, cobalt, and copper sulphate suitable. The proportions of the metals in his solutions are:

Co.	Ni.	Cu.
1	1·48	2·16

The quantities of the salts used in the preparation of the fluid referred to in my paper give the following ratios between the metals:

Co.	Ni.	Cu.
1	1·49	2·46

NOTICES OF BOOKS.

A Pocket-book for Chemists, Chemical Manufacturers, Metallurgists, Dyers, Distillers, Brewers, Sugar Refiners, Photographers, Students, &c. By Thomas Bayley, Assoc. R.C.Sc.I. Second edition, with additions. London: E. and F. N. Spon.

We are not surprised that a second edition of this invaluable *vade mecum* has been called for. If we point out anything which to us seems a sin of omission or of commission, we do so not with the desire to find fault, but in accordance with the concluding paragraph in the preface. It seems to us that the "distillers, brewers, and sugar refiners," get a rather too preponderating share of space, *i.e.*, one-sixth part of the whole volume, or nearly three times as much as is bestowed upon all the other chemical arts and manufactures taken collectively.

The rule given for the respective conversion of Fahrenheit into Centigrade, and *vice versa*, is applicable only for temperatures above freezing-point. For degrees between 32° and 0° F., and for those below 0° F., two further rules are required. The "Polar" system of weights and measures seems to have certain advantages over the metric system.

Agricultural chemistry has received here little attention. Tables for the rapid valuation of manures would be useful to many, and so would notes on the weights, absorbent powers, &c., of different classes of soils, and on the average composition and value of the raw materials used in manure making. In like manner metallurgy and the tinctorial arts fare but scantily. The price list of apparatus is scarcely necessary; the same may be said of the wages table, and of the ready reckoner. On the other hand, tables showing the value of metric weights, from a gramme upwards in English ounces and pounds, and a similar table for converting cubic centimetres and litres into fluid ounces and pints would have been very valuable to, *e.g.*, dyers, who often meet with French or German recipes.

What to do in Cases of Poisoning. By W. Murrell, M.D., M.R.C.P., &c. London: H. K. Lewis.

We have here a useful little manual for the faculty. The suggestion of an antidote bag fitted with the appliances and drugs needed in poisoning cases is exceedingly judicious, and may often save precious time, which here is everything. After some general remarks on the use of the stomach-pump and on the selection of emetics, the author gives an alphabetical list of poisons, with the treatment to be adopted in each case. Here we note certain omissions. There is no mention of aniline, which, now it has become an article of commerce, may occasionally give rise to accidents. Three native poisonous plants are also overlooked, mezereon, bryony, and arum.

Concerning the directions for snake bites, we entertain some misgivings. It is said "the wound should be thoroughly washed and sucked." But the poison of the more deadly serpents, such as the cobra, appears capable of causing alarming symptoms if taken internally, so that sucking might prove a dangerous proceeding. We also find the remark that "bleeding followed by transfusion might in some cases prove of avail." From the form in which this advice is given we should doubt whether the author can produce an instance of its having been tried with success. The *rationale* of bleeding in such a case might be thus stated: Here is a polluted river; to purify it, remove a portion of the water!

In the instructions for a compound case of poisoning with opium and chloral we find an error, clerical or typographical, which may be perplexing. The passage reads: "Should the symptoms of strychnia poisoning predominate give a hypodermic injection of gr. 1-80 of sulphate of strychnia."

We are glad to see that Dr. Murrell points out the danger of administering oil in certain cases (cantharides and phosphorus), especially as a paragraph has been widely circulated in the lay press recommending large doses of oil as an antidote for all poisons. We note a few typographical errors, such as "apomorphic" for "apomorphia," "phosphorous" for "phosphorus," &c. The author has not adopted the newest chemical terminology, and, in despite of South Kensington, makes the organic bases end in *ia* instead of *ine*, and writes, *e.g.*, "sulphate of magnesia," instead of the orthodox "magnesium sulphate."

Inorganic Chemistry, Theoretical and Practical. An Elementary Text-book designed primarily for Students of Science Classes connected with the Science and Art Department of the Committee of Council on Education. By W. Jago, F.C.S., &c. London: Longmans and Co.

Practical Chemistry. Adapted to the First Stage of the Revised Syllabus of the Science and Art Department. By J. Howard, F.C.S., &c. London and Glasgow: W. Collins, Sons, and Co., Limited.

We have here two more elementary treatises on chemistry, one of them a new work and the other a new edition. Both are written under the haunting presence of the Science and Art Department and with reference to examinations. Each goes over substantially the same ground; each contains, as appendix, a selection of questions taken from former examination-papers. Mr. Jago has an admirable preface, in which he explains the unfortunate predicament in which teachers of science find themselves placed by the examination-mania and its promoters. We only hope that his plain speaking may not be avenged upon his pupils.

Mr. Howard, who, in his former editions, used the Kensingtonian notation only, has now given in addition the notation and formulæ used by Professors Williamson and Thorpe.

CORRESPONDENCE.

ASSAY OF CUPRIFEROUS BLENDE.

To the Editor of the Chemical News.

Sir,—Well knowing the amount of trouble and annoyance caused to assayers and analysts, in the assay of cupriferous blendes, by the different methods in use for disposing of the copper, and also the frequent disagreement in results, I have great pleasure in sending you for publication in your Journal a method which is as rapid as it is accurate, the only part which is original being the simple and effective way of disposing of the copper. It is as follows:—

½ grm. of the blende is taken and treated with aqua regia and evaporated: it is re-moistened with hydrochloric acid, and re-evaporated, dissolved in water with a drop or two HCl, 10 to 20 c.c. of ammonia added, and the iron filtered off and washed.

The filtrate, which is now about 200 to 250 c.c. in volume is acidified with HCl, heated and placed in a porcelain dish ready for buretting with ferrocyanide of 0·01 strength. To the solution of zinc and copper I add sodic sulphide solution enough to precipitate the whole of the copper and leaving a little excess, then proceed with the buretting with ferrocyanide and uranium acetate as indicator.

In some experiments which I made I took a non-cupriferous blende and weighed out six samples into three, of which I put some sulphate of copper solution equal to 2½ per cent copper in the blende, and proceeded with them as above explained, and obtained perfectly concordant results.—I am, &c.,

R. Monger.

Laboratory, Middle and Upper Bank Copper Works,
Swansea, October 17, 1881.

AFFINITY AND VALENCY.

To the Editor of the Chemical News.

Sir,—Mr. Brown has attempted to deal with a vast subject within very narrow limits, and in offering certain criticisms of his conclusions I shall endeavour to follow his example. Chemical and Human Philosophy present an interesting parallelism, which is in no point more conspicuous than in the greater conflicts which are waged in either department of scientific investigation. In the latter the individual and his will are to one school the essential phenomena of life, while another section of thinkers impressed with the majesty of "law," and the stupendous movements of Nature, are somewhat impatient of their trivial incidents, and so refuse them objective reality. Since the days when Berthollet opposed the "special" interpretations of chemical reactions with his transcendental theory of Chemical Statics, to the time when Berthelot and Thomson would make our science tributary to the greater philosophy of Energy, there has not been wanting a well-organised opposition of those who are inclined to give more weight to the individual characteristics of the elements as the essential cause of chemical reactions. The controversy having reached the citadel, and Mr. Brown being persuaded that the concurrence of representative opinion expressed at the York Meeting of the British Association has assigned to Valency a position in which it ceases as a conditional phenomenon to have much substantive value, we have to enquire whether he is justified by his arguments in forsaking what *has been* a stronghold of chemical thought, before the "Cosmopolitans" have actually taken possession?

In the first place his main argument suffers from a strange confusion of the terms "Chemical Energy" and "Affinity," and from the general looseness of his opening sentence: "It is generally supposed that (in combining) the chemical energy or affinity of the atoms is *neutralised*, such neutralisation . . . similar to that which takes place when a conductor charged with + E . . . with another which has received a negative charge." It surely was not necessary for the success of the doctrine which Mr. Brown would expound to begin by tilting with a "man of straw." The ordinary "supposition" would, I think, be that the chemical energy of the atoms in combination is less than in the uncombined state, by the work done during the change of state; as regards the matter which has taken part in the reaction that it is unchanged in every respect; lastly, as regards the special property of affinity, that, to retain Mr. Brown's illustration, molecules of HCl, presented to further molecules of H, would suffer no disturbance, because the affinities of the H and Cl atoms each with each is satisfied. The reasoning by which the straw man is ventilated is still more extraordinary. "The molecule H_2 is supposed . . . two atoms of hydrogen united together by the force of chemical affinity precisely as a H atom is united to a Cl atom in HCl. Now if neutralisation takes place . . . it must be complete, *for they are identical*. . . . &c."

The only excuse for this poor logic is in the confusion of terms alluded to, which has propagated itself to the two expressions, "precisely in the same manner" (stated), and "precisely in the same degree" (implied). Let me use an illustration: a cube of lead above the surface of the earth will attract a second cube of lead, which is in contact with it, but will this affect the work done by the fall of each to the ground? This is the parallel that would suggest itself to most minds as fairly complete, and is a sufficient justification of the "ordinary" supposition. Mr. Brown next wishes to show "that the atoms of hydrogen and oxygen which form the molecule (of water) retain their original attraction when thus combined together." And having shown it to his satisfaction by discussing the three alternative hypotheses, he generalises the proof, and closes his case by an inconsequent adaptation of these arguments to the "reasonable" ascription of "the phenomena of valency to the conditions of space and motion under which the atoms are placed." Mr. Brown will perhaps re-state his case for the Transcendental School unless he deems these objections trivial. Until he does I do not feel justified in trespassing farther upon your space in the discussion of a problem which I confess, without the fear of being accused of modesty, is considerably beyond me.

The italics throughout the above are mine.—I am, &c.,

C. F. C.

A NEW FORM OF WASH-BOTTLE.

To the Editor of the Chemical News.

Sir,—Some few months ago I devised a form of wash-bottle which I have found to be very effective, and as it is also very easily made I have thought it worth while to make it known to a wide circle.

The improvement consists in a modification in the form of the blowing-tube, by means of which a continuous jet of water can be obtained for some time after ceasing to blow, and steam and badly-smelling vapours are prevented from entering the mouth.

The blowing-tube is made as follows:—Bend a piece of glass tubing to form the same angle as that of the blowing-tube of an ordinary wash-bottle, then bend one end completely round in a plane at right angles to the plane of the angle previously made, and break off the straight portion of the tube a little way from the bend. Now bend another piece of tubing completely round, and

break off one of the arms very near the bend. This last made tube is then put through its hole in the cork of the bottle, and joined by a short piece of india-rubber tubing to the shorter limb of the other tube. The two tubes thus joined are tied together at the top by a piece of string. The cork of the bottle should project some little way in order that the india-rubber tube may be closed at will by pressing it with the thumb against the side of the cork.

When washing with boiling water, &c., close the india-rubber tube with the thumb before commencing to blow, and before ceasing close it again in order to prevent steam from getting into the mouth, and also to get a continuous jet.—I am, &c.,

A. E. Johnson.

St. George's Hospital, S.W.

CHEMICAL NOTICES FROM FOREIGN SOURCES.

Note.—All degrees of temperature are Centigrade, unless otherwise expressed.

Comptes Rendus Hebdomadaires des Séances, de l'Académie des Sciences. No. 12, September 19, 1881.

Relative Resistances which should be given in Dynamo-electric Machines to the Active Coils, to the Inductor Electro-magnets, and to the Interior Circuit.—Sir W. Thomson.—This memoir has appeared also in English.

Experiments made in 1826 on the Electric Currents produced by Lightning far from the Place of Observation, and the Recent Studies of M. René Thury on the Sounds of Telephones during Storms.—D. Colladon.—M. R. Thury has stretched a copper wire horizontally between two houses at the height of the roofs, and connected with the earth by means of water-pipes. To this wire was joined a telephone, whose resistance measured 4·5 ohms, and another similar apparatus of 25 ohms. On occasion of every storm, near or remote, the flashes of lightning have been accompanied by a very characteristic sound perceived in the telephones, at the same instant when the lightning was seen, at whatever distance, and resulting consequently from the inductive action of the discharge upon the wire. These telephonic experiments offer a very easy method for studying the induction effects produced by these lightnings, and of measuring the speed of transmission of these influences, even to great distances.

Measurement of the Rotation of the Plane of Polarisation of Light under the Magnetic Influence of the Earth.—Henri Becquerel.—It results from the author's experiments that the yellow rays D, traversing a column of 1 metre of carbon disulphide at 0°, under the influence of terrestrial magnetism, at Paris, and in a direction parallel to the dipping needle, experience a simple magnetic rotation of 0·8697′ from the right to the left, for an observer supposed to be laid horizontally with his head towards the magnetic north.

New Sulphur Salts produced with Phosphorus Sesqui-sulphide.—G. Lemoine.—The author has discovered a new series of salts, the sulphoxy-phosphites, that is, phosphites where 2 atoms of oxygen are replaced by 2 atoms of sulphur. They recall the sulphoxy-arseniates of MM. Cloëz and Bouquet, and the sulphoxy-phosphates of M. Würtz. In addition, certain of these salts contain sulphuretted hydrogen, which takes the place of the water of crystallisation, and even the constitutional water necessary to the existence of the phosphites.

Tungsto-boric Acid and its Salts.—D. Klein.—The author describes the tungsto-boric acid and its barium, mono- and di-sodium, potassium, ammonium, magnesium, aluminium, chromium, manganese, cadmium, nickel, cobalt, uranium, copper, zinc, lead, thallium, silver, cerium, and mercury salts.

Determination of Phosphoric Acid by Standard Solutions.—E. Perrot.—The author's process is based on the precipitability of calcium phosphates by ammonia; the solubility of calcium and magnesium phosphates in acetic acid, and the insolubility of iron and aluminium phosphates in this reagent; and on the power of the soluble phosphates, acid or basic, to precipitate salts of silver as a yellow tribasic silver phosphate, insoluble except in ammonia. He dissolves 6·895 grms. pure silver nitrate in distilled water, and makes up to 1000 c.c.; this corresponds to 4·565 grms. metallic silver per litre; 100 c.c. of this solution precipitate 0·710 grm. phosphoric acid. He dissolves 5·414 grms. sodium chloride in distilled water, and makes up to 2000 c.c.; 100 c.c. of this solution precipitate 0·500 of silver. He dissolves the phosphatic matter in nitric acid of sp. gr. 1·030. The solution is filtered and the insoluble part washed with hot distilled water; the washings are added to the acid liquid, which is super-saturated with ammonia. The precipitate is washed with ammonia water upon a small filter, and it is then dissolved upon the filter (changing the recipient) by sprinkling it with acetic acid. The calcium and magnesium phosphates alone are dissolved. The liquid is mixed with ammonia till a precipitate begins to appear, which no longer dissolves on shaking. This precipitate is made to appear by the addition of a drop of acetic acid. This liquid should be collected in a stoppered bottle, holding 250 c.c. There are then added by means of a graduated pipette, 100 c.c. of the standard silver solution. On agitation the characteristic yellow precipitate of silver phosphate appears. When it has settled, the excess of silver remaining in the liquid is determined by running in the salt solution from a graduated burette.

No. 13, September 26, 1881.

Researches on the Gymnotus conducted by the Late Dr. Sachs.—M. du Bois-Reymond.—The author, in conjunction with Dr. Fritsch, has edited the hitherto unpublished researches of Dr. Sachs on the Gymnotus.

Photometric Comparison of Sources of Light of Different Colours.—A. Crova.—The author uses a spectro-photometer. If we illuminate the semi-discs of the screen of a Foucault's photometer with an electric light and with a standard Carcel lamp, and bring the two illuminated spots to touch each other, it is very difficult to judge of the equality of the illumination, as one of the halves has a bluish tint in comparison with the other, which appears to be of a yellow-orange, and the lamp may be moved within very wide limits without the eye being able to judge if an equality of illumination has been really obtained. But if whilst looking at the screen we place before the eye two Nicol prisms, the right sections of which are rectangular, and between which is placed a plate of quartz perpendicular to the axis and of 9 m.m. in thickness, the two fields then appear of a whitish green colour, and if the distance of the standard lamp is varied there comes a moment when equality of intensity is obtained, and the boundary line between the two fields disappears. A very small movement of the lamp suffices then to show a distinct contrast between the two spots.

Studies on the Chemical Action of Light.—G. Lemoine.—It is known that in sulphur and phosphorus, light produces the same isomeric transformations as heat. The case is the same with styrolene, which is converted into meta-styrolene by prolonged exposure to the sun. Bodies in solution are not always affected in the same manner by light as when solid. Silver chloride is not affected by light when dissolved in ammonia. The action of light upon various bodies, such as chromic acid, silver oxide, mercuric oxide, gold chloride, &c., depends to a very great extent on the presence of traces of organic dust. The red end of the spectrum is much less efficacious than

the violet end, though in most cases if the action is sufficiently prolonged the same result is ultimately obtained.

Researches on Tropine.—M. Ladenburg.—Not suitable for abstraction.

A Ureometer.—M. de Thierry.—The author has laid before the Academy an instrument for determining the urea in urine. The author's process is based on the known decomposition of urea by sodium hypobromite.

Journal de Pharmacie et de Chimie.
June, 1881.

The Peptons.—A. Petit.—This paper is medical rather than chemical in its tendencies.

A Rapid Process for the Determination of Uric Acid.—A. Petit.—By operating as follows the author effects the determination of uric acid in two hours:—200 c.c. of filtered urine are mixed with 5 c.c. of fuming hydrochloric acid, and the mixture is beaten up for five minutes in a beaker, care being taken not to scratch the glass. The liquid, which is clear at first, becomes turbid and deposits the uric acid in the form of very small crystals. It is let stand for an hour in a cool place, and filtered through a double filter previously tared. Paper which filters quickly must be selected. The filters are then washed with alcohol, dried at 100°, and the difference of weight between the two, multiplied by 5, gives the proportion of uric acid in a litre of urine.

A Reagent for Distinguishing the Ptomaines from the Vegetable Alkaloids.—P. Brouardel and E. Boutmy.—Already noticed.

Apparatus for the Treatment of Metallic Sulphides with Bromine.—E. Reichardt.—This paper requires the accompanying illustration.

Studies on the Kernel of the Date.—M. Georges.—This kernel can only furnish a very poor article of diet. The absence of starch and the small proportion of albuminous matters do not allow it to be classed with any of the ordinary nutritive matters.

July, 1881.

Atropine.—J. Regnauld and F. Valmont.—The principal conclusions of the authors are:—The atropine of medicine is a mixture in variable proportions of two isomeric crystalline alkaloids, possessing the same therapeutic properties. One of these is atropine-α (atropine of Ladenburg); the other is atropine-β, or preferably atropidine (hyoscyamine of Ladenburg). Atropidine exists in such abundance in belladonna that it forms about two-thirds of the crystalline atropine of the codex. It is the crystalline alkaloid of all the mydriatic Solanaceæ and of Duboisia, and has been improperly named datu ine and duboisine.

Researches on the Formic Ethers.—MM. Berthelot and Ogier.—Already noticed.

Artificial Production of Vivianite.—J. Girardin.—Hydrated ferric phosphate is produced by incinerating bone-black which has been previously used in the decolouration of beet-root sugar.

Complex Function and the Constitution of Morphine.—P. Chastaing.—The author concludes that morphine is a phenol.

Assimilation of Nitrogen by Plants.—M. Lamatina.—The author is of opinion that plants require to assimilate nitrogen in three states: In the nitrates occurring in the soil, in the ammonia of the atmosphere, and in the protoxide of the atmosphere. The nitrogen in the state of nitrate absorbed by the roots is destined for the transportation and diffusion of the mineral substances, and especially of potash in the leaves. The nitrogen absorbed as ammonia by respiration serves for the formation of the albumenoids. The nitrogen absorbed as protoxide serves as the complement of the nourishment of the plant, acting as a corrective by neutralising the excess of the bases, and concurring in the formation of the alkaloids.

Bulletin de la Société Chimique de Paris.
No. 11, June 5, 1881.

Separation of Zinc from Cadmium and the Determination of the Latter.—M. Kupfferschlæger.—A complete separation can be effected in a few hours by simply plunging a slip of bright zinc into the mixed solution in a test-tube, and leaving it there till all apparent action has ceased, decanting the liquid, washing the deposit of cadmium first with boiled water and then with alcohol, drying with exclusion of air, and weighing. The author operates on a neutral solution of the sulphates, previously heated to expel the air. The test-tube is loosely stoppered.

Quick Process Employed in the Municipal Laboratory for the Determination of Lead in Samples of Tin.—M. Roux.—The alloy is laminated, and 2·5 grms. are dissolved in 15 c.c. nitric acid in a flask marked at 250 c.c. The nitrous vapours are expelled by boiling, and after 40 c.c. of a saturated solution of sodium acetate have been added, it is diluted to 250 c.c., and the stannic acid is allowed to deposit. Of the clear supernatant liquid 100 c.c. are taken, corresponding to 1 grm. alloy, and there are introduced into it 10 c.c. of a titrated solution of potassium bichromate containing 7·13 grms. per litre, and of which 1 c.c. throws down 1 centigrm. of lead. After the chromate of lead has been deposited, 10 c.c. more are added, and so on till the liquid is coloured yellow by the excess of bichromate. The liquid is filtered, the precipitate washed, and the excess of bichromate determined by means of a solution containing per litre 57 grms. double sulphate of iron and ammonium and 25 grms. sulphuric acid. This liquid is preserved in a sort of washing bottle under a layer of petroleum or benzol. Nevertheless its standard must be frequently verified. To ascertain the excess of bichromate employed spots are made upon a white porcelain plate with a very dilute solution of potassium ferricyanide preserved in a black bottle. As long as there is not an excess of ferrous oxide in the liquid, the spots retain their reddish yellow colour, but as soon as the bichromate is completely reduced the spots take a tint, green at first and then blue. If lead is precipitated in presence of stannic acid, there occurs an error of about 2 per cent, in consequence of the potassium bichromate mechanically entangled in the precipitate. If the liquid does not appear red after titration with iron, enough sodium acetate has not been added.

No. 2, July 20, 1881.

Formation-heat of Various Organic Compounds.—MM. Berthelot and Ogier.

Thermic Formation of Pyrogenous Carbides.—M. Berthelot.

Remarks on the Characters of Organic Chlorinised Gases and Vapours.—M. Berthelot.

Ethyl Peroxide.—M. Berthelot.—These four papers have been already noticed.

Les Mondes, Revue Hebdomadaire des Sciences.
No. 6, June 9, 1881.

The French Association for the Advancement of Science will meet next year at La Rochelle.

The Methanometer.—D. Monnier.—This instrument is an automatic indicator of the presence of "fire-damp." This gas, in contact with an excess of air and under the influence of the induction-spark or a red-hot platinum wire, is decomposed into naphthalin, carbonic acid, and water. From this decomposition there results a depression which is transmitted in Monnier's apparatus to a manometer, the mercury of which on reaching a certain level sets up an electric current.

No. 7, June 16, 1881.

The telegraphic communication between Souk-el-Arba and Medjez-el-Bab being interrupted, it was found that an enormous serpent had coiled itself around the wire and a post, thus interfering with the conductivity of the line.

Influence of the Contact of Air upon Fermentation.—The conclusion drawn is that in cases where it is desired to effect a very rapid fermentation, access of air is indicated. If, on the contrary, a slower fermentation is desired and a greater development of cellules, the influx of air should be reduced.

No. 8, June 23, 1881.

The alcoholometer of Gay-Lussac has been officially recognised in France as obligatory both in administrative and in private affairs.

M. de Rossi concludes that explosions of fire-damp are always preceded by slight microseismic undulations and sounds, too feeble to be detected by the ear. He proposes the establishment in the neighbourhood of coal-mines of stations fitted up with microseismographs and microphones so as to detect the approach of danger.

The duplex telegraph of the Marquis Tommasi is said to have been successfully tried on the line from Paris to Mantes.

Spectroscopic Researches.—G. L. Ciamician.—The author describes the spectrum of carbon and cyanogen, which seems composed of two parts, one of which resembles that of nitrogen. He indicates a spectrum of the second order for boron. He groups the elements as follows:—

B, Al, C, Si,	N, P, As, Sb,	O, S, Se, Fe,
Fl, Cl, Br, I,	Na, K, Rb, Cs,	Mg, Ca, Sr, Ba,

and admits that in each group the elements are formed of a fundamental matter and of several atoms of oxygen. The atomic weights calculated according to this rule differ notably from those obtained by experiment.

Nos. 9 and 10, June 30 and July 7, 1881.

These numbers contain no original chemical memoirs.

No. 11, July 14, 1881.

Means of Detecting the Sophistications of Olive Oil with other Oils.—The oils employed at Marseille for the adulteration of olive oil are the oils of colza, sesame, cotton, and earth-nuts. Colza oil is detected by means of the sulphur which it contains; 10 grms. of the sample are saponified in a glass capsule with an alcoholic solution of caustic alkali free from sulphides. The mixture is stirred with a silver spoon, and if this is blackened, colza, or at least some cruciferous, oil is present. For the detection of the oil of sesame a little sugar is added to hydrochloric acid at 30° (Baumé ?), which is then mixed with an equal bulk of the oil in question. The mixture is well shaken up, and the least traces of oil of sesame are indicated by a red colouration. For the detection of cotton-seed oil there is added to the sample an equal volume of nitric acid at 40°. On stirring the mixture takes a coffee colour. The detection of oil of earth-nuts is less simple. The sample is saponified with an alcoholic solution of potash, the soap separated as completely as possible, heated to expel the alcohol, and treated with enough hydrochloric acid to neutralise the alkali. The supernatant fatty acid—arachidic acid—is collected and dissolved in boiling alcohol, from which it separates in a characteristic white nacreous form.

No. 12, July 21, 1881.

The company by which *Les Mondes* is published was declared dissolved on July 16th. The journal will, however, continue to appear.

Aniline hydrochlorate dissolved in water in the proportion of ½ kilo. per hectolitre, is used for the destruction of the asparagus beetle (*Crioceris asparagi*).

The Cyclides and the Encyclides.—Dr. C. Brame.—This memoir requires the accompanying illustrations.

The Editor expresses the opinion that the Faure accumulator does not solve the question of domestic electric lighting.

The "crackling" of tin is not peculiar to this metal, but may be recognised in other metals when in a semi-crystalline state.

Bulletin de la Société d'Encouragement pour l'Industrie Nationale. 3e Série. Tome viii., No. 91.

On Hydrocellulose.—M. Aimé Girard.—The author has established some years ago that cellulosic matter, in whatever form, if submitted to the action of acids under determined conditions, passes before saccharification into an intermediate state of hydration. The cellulose then loses its normal cohesion, and becomes absolutely brittle. In this state the author names it hydrocellulose. It retains, however, the chemical properties of normal cellulose, and especially that of forming nitro-compounds, which are excessively friable. If such nitro-compounds are prepared with cold and concentrated acids they are explosive; with hot and dilute acid they are soluble in mixtures of alcohol and ether, and are suitable for the manufacture of photographic collodion.

Gas and Electricity considered as Thermic Agents.—Dr. W. Siemens.—A lecture delivered at Glasgow.

On Electric Lighting (the Brush System).—An extensively illustrated paper.

NOTES AND QUERIES.

*** Our Notes and Queries column was opened for the purpose of giving and obtaining information likely to be of use to our readers generally. We cannot undertake to let this column be the means of transmitting merely private information, or such trade notices as should legitimately come in the advertising columns.

Chromate of Iron.—Can anyone inform me as to the following in relation to chromate of iron used generally for the manufacture of chromate or bichromate of potassium, &c. At what price could such chromate of iron, containing from 50 to 51 per cent of oxide, find a ready sale in England? What quantities would be readily taken up on the market? Would it be difficult to find purchasers? It is understood that the chromate of iron now consumed in England comes from Turkey, from a property belonging to the Sultan's mother. Is that so?—W. L. W.

Arsenic in Iron Pyrites.—The statements on this subject are so various and conflicting that I should feel much indebted to any chemist who has worked on it for reliable information as to amount in any ores. The percentage being generally small, probably under 1 per cent in such ores as the Spanish and under 0·5 per cent in some from other places, it is by no means easy to estimate the arsenic, or in many cases even to detect it, when practical working shows it to be present. Can anyone who has had experience point out the best methods for qualitative or quantitative analysis, or inform me where such are described? Various plans, both qualitatively and quantitatively, have been tried in my laboratory, and I should have pleasure in giving anyone interested information about them.—H. B. Gibbins, Neath.

MEETINGS FOR THE WEEK.

Thursday, 3rd.—Chemical, 8. "On Citraconic and Mesaconic Ethers and Malic and Fumaric Acids," by W. H. Perkin. THE CHEMICAL NEWS.

Vol. XLIV. No. 1145.

ALTERATIONS IN THE PROPERTIES OF THE NITRIC FERMENT BY CULTIVATION.*

By R. WARINGTON.

The earlier researches on nitrification conducted in the Rothamsted Laboratory have been already communicated to the Chemical Society. In the second communication (*Trans. Chem. Soc.*, 1879) some experiments were described (Sixth series), in which a solution of chloride of ammonium, containing the usual nutritive ingredients, was seeded from an old solution which had some months before undergone a nitric fermentation; the result of this seeding was a purely nitrous fermentation, no nitric acid apparently being produced. Experiments have since been made on the conditions which respectively determine the formation of nitric and nitrous acid: a preliminary notice of the results is now communicated.

When a small quantity of fresh soil is employed to seed solutions of chloride of ammonium supplied with nutritive ingredients, a pure, or nearly pure, nitric fermentation is obtained if the solution is sufficiently shallow and dilute, and the temperature low; this is the case, for instance, when 80 milligrms. of chloride of ammonium are present in 1 litre, the column of the liquid 4 or 5 inches in depth, and the temperature about 15°. Under such circumstances only a trace of nitrous acid is formed, and this changes into nitric acid before the conclusion of the action. If the solutions employed are much more concentrated, or the temperature is considerably raised, large quantities of nitrous acid are produced. This formation of nitrous acid may be avoided to a great extent by diminishing the depth of the solution, but at the temperature of 30° it is very difficult to avoid the formation of considerable quantities of nitrous acid, even with small depths of solution. In all cases in which soil has been used as seed the nitrous acid formed exists only temporarily in the solution, the final product of the fermentation being always nitric acid.

Soil added to a solution of nitrite of potassium, supplied with nutritive ingredients, readily converts the nitrite into nitrate.

When solutions, which have been seeded with soil and undergone the nitric fermentation, are themselves employed as seed for new solutions of ammonia, the final result as before is nitric acid; but this is apparently true only when the solution used as seed is not at most more than a few months old; beyond this age the result of the fermentation is apparently only nitrous acid, and this nitrous acid does not further change into nitric, even in several years, unless a certain visible change occurs in the solution to be presently mentioned. When a solution which has undergone this nitrous fermentation is used as seed, it again produces a purely nitrous fermentation, the nitrous acid being constant as before. The nitrous ferment just described is without effect on nitrite of potassium.

The results just mentioned are perfectly in accordance with the facts recently published by Pasteur, who finds that by allowing the cultivation of an organism (as that producing chicken cholera) to become old, an organism is obtained of diminished energy, and which when cultivated continues to produce organisms of the same diminished energy.

If solutions which have nitrified are kept for a considerable time, a white organism not unfrequently appears in spots on the surface of the liquid, and under favourable conditions spreads over the whole surface. Viewed by lens, it appears as a mass of interlaced fibres. This organism has been examined microscopically by Dr. M. Masters, F.R.S., and more fully by Prof. E. Ray Lankester F.R.S.; both pronounced it to be a bacterium. Wherever this surface organism appears, any nitrites that may be present are speedily converted into nitrates; a solution of nitrite of potassium is also speedily converted into nitrate. The experiments as yet made with this organism leave it doubtful whether it has any power of oxidising ammonia. This part of the subject requires, however, further investigation. There can be little doubt that this surface organism is a stage in the development of the nitrifying ferment.

The nitrifying ferment appears capable of existing in two, or perhaps three, conditions, producing definite chemical effects.

1. The nitric ferment of soil, which converts both ammonium salts and nitrites into nitrates.
2. The altered ferment, which converts ammonium salts into nitrites, but fails to change nitrites into nitrates.
3. The surface organism, which changes nitrites into nitrates.

* Read before the British Association, York Meeting, Section B.

ON THE CHROME IRON ORE OF JAPAN.*

By Professor EDWARD DIVERS, M.D.

The serpentine rocks of Japan, like those found elsewhere, contain small quantities of chrome iron oxide; but a few years ago masses of this mineral were sent from Oîta Prefecture (Bungo) to the Tôkiyô Industrial Exhibition, and its nature then recognised. It has lately been analysed in the laboratory of the Imperial College of Engineering, Tôkiyô, by my former pupil, Mr. T. Haga, now one of the Instructors in Chemistry in the College.

It is massive, has a specific gravity 4·50, and a hardness 5·5, and is of a grey-black colour without any shade of brown except where weathered. Its fracture is partly slaty, partly crystalline, showing numerous large faces inclined at all angles. Its lustre is resinous to submetallic, so that in appearance it is much like coal. Its powder is brown. Besides brown and green coatings on the faces of natural fractures in the mass, there are many small deposits of a greyish pink, but nearly white, soft, and unctuous mineral. The behaviour of this chrome iron oxide to heat, presents nothing needing to be recorded, beyond that it slowly *gains* in weight. It contains only traces of magnetic matter.

Reduced to very fine powder and heated for three hours with hydrochloric acid, 2·53 to 2·87 per cent dissolve, which, together with some of the silica in the ore, make perhaps 4 per cent decomposed. The soluble part has been separately analysed. An analysis of the soft white matter has also been made, but the portion of this which could be got was very small, and largely mixed with the chrome iron oxide. The following are the results of analyses:—

1. *The Whole Ore, Air-dried.*

	I.	II.	Mean.
Chromic oxide	59·39	59·20	59·30
Ferrous oxide	28·32	28·22	28·27
Chrome iron oxide ..	87·30		
Magnetite	0·29		
Magnesia	9·17	(9·10 to 9·24)	
Silica	1·58		
Alumina	0·80	(0·82 to 0·78)	
	99·14

oxygen), additional oxygen if present, and other substances which may have escaped detection.

2. *The Part Decomposed by Hydrochloric Acid.*

	I.	II.	Mean.
Chromic oxide.. ..	0·32	0·38	0·35
Iron oxide (if ferric)..	0·53	0·55	0·54
Magnesia	1·17	1·44	1·30
Alumina	0·51	0·50	0·51
Silica (assumed as)			1·30

Part at least of the iron dissolved in the ferrous state. The residual ore still yielded traces of soluble matter to fresh acid.

3. *The Pinkish White Mineral.*

After allowing for 36·5 per cent of admixed chrome iron oxide.

Silica	32·6
Magnesia	28·7
Alumina with a little ferric oxide ..	27·4
Water (loss on ignition)	11·3
	100·0

This analysis was made by Mr. Kawakita, another of the Instructors, in the unavoidable absence of Mr. Haga.

The tabular statement of the composition of the ore shows that it is in almost exact agreement with that of pure ferrous chromite, as regards the ratio of iron oxide to chromium oxide. No such pure ore has hitherto been recorded as occurring, I believe, unless possibly in the papers of Christomanos, which I have only seen in abstracts. The insolubility of the iron in acids and its non-magnetic character prove that it is really combined as chromite. There remains the magnesia to account for. This cannot be in the free state, for not only is the occurrence of free magnesia in nature unknown and improbable, but in this mineral the magnesia, like the iron oxide, is for the most part insoluble in acid. From the abstracts (*Journ. Chem. Soc.*, 32) of his papers, I learn that Christomanos in one paper asserts that pure chromite is always $FeCr_2O_4$, and all other constituents of the ore, part of the matrix, and in another paper admits the existence of compounds of ferrous oxide with chromic oxide in three proportions other than that of the ordinary spinel type. I see nothing for the case of the Oïta ore, but to accept the view that the magnesia is a chemical part of it, the proportion of which, after deducting soluble magnesia, is almost exactly that required by the formula,—

$$MgO,2FeO,2Cr_2O_3,$$

corresponding to the $3FeO,2Cr_2O_3$ of Christomanos.

Almost Insoluble—

	Calculated for $MgO,4FeO,2Cr_2O_3$.	Found.
Chromic oxide	59·30	59·30
Ferrous oxide	28·00	27·90
Magnesia	7·78	7·93
	95·08	95·13

Soluble, and Silica—

[Above magnes. ferr. chromite (about)	0·57]
Hydrous magnes. alum. silicate.. ..	3·62
Magnetite	0·29
	99·04

The visible presence of the white mineral, and the magnetic character of a very minute part of the powdered mineral serve to confirm the propriety of the above arrangement.

The estimation of chromium and iron was made by the usual volumetric methods. To bring the ore into a soluble condition, Dittmar's method was employed, this method being very satisfactory, and, in Mr. Haga's hands, much easier than described in *Dingl.*

Fused borax 2 parts and dry potassium sodium carbonate 3 parts were fused together in a platinum crucible till effervescence ceased, and the whole cooled. About 1 part of very finely-powdered ore was then placed on the top, and the crucible covered and slowly heated to fusion. When the powder had become moistened with the melted flux, the lid was removed and the crucible kept at a red-heat by a Bunsen flame. The liquid mass was occasionally stirred with a small platinum spatula. When particles of ore were no longer visible in the mass adhering to the spatula, the heat was maintained for only a few minutes longer, and the crucible then quickly cooled to favour the detachment of the mass. One hour was sufficient for 1 grm. of ore, and half an hour for half a grm. In this time, indeed, all the chromium may not have become chromate, but it would be all soluble in acid. Should the time have been too short, particles of ore will be visible in the bottom of the fused mass after removal from the crucible, and the mass must then be replaced and again heated. Unless the time of heating has been prolonged, it is safer to dissolve all up in sulphuric acid, oxidise any unoxidised chromium salt with a few drops of permanganate solution, and remove excess of permanganate by sodium carbonate and alcohol. A temperaturature for fusion so high that the crucible becomes attacked by the fluxes is quite unnecessary.

ON THE SODIUM ALUM OF JAPAN.*

By Professor EDWARD DIVERS, M.D.

The mineral sodium alum, since called Mendozite, was described by Thomson in 1828, as occurring in S. America (St. Juan, near Mendoza). Its occurrence has not been noticed elsewhere.

Rammelsberg (*Mineral. Chemie*) gives a series of percentages as obtained by Thomson, and refers them to an alum with 20 molecules of water. Dana ("System of Mineralogy") gives a different series as obtained by Thomson, and refers them to an alum with 22 molecules of water.

My late assistant, Mr. J. Mori, once a pupil of the Royal College of Chemistry, South Kensington, analysed the specimen I have now to describe, and obtained the following results:—

	Found.	Calculated for $Al_2O_3,Na_2O,4SO_3,24H_2O$
Alumina	11·27	11·23
Soda	7·26	6·76
Sulphuric oxide ..	34·73	34·90
Water..	46·74 (by diff.)	47·11
	100·00	100·00

The soda is too high, otherwise the results are most satisfactory, but error in excess here is probable from imperfect ignition to expel ammonium sulphate. Thomson found 7·96 soda, whereas for 22 aq. alum only 7·1 are required. Potash is absent and only traces of iron, calcium, and insoluble matter are present.

Sodium alum, therefore, occurs in nature of the normal type with 24 molecules of water.

It occurs as an efflorescence on decomposing sodium felsite (albite), with pyrites scattered through it. It is found in the province of Idzumo in the prefecture of Shimané, Japan, not far from the coast. Like that examined by Thomson it is not produced by a *solfatara*, though Shimané, like many parts of Japan, includes such. The alum is said to be obtainable in considerable quantity, but as a second parcel forwarded to me was damaged in transit by the leakage of bottles of natural alum water, I have only been able to examine very small specimens as yet.

* Read before the British Association, York Meeting, Section B.

It occurs in two forms, one massive, finely fibrous, greyish white, translucent, and also in friable opaque tears, slightly coloured by iron hydrate or oxide.

TABLE FOR THE CORRECTION OF SACCHARIMETRIC TESTS BY INVERSION.

By P. CASAMAJOR.

In a paper "On the influence of Variations of Temperature on the Deviation of Polarised Light by Solutions of Inverted Sugar," published in 1879,* I endeavoured to show the principles on which is founded the method, so important in sugar analysis, of correcting the direct test of the optical saccharometer, by taking into account the test after inversion. In this communication I will assume that the reader is familiar with the subject, and I propose to enter only very briefly into it.

Clerget, to whom this method of correction is due, published a table in the *Annales de Chemie et de Physique* (vol. xxvi., 3rd series, p. 175), by means of which the desired rectification may be obtained without the need of any calculation, beyond taking the algebraical difference of the indications of the saccharometer before and after inversion. There is also a table by Dr. Tuchshmid which is essentially the same as Clerget's. Although these tables are published in several works on sugar, many persons who need to use them find great difficulty in obtaining them. There is the resource of copying them by hand, but they are so extensive that this would involve an amount of labour which few persons like to undertake.

The following table will be found useful by persons who have not those spoken of. It is very short, and it would be little trouble to copy it. It requires but one operation more than Clerget's table, which is to multiply the algebraical difference of the two readings by a certain factor, corresponding to the temperature of the inverted sugar solution at the time of observation.

To understand how the numbers of this table were obtained, we must bear in mind that the deviation, caused by inverted sugar, varies with the temperature. For a solution of pure sugar, giving 100 to the right, the indication, after inversion, is 44 to the left or -44, if the observation is made at 0° C. For every Centigrade degree above 0, the deviation becomes half a division less of the negative scale. If we call the temperature t, the law of deviations after inversion is given by—

$$-\left(44-\frac{t}{2}\right).$$

For a temperature of 10° C. the deviation is 139; for 20° C. the deviation is 134, &c.

If D is the indication of the saccharometer before inversion, and D′ the indication after inversion, D+D′ will be the algebraical difference, and for a solution of pure sugar with D = 100,—

$$D+D'=144-\frac{t}{2}.$$

If the direct test is not 100, and if we call the correct test Δ, we will have—

$$\frac{\Delta}{D+D'}=\frac{100}{144-\frac{t}{2}}$$

whence—

$$\Delta=D+D'\times\frac{100}{144-\frac{t}{2}}$$

If for every degree Centigrade, we calculate this quantity,—

$$\frac{100}{144-\frac{t}{2}}$$

we may form a table by writing it down opposite to every degree of temperature. We will then have, in a second column, the factors by which to multiply the difference of the indications before and after inversion, so as to obtain correct results. This table is given below.

Table of Factors corresponding to $\frac{100}{144-\frac{t}{2}}$

Degrees C.	Factor.	Degrees C.	Factor.
10°	0·719	26	0·763
11	0·722	27	0·766
12	0·724	28	0·768
13	0·727	29	0·771
14	0·730	30	0·774
15	0·732	31	0·777
16	0·735	32	0·780
17	0·738	33	0·784
18	0·740	34	0·787
19	0·743	35	0·790
20	0·746	36	0·793
21	0·749	37	0·796
22	0·752	38	0·800
23	0·754	39	0·803
24	0·757	40	0·806
25	0·760		

Numerical Example.—If the direct reading of the saccharometer is 90, and, after inversion, -27, the temperature being 25° C., then D+D′ = 117. Referring to the table we find, opposite to 25° C. the factor 0·760. This number, multiplied by 117, gives 88·9, which is the correct result.

UPON THE ACTION OF OXYGEN, OZONE, AND NASCENT OXYGEN UPON BENZENE.*

By ALBERT R. LEEDS.

I.—Oxygen.

The first set of experiments was instituted to determine whether oxygen alone, in sun-light or diffused light, or oxygen together with platinum black, in sun-light or diffused light, would oxidise benzene after long-continued exposure. In every case a negative result was obtained, except in that of oxygen and platinum black brought into contact with benzene and a little water in a litre flask, and exposed to the direct sun-light. In the course of a few hours the liquid became slightly yellow, and at the end of eight days was dark yellow and intensely acid. A large amount of oxalic acid had been formed, but no acetic acid and no phenol.

II.—Ozone.

The earliest experiments upon the action of ozone upon benzene were made two years ago with the object of further studying the remarkable products obtained by Houzeau and Renard in the course of their investigation upon this subject † Along with small amounts of formic and acetic acids, they obtained a gelatinous body which, when dried *in vacuo*, formed a white amorphous solid, and which they called ozobenzene. It was permanent only at low temperatures, and on gentle warming exploded with tremendous violence. Fearing the possible formation of this dangerous substance, the first experiment was made upon 1 grm. of benzene, but the amount operated

* See CHEMICAL NEWS, vol. xxxix., pp. 212 and 234; also *Journal of the American Chemical Society*, vol. i., p. 26; *The Sugar Cane*, vol. xi., p. 296; *Moniteur Scientifique*, Juin, 1879, p. 647; *Zeitschrif des Vereins*, July, 1879, p. 683.

* From the *Journal of the American Chemical Society*, vol. iii.

† *Comptes Rendus*, 76, 572.

upon was gradually increased, until in the eighth and final trial, it amounted to 35 grms. In some experiments the benzene was cooled by a freezing mixture; in other trials it was ozonised at common temperatures; and in the last the temperature was kept at 50°. The benzene was exposed to the oxygen, strongly ozonised by the silent discharge, and containing about 70 m.grms. of ozone in the litre, either in shallow dishes placed under a receiver through which the perfectly dry ozonised gas was kept flowing, or in Geissler bulbs connected with other bulbs to arrest the volatile products of ozonation. But in every case the results were the same. Large volumes of carbonic acid were given off, and the benzene, as it diminished in volume, became converted into a dark yellow, oily mass, containing crystals of oxalic acid. In other cases, when the ozonation was performed in bulbs, an amorphous blackish mass separated out on the sides of the vessels. From these residues no crystalline bodies could be obtained either by the use of solvents or by sublimation. No indications whatsoever were noted of the white explosive body spoken of by Houzeau and Renard.

Besides carbonic and oxalic, formic and acetic acids were obtained, the latter in considerable quantity. Especial care was paid to the detection of phenol, but, as far as our tests were concerned, no evidence of the presence even of a trace of this body was obtained. Hydrogen peroxide was likewise absent.

III.—Nascent Oxygen.

The fact that triatomic oxygen (O_3, ozone or active oxygen) is not capable of oxidising water to the form of peroxide of hydrogen, while monatomic oxygen (O, or nascent oxygen) is, rendered it probable that a similar difference would be observed in the effects of ozone and of nascent oxygen upon benzene. This supposition has been confirmed by experiment. The nascent oxygen was obtained by the action of phosphorus, partially submerged beneath the surface of water, upon air at common temperatures. When no benzene is present, the nascent oxygen oxidises the oxygen molecule to the form of ozone, the water molecule to hydrogen peroxide, and the nitrogen molecule in the presence of water to ammonium nitrate. But on the addition of benzene the ozone reaction disappears. The resulting products differ, according as the reaction takes place in sun-light or in diffused light. In the former case, after prolonged exposure, large amounts both of phenol and oxalic acid are formed, the phosphorus is converted into yellowish red amorphous phosphorus, and the liquid remains colourless. In the latter case, the flask being kept in a warm place, the liquid becomes of a dark brown colour, and abundance of oxalic acid, but no phenol, is formed. At common temperatures the phosphorus goes into solution in the benzene, and is gradually converted into a mass of white dodecahedral crystals, the liquid remaining colourless. It is only when the temperature is above the melting-point of the phosphorus (in these trials 50° to 70°) that the dark brown liquid is produced. Curiously enough, though the flask becomes filled with dense white fumes, no inflammation took place at these elevated temperatures, the benzene vapour apparently protecting the phosphorus from ignition. Excess of calcium chloride was added to the syrupy liquid, the dense precipitate of calcium phosphate and oxalate (somewhat dark from a portion of the organic matter carried down at the same time) filtered off, and the filtrate evaporated to dryness. The soluble portions were then dissolved out with the least possible amount of water, the excess of calcium precipitated out by potassium sulphate, the whole evaporated to dryness, and treated with absolute alcohol. As a small portion of the potassium chloride was taken up by the alcohol, this extract was again evaporated to dryness, and the operation repeated three times, when only the organic matter remained in solution. It was of a yellow colour and pasty consistence, but as it could not be made to crystallise, and furthermore was in small amount, its further investigation was abandoned.

After my own research was in progress I found that Prof. F. Hoppe-Seyler,* starting out from similar views as to the effects resulting from the action of nascent hydrogen upon oxygen, had performed a series of interesting experiments with hydrogenised palladium foil. A piece of such foil shaken up along with benzene, water, and air, in a flask, and allowed to stand for a time, yielded an amount of phenol sufficient, after its conversion by the addition of bromine water into tribromphenol, for analysis. Besides the phenol, Hoppe-Seyler obtained a body which turned brown on the addition of potash.

On repeating the experiment I obtained a very abundant reaction for phenol. On addition of lime-water, the colouring-matter which had been formed at the same time was thrown down as a yellowish brown precipitate. Not a trace of oxalic acid was present.

To my own mind no satisfactory explanation could be given of the formation of phenol under these circumstances, except upon the supposition of the production of peroxide of hydrogen as an intermediate step. In the case of phosphorus oxidising in moist air, the contemporaneous formation of both ozone and peroxide of hydrogen, by the action of the nascent oxygen upon the oxygen and water, is a demonstrated fact.

Three suppositions therefore were admissible:—Either the phenol was formed by the direct action of the nascent oxygen; or 2nd, by the action of the ozone; or 3rd, by the action of peroxide of hydrogen. The first supposition requires that the oxygen should produce by direct synthesis a molecule of phenol, which is in the highest degree improbable. The second supposition is inadmissible, since the non-formation of the phenol by treatment with ozone had been abundantly proven. The third supposition admitted of the rational explanation expressed by the formula, $C_6H_6+HO-OH=C_6H_5OH+H_2O$.

Two modes of testing the validity of the third hypothesis presented themselves. The first was that of bringing the hydrogenised palladium foil into contact with water and air in a flask, and ascertaining if the oxygen rendered nascent by oxidation of the hydrogen would oxidise the water to the form of hydrogen peroxide. In case an affirmative result was obtained in this experiment, it would be important to try the second test of treating benzene directly with a peroxide of hydrogen solution.

A strip of palladium, after remaining for several hours as the negative pole of a battery of six Bunsen elements, in water acidulated with sulphuric acid, was placed, along with 10 c.c. of ammonia-free water, in a half-litre flask filled with air. At the end of three days the water was tested with guaiacum and solution of diastase. It developed a deep blue colour. On addition of cadmium-iodide-starch solution, iodide of starch was formed, and on titration with sodium hyposulphite it was found that the total quantity of hydrogen peroxide present in the 10 c.c. of water amounted to 0·67 m.grm.

It is not improbable that both ozone and ammonium nitrate are likewise formed in the course of this reaction, but of the former no satisfactory indication was obtained, and the latter was not looked for, inasmuch as it would have required the repetition of the experiment on a much larger scale and with many additional precautions.

The successful issue of this experiment encouraged us to try what otherwise would not have been attempted—the treatment of the benzene with H_2O_2. Twenty c.c. of benzene were allowed to stand at common temperatures for two days in contact with 300 c.c. of a slightly acidulated 1·2 per cent solution of hydrogen peroxide. The liquids remaining colourless, the flask was attached to a reflux condenser and placed in a water-bath. After the water in the bath had been kept boiling for several days, it was saturated with chloride of calcium, and the digestion continued at this temperature for two days longer. At the end of this time the liquid had become yellow, and was found to contain, beside the colouring-matter, oxalic

* *Ber. der Deutsch. Chem. Gesell.*, 12, 1551.

acid and phenol. A very abundant precipitate was thrown down from the aqueous solution on addition of bromine water, and this precipitate of tribromphenol, after recrystallisation from alcohol, was found to weigh 0·25 grm.

In conclusion, not only is the direct conversion of benzene into phenol by the action of hydrogen peroxide of much interest, phenol having hitherto been obtained only by some indirect process, but it supplies a satisfactory demonstration of the validity of the third hypothesis above stated.

NOTE ON THE PRECIPITATION AND PURIFICATION OF BARIUM SULPHATE.

By T. O'CONNOR SLOANE, A.M., Ph.D.

To obtain a precipitate of barium sulphate that will not run through the filter-paper, the following rules should be observed:—The solution should be barely acid. This end in best secured by the use of cochineal or some equivalent solution. By using the coloured matter in the fluid form, a solution can be neutralised in quarter of the time, and with far more exactness than when its reaction is tried with litmus paper. The precipitant is added when the solution is nearly boiling, and the liquid is kept at that temperature for some time. A heavy precipitate will be formed with perfectly clear supernatant liquor. It is quite certain if any iron be present that some will be carried down, and the ignited barium sulphate will not be white. Many ways of treating the precipitate after ignition have been recommended. I will refer to only two in the hurried way. The first is, to boil it with dilute hydrochloric acid; the second, to boil it with concentrated sulphuric acid, then dilute and filter. If the first course be pursued, any barium sulphide present will be dissolved, thus causing a loss. This is quite a common case, as the filter-paper reduces the sulphate in the ignition. If treatment with concentrated sulphuric acid be adopted, any other salts of barium present will be rendered insoluble, and excess of weight be caused. In the dry way, fusion with sodium carbonate and a little sodium nitrate, and subsequent determination of the sulphuric acid, may be recommended as very efficacious, but it is troublesome.

Some time ago I had occasion to make a great many sulphur determinations in coal. I was much annoyed by the precipitation of iron with the barium sulphate. I adopted the following simple method of purification, and it always secured a perfectly white precipitate:—

The sulphuric acid was precipitated with great care, as already described, so as to obtain a clear supernatant fluid. The solution was decanted to the last drop through a filter-paper. To the precipitate left in the beaker were added 5 or 10 c.c. of concentrated hydrochloric acid. The beaker was then carefully held over and just touching a hot plate until the acid was in full ebullition. By holding the beaker in an inclined position there will be no danger of spirting. The boiling was kept up for about a minute. After cooling it was diluted, cochineal solution added, over-neutralised with ammonia, slightly acidified, and filtered. This always gave perfectly white precipitates.—*Journal of the American Chemical Society.*

QUALITATIVE TEST FOR CARBON DISULPHIDE AND CARBON DIOXIDE IN COAL-GAS.

By T. O'CONNOR SLOANE, A.M., Ph.D.

A PIECE of caustic potash a few m.m. long is dissolved in 10 to 20 c.c. of alcohol. If, after standing protected from the air, a homogeneous and clear solution remains, it is ready for use. Otherwise, after settling, the clear fluid may be decanted. It is placed in a suitable absorption tube, and a cubic foot or more of gas passed through it. It is then poured into a test-tube. If the gas contained carbonic acid, an oily-looking colourless solution of potassic carbonate in water will underlie the alcohol. This last will be coloured more or less.

The alcoholic solution, if any carbon disulphide was in the gas, will contain a so-called xanthate of potash, and may be boiled and tested for sulphuretted hydrogen.

A more demonstrative method is to add excess of copper salt, filter out the precipitated cupric compounds, and pour ammonia through the filter-paper, when a highly characteristic precipitate of cupric xanthate will remain on the filter-paper.—*Journal of the American Chemical Society.*

CONTRIBUTIONS FROM THE CHEMICAL LABORATORY OF HARVARD COLLEGE.*

By JOSIAH PARSONS COOKE, Director.

IN a paper presented to the Academy, and published in its *Proceedings*, vol. xiii., page 1, we gave the results of our investigation of the haloid compounds of antimony up to that time, including a revision of the atomic weight of this element. We did not directly answer the criticism which this paper called forth, except so far as to present to the Academy, March 10, 1880, and to publish in these *Proceedings*, vol. xv., page 251, a preliminary notice of experiments then in progress which furnished the best possible answer to the unfounded assumptions of the critic. We also gave brief notices of our work from time to time in the *American Journal of Science*. But now that the work is ended for the present (or at least must be suspended for a considerable period), we propose to bring the results together in the present paper.

1. THE OXIDATION OF HYDROCHLORIC ACID SOLUTIONS OF ANTIMONY IN THE ATMOSPHERE.

In our first paper (*loc. cit.* page 21) we made the following incidental observation in explanation of certain precautions which we found to be necessary in order to secure the precipitation of pure antimonious sulphide:—

"The precautions here described may seem unnecessary to those who are not familiar with the fact that a solution of antimony in hydrochloric acid oxidises with very great rapidity in the air,—fully as rapidly as the solution of a ferrous salt. A solution reduced as we have described, which has at first no action on the iodised starch paste, will strike the blue colour after it has been exposed to the air for only a few minutes. This property of an acid solution of antimonious chloride is mentioned by Dexter, in the paper already referred to, but we were wholly surprised by the energy of the action. By means of it, antimony can be dissolved in hydrochloric acid without the aid of nitric acid, or of any other oxidising agent save the air, if only a certain amount of antimonious chloride has once been formed. When, after exposure to the air, the solution is boiled over pulverised antimony, the solution is reduced, and a further portion of the metal enters into solution. After a second exposure, the same process can be repeated, and so on indefinitely. The process is very slow and tedious, but, in one experiment, we succeeded in bringing into solution in this way several grammes of antimony."

On the sole basis of this language we have been represented as asserting that such antimony solutions oxidise in the air as rapidly as a solution of *ferrous chloride*, and experiments on comparatively dilute solutions of antimonious oxide in hydrochloric acid have been adduced as proofs that our observation was incorrect.

As is evident from the context, the statement just quoted, although the result of a very extended experience, was not based on quantitative measurements. What we noticed

* Presented to the American Academy of Arts and Sciences, May 11, 1881.

was that the solutions *were very quickly acted on* by the oxygen of the atmosphere, and we freely admit that the expression here italicised is a more accurate description of our observation than the words originally used as quoted above. But our meaning was not left in doubt, for we expressly say, immediately after, that the process is very slow and tedious. In regard to the phenomenon in question, the effects are so obvious, when once attention is called to them, that it is entirely unnecessary to confirm our previous observations except so far as to add the following quantitative determinations, which will serve to give an accurate idea of the extent of the action under the only conditions we have investigated, or in regard to which we have written.

In order to determine the amount of oxidation caused by the action of the atmosphere on a solution of antimony in hydrochloric acid, we reduce the oxidised solution by boiling the liquid over antimony bullets, and determined the loss in their weight. This method is fully described in our original paper, and is based not only on the reducing of the metal, but also on the fact repeatedly observed, that, after the reduction was complete, the smallest excess of the finely pulverised metal would not dissolve, even after prolonged boiling, and in the presence of a large excess of acid, if only the solution was protected from oxidation.

We began our experiments by dissolving 1·0036 grms. of pure antimony (a portion of the same used in our experiments on the synthesis of antimonious sulphide) in about 30 cubic centimetres of pure hydrochloric acid (sp. gr.= (1·175), adding 3 cubic centimetres of very dilute nitric acid containing only about 5·4 per cent of HNO_3). After the solution was completed we added bullets made of pure antimony (the same that had been used in our previous experiments), and boiled the solution in an atmosphere of carbonic dioxide, using the same apparatus which we described in our previous paper (*loc. cit.*). After the reduction was ended, the solution was transferred to a flat-bottomed flask through a platinum tunnel, on which the bullets were retained; and, after washing into the flask the last traces of the solution, with as small an amount of hydrochloric acid as possible, the tunnel was removed, the bullets washed with water, and again weighed as at first on the platinum tunnel. In reducing the original solution, 0·4100 of a gramme of antimony were dissolved from the bullets. The solution now containing 1·4136 grms. of antimony was next exposed to the air for different successive periods of time in a room having a varying temperature of from 15° to 30°, sometimes in the shade, and at other times on a window seat, where the sun's direct rays fell on the flask during several hours of each clear day.

We give in the following table the weight of antimony dissolved from the bullets after each sucessive exposure to the air, the amounts in each case being determined with all the precautions described above, and still more at length in our former paper:—

Weight of Sb originally dissolved		1·4136
1. Dissolved from balls after 3 days' exposure,		0·0150
2. „ after 5 days		0·0295
3. „ „ 10 „	May 17 to May 27	0·0600
4. „ „ 23 „	May 27 to June 19	0·1340
5. „ „ 37 „	June 19 to July 26	0·2960
6. „ „ 120 „	July 26 to Dec. 24	0·4481
		0·9826

During these experiments the volume of the solution was gradually increased by the hydrochloric acid used in washing as above described, so that at least the volume amounted to 100 cubic centimetres.

It will be noticed that the amount of oxidation increased with the time of exposure, and that, so long as the amount was small, it was as nearly proportional to the time as could be expected under the varying conditions. The increased activity shown by determination No. 5 appeared to be due to the intensely warm weather and bright sunshine during the period, and the last determination would seem to indicate that, after the oxidation reached a certain limit, the process went on more slowly, as we should naturally expect; but, with the greatly varying conditions during this long period, no certain conclusion can be drawn in regard to the effect of any single cause.

The action we are discussing is entirely in harmony with the chemical relations of antimony. The most striking characteristic of this elementary substance is its tendency to form compounds of the radical antimonyl, SbO. The oxychlorides, the oxybromides, and the oxyiodides, whose relations we have discussed so fully in our previous papers, are examples in point, and we have been continually surprised by the appearance of such compounds in reactions in the most unexpected ways. In this respect antimony closely resembles vanadium, and with this element antimony is more closely allied than with its familiar associate, arsenic. What the precise reaction is in the present case we are not prepared to state. That it is not the simple conversion of a terchloride into a pentachloride we are convinced; but, in order to elucidate the subject, further investigations are necessary.

In this connection we may appropriately add that while the above determinations were in progress we repeated the experiment described on page 19 of our previous paper (*loc. cit.*). We treated in an open flask 5 grms. of finely powdered pure metallic antimony with 50 cubic centimetres of strong and pure hydrochloric acid, to which we added only 1 cubic centimetre of the very dilute nitric acid (5·4 per cent) described above. The flask was placed in a warm, protected place (30° C.), and shaken from time to time. Soon the acid became coloured reddish-yellow, and the chemical action began. When it had apparently ceased, the contents of the flask were shaken together, and the solution became at once as colourless as water; but, on standing in the air, the colour rapidly returned, spreading from the surface of the liquid downward. These phenomena were repeated again and again during four or five months, untill the whole of the metal dissolved. According to the reaction usually assumed to take place under these circumstances, 5 grms. of metal would have required 50 cubic centimetres of acid, so that the effect was obtained with only one-fiftieth of the amount required by this theory.*

(To be continued.)

NOTICES OF BOOKS.

The Structure of the Cotton Fibre in its Relation to Technical Applications. By F. H. BOWMAN, D.Sc., F.L.S., F.C.S., F.G.S., &c. Manchester: Palmer and Howe. London: Simpkin and Marshall.

WE have here a very interesting and elaborate monograph based upon microscopical and chemical investigation, and valuable both from a scientific and an industrial point of view. The contents of the work were first laid before the public in a course of three lectures delivered before the students of the Bradford Technical School, during the spring of 1880. Their publication was requested at that time, but Dr. Bowman wished to complete and to publish at the same time a series of investigations on the structure of wool. As, however, other engagements have prevented,

* Although in our synthesis of antimonious sulphide it was our constant study from the first to prevent the oxidation of the product and although we most carefully guarded every phase of the process yet the theory was advanced that the apparent weight of the product was *increased* by a partial oxidation of the antimonious sulphide at the temperature at which the red was converted to the grey modification. In answer to this wholly gratuitous assumption, it is only necessary to say; 1. That the oxidation of the dried precipitate at this stage of the process is a well-marked phenomenon, with every phase of which we are acquainted. 2. That the oxidation is always attended with a *loss* of weight. 3. That the products of our determinations were always examined, and have been in two cases preserved, and that these do not show the least signs of oxidation.

for the time being at least, the execution of this design, the author has been induced to issue the present volume as it stands.

Dr. Bowman begins with some very appropriate remarks on the importance of technical knowledge, upon which, speaking not merely as a man of science, but as a practical manufacturer, he feels that the future of this country must greatly turn. He complains that, as a nation, "we have been unquestioningly following the rules of thumb which practical experience has shown will lead to certain desired results, without inquiring or considering whether these might not be better obtained in some other way." He adds:—"We often go astray in assuming that a process is far more simple than it really is, and in so doing we often overlook something which would, if observed, lead us to alter our method of procedure entirely," —a very judicious hint. Here, as in several passages of the book, the author insists on the value of the microscope to the manufacturer and the dyer. By its use the causes of unexpected and puzzling imperfections in the goods may often be detected, and a way struck out to avoid them in future. Before discussing the typical structure of the cotton fibre, he briefly notices the species of the cotton-plant, concerning the number of which botanists are by no means agreed. He gives tables of the length, diameter, and variation in the fibres from different sources. Next follows an account of the changes which the fibre undergoes whilst ripening. In early stages of their formation the growing cells are filled with juices of an astringent character, whilst in the ripe fibre the cell walls consist of almost pure cellulose. Hence it may be readily foreseen that the action of mordants, colours, &c., will be modified according as the fibre is mature or not, or as its development has been modified by unfavourable season. As regards the microscopical character of the fibre Dr. Bowman substantially confirms the results obtained by Mr. Walter Crum, F.R.S., in 1863. He describes its general appearance as that of "an irregular, flattened, and somewhat twisted tube, the tubular form in some cases being entirely lost, and the appearance resembling that of a wrinkled, twisted, irregular ribbon." By these characters it is easily distinguished from the fibres of wool and silk. As regards the internal structure of the fibre when seen by transmitted light, the author divides cotton fibres into three classes: Those where no internal structure is apparent, as occurs most frequently in immature and in over-ripe cotton; those whose structure is simply tubular, and those where the interior of the cell is filled up with secondary deposits. Want of visible structure is sometimes owing to a part of the length of the fibre being filled up with a solid, transparent, but impermeable matter. Such fibres, which the author calls "kempy," and indeed all fibres not perfectly cellular, do not dye up a full shade, but receive merely a slight stain. Hence their occurrence in cotton goods is a great inconvenience to the dyer and printer, who are often perplexed to account for the uneven and meagre shades they obtain. Mr. Crum, as is well known, held that the dyeing of cotton was almost a purely mechanical operation, the outer sheath of cellulose acting as a dialyser. With this view the author does not entirely agree. He admits the osmotic action of the sheath of cellulose, and considers that this action should be carefully studied with a view to regulating it at pleasure. He admits, also, that cellulose is, chemically speaking, a body of a very inert or indifferent character. Still, he considers it not improbable that in some cases tinctorial matters may unite with cellulose, forming compounds sufficiently stable to resist the action of water. But whether these are true definite compounds, such as those of acid and base, he thinks unproven. The fixation of the colour may further depend, not upon the cellulose itself, but upon the juices of the plant not fully transformed into cellulose.

The following is an interesting example of the necessity of cleanliness in manufacturing operations, and of the very trifling causes, as they seem to the outsider, which interfere with the dyer's success:—A number of pieces were found covered with small white marks where the thread had refused the dye. These spots were visible in all shades, but more in slates and blues than in browns and blacks. Microscopic examination proved that the fault was not due to the presence of any foreign fibre, or of immature cotton. But these spots were always associated with a knot in the yarn, or a thicker place—"the result of a piecing up of a roving, either in the card-room or spinning room." The fingers of the work-people had come in contact with the threads at these points, and the perspiration and moisture of the skin had caused the parts to resist the dye! In proof of this theory, grey pieces out of the same lot were scoured before dyeing, and came up perfectly free from spots.

The following incident is also instructive:—One season, when very fine Egyptian yarns were being used, chiefly for delicate shades, the author was consulted in cases where individual fibres and masses of fibres had turned black or dark wherever salts of iron had been used in dyeing. This blackening arose from the presence of a tannin-like body present in the juices of the growing cotton-fibre, and which from the want of sun during the growing season had never changed into more neutral compounds. The next season, with the same class of goods and the same dyes, this defect hardly ever was met with.

Passing over much matter valuable to the spinner and weaver, but of no chemical interest, we find the author returning at length to the theory of dyeing. He considers that in wool and silk there is an affinity for colouring-matters, producing true chemical combination. He agrees in fine with the illustrious Chevreul that colours are fixed in the fibre by chemical affinity, by mechanical mixture, or by the joint action of both. Exceedingly valuable are the illustrations, showing cotton fibres in different states dyed with turmeric, indigo, aniline-blue, and alizarin, all magnified 450 diameters. On comparing them, we find that the unripe pellucid fibre, and still more the "kempy" fibre, have received the colour merely in spots or blotches, the rest of their tissue remaining perfectly white. In the fully-ripe fibre the colour is much more evenly distributed, and no white patches appear.

The author holds that we are still "far remote from the standard of perfect dyeing," and that we are much more advanced in the mechanical than the chemical treatment of the raw material. "One of the directions in which we are to look for increased perfection in our finished goods must be in the determination of the means which can be employed in the preliminary preparation of the fibre, so as to enable it better to perform its function as a dialyser, and thus absorb a larger amount of colouring-matter, and distribute it more evenly."

We must here conclude this slight sketch of Dr. Bowman's work by pronouncing it a most valuable contribution to tinctorial literature, and by expressing the hope that he may soon find opportunity to complete his investigations on the fibre of wool.

Technical Vocabulary, English-French, for Scientific, Technical, and Industrial Students. By Dr. F. J. Wershoven. London, Paris, and Boston: Librairie Hachette et Cie.

We have often remarked with dissatisfaction to what a degree scientific and industrial words and phrases are excluded from ordinary dictionaries and vocabularies. We find men who are, *e.g.*, very good French scholars, who can read a French novel or play as if to the manner born, and can converse with freedom and elegance. But of industrial and technical French they know no more than they do of Chinese. Certainly in an age like the present this is a state of things at once discreditable and inconvenient. For multitudes of people the only motive for studying the French language is the desire to have at

command its scientific and technical literature. Dr. Wershoven deserves the gratitude of all this numerous class for the work before us, which will prove a valuable companion for all who are studying the applied sciences. After a careful examination of this vocabulary we are happy to bear testimony to the accuracy with which French technical phraseology is rendered into idiomatic English. It must be remembered, however, that the book, the English and French indexes excluded, runs merely to 268 pages, which is but small scope for the technical language of the sciences and their connected arts. The biological sciences and their applications in medicine, in hygiene, and agriculture do not fall within the author's plan. The chemical manufactures, too, receive a less share of attention, comparatively speaking, than does pure chemistry, or than do the mechanical arts. Dyeing, tissue-printing, bleaching and colour making, the manufactures of soap, manures, &c., figure here but to a small extent. On the other hand, beer, sugar,—which can scarcely any longer rank as an English manufacture—and paper are dealt with at some length, as are also earthenware, glass, and metallurgy. One of the very few instances of an expression not perfectly idiomatic is on page 156. Speaking of the standard (French) for gold coin he writes—"The law allows a variation (an allowance of 3-1000)." The English term here is a "remedy." It would be very difficult to do more than Dr. Wershoven has effected within such narrow limits, and we venture to suggest to him the desirability of a companion volume, taking up the thread where it is here let fall.

Elements of Agricultural Chemistry and Geology. By the late Professor J. F. W. Johnston, F.R.S., and C. A. Cameron, M.D., &c. Twelfth Edition. W. Blackwood and Sons: Edinburgh and London.

The appearance of the twelfth edition of this standard work may serve as a reply to certain remarks in a work on the same subject which it was our duty not long ago to examine. In the volume before us English literature does possess a work on agricultural chemistry fully on a level with the present state of science.

The principal new features of this edition are a summary of the experimental results of Messrs. Lawes and Gilbert, and an account of the recent experiments on phosphatic manures made by the Agricultural Association of Aberdeenshire. The latter experiments seem to point to conclusions not quite in harmony with generally received theories. The Association felt warranted in declaring "that phosphates of lime decidedly increase the turnip crop; but that farmers need not trouble themselves to know whether the phosphates are of mineral or of animal origin." Hitherto mineral phosphates, undissolved, have commonly been valued at a decidedly lower rate than animal phosphates, and "bone manures" have fetched more money than ordinary superphosphate, though containing neither a large percentage of "soluble phosphate" nor of total phosphates.

The second conclusion, based on the results of forty experiments, is likewise novel—"That soluble phosphate is not superior to insoluble phosphate to the extent that is generally supposed."

As concerning nitrogenous manures, they infer from one hundred experiments that—"Nitrogenous manures have little effect on turnips used alone, but when used along with insoluble phosphates they increase the crop; that the addition of nitrates to soluble phosphates does not seem to increase the solids or dry matter in crop; that there is no material difference between the effects of equal quantities of nitrogen in nitrate of soda and in sulphate of ammonia; that fineness of division seems nearly as effective in assisting the braird and increasing the crop as the addition of nitrogenous manures. Hence the most economical phosphatic manure for turnips is probably insoluble phosphate of lime, from whatever source, ground down to an impalpable powder."

Another course of experiments consisted in applying different classes of phosphates, with or without nitrogen, to the land in one year, taking then three successive crops of turnips without further manuring, and noting which application was most productive for the three years' period. Highest stood: steamed bone-flour, dissolved phosphate with nitrogen, and roughly crushed bones. In a medium class came undissolved phosphate with nitrogen, and mineral phosphate, either dissolved or undissolved. Lowest came animal phosphate, dissolved or undissolved.

We certainly think that the different kinds of manure here mentioned are not specified with the needful clearness. We want to know the difference between the "undissolved animal phosphate" in the lowest class and the "steamed bone-flour" in the highest. But if the results obtained in these experiments are confirmed under other circumstances of soil and climate superphosphate must without doubt decline in public favour. If, as seen in the lowest class, dissolved and undissolved animal phosphates give substantially the same results, why need we go to the cost of making sulphuric acid and applying it to the bones?

In certain experiments performed by Dr. Cameron on mangels, finely-ground coprolite gave per equal weights of anhydrous phosphoric acid, a heavier crop than coarse bone-ash, which is a much more expensive article.

Certain experiments described by Dr. Voelcker are remarkable as pointing in the same direction. He applied finely-ground coprolites, Redonda phosphate, precipitated phosphate, and raw bone-meal in comparison with dissolved coprolites, using the same money's worth in each case. As compared with an unmanured plot ground coprolites gave an increase of 3¼ tons of swedes per acre, Redonda phosphate 5¼ tons, bone-meal only 1 ton 13 cwts., precipitated phosphate 5 tons 6 cwts., dissolved bones 5 tons 13 cwts., and dissolved coprolites 6 tons 13 cwts. These results present Redonda phosphate in a new light. As an aluminium and iron phosphate it has been neglected as incapable of supplying food to plants. But as in these experiments it surpasses bone-meal and precipitated phosphate, and falls but little short of dissolved phosphates, its value must be re-considered.

As regards the direct assimilation of atmospheric nitrogen by plants, the authors, in agreement with Boussingault and in opposition to Ville, decide in the negative. The statement that urea is assimilated by plants without decomposition is fully proved by Ville and Hampe.

The authors mention that on the Lodge Farm, Barking, there have been produced ten crops annually of Italian rye-grass of about 9 to 10 tons each. But how much of this is merely water!

The present edition of this work is admirably got up, and furnished with a double index—for the subject-matter and for the authors referred to.

CORRESPONDENCE.

BLOWPIPE CHEMISTRY.

To the Editor of the Chemical News.

Sir,—Blowpipe Chemistry, or "Pyrology," is now pretty generally admitted to have been heretofore much neglected in England, France, and even Germany, except at Freiberg. It is the travelling mineralogist's chief assistant, and ought to be (next to a knowledge of palæontology) the geologist's. The modern discriminating chemist has almost come to delegate to it and to the spectroscope his entire qualitative work. The metallurgist now regrets that he has neglected to devote at least a chapter to its merits, whilst even the chemical agriculturist and the medical practitioner would find, by treating poisoned organisms and then healthy ones in boric acid, &c., separately before the blowpipe, such radical reactionary differences as would probably enable the results to afford to a

clever man, provided with a microscope, valuable clues of the causes of all disease. The farmer, or intending purchaser of lands, by treating weeds grown in soils or manure heaps in the same simple manner, would arrive at a fair qualitative knowledge of the chief mineral characteristics of the latter, without the expensive or nasty resort of a regular analysis.

The above are a few advantages which, I believe, would immediately follow a little more encouragement by some of our leading physicists and chemists of the study of pyrology by means of the simple mouth-blowpipe or hand-blower; but if the science were once fairly grasped and applied *on the large scale* by such men as those, it seems to me obvious that some remarkable and most important discoveries would soon be made by them. For instance, boric acid has been found, when treated before the blowpipe with various substances, to afford novel and interesting reactions and chemical compounds, unexpected even at Freiberg. What, then, would be the probable results and benefits to science should one of the distinguished men above alluded to, with the means placed at his disposal by a rich and appreciative government or people, treat its analogue silicic acid *as a reagent* similarly before the oxy-hydrogen blowpipe? It is evident that many minerals (silicates) could be *made* in this way, and important knowledge afforded to geologists and others of the actual working of Nature in the formation of some of her rocks. The only question would be as to the nature of a support for the assay which could withstand heat sufficient to fuse silica, and I would suggest the trial of a *thick* piece or block of aluminium for the purpose.—I am, &c.,

W. A. Ross.

Acton, W., October 26, 1881.

SOURCES OF POTASH.

To the Editor of the Chemical News.

Sir,—Owing to the restriction of the output of potash salts at the Stassfurth and other salt-mines in Germany, the relations between supply and demand for potash products is so strained that the price of muriate has risen to £8 7s. per ton f.o.b. Hamburgh for 80 per cent, and there does not seem to be any reason why further action of the German Government may not occasion a still greater advance in price. However pleasant this may be for producers of potash salts in this and other countries, consumers of the article in question who are compelled to pay the high price for muriate without being able to secure an advance in the returns for their finished article, naturally feel aggrieved at the position in which they are placed. As one of the grumblers may I ask, through the medium of your journal, if any attempts have been made to find sources of potash, similar to those in Germany, in the vicinity of our salt deposits. It is said that the potash salts now so extensively worked at Stassfurt and Leopoldshall received at first the name "abraumsalze," because common salt being the mineral sought for, they were looked upon as rubbish or waste (hence the word "abraum"). These now valuable salts occur in beds of great thickness over the rock-salt deposits. In opening out the new salt fields of Fleetwood and Middlesborough, I would like to call the attention of those concerned to the possible existence of similar potash deposits, knowing that the discovery and working of such would not only relieve us from a monopoly foreign to us in more senses of the word than one, but prove a source of profit to the owners.—I am, &c.,

Kalium.

Manchester, October 26, 1881.

Reaction for Gallic Acid.—Ammonium picrate produces in solutions of gallic acid a red colouration, which in a few seconds passes into a fine green. Pyrogallic acid and tannin give also a red, which remains unchanged.—*Polyt. Notizblatt.*

CHEMICAL NOTICES FROM FOREIGN SOURCES.

Note.—All degrees of temperature are Centigrade, unless otherwise expressed.

Comptes Rendus Hebdomadaires des Séances, de l'Académie des Sciences. No. 14, October 3, 1881.

Decision of the Congress of Electricians on the Unities of Electric Measures.—For these measures there are adopted the fundamental unities—centimetre, gramme, second, and this system is briefly designated by the letters C. G. S. The practical units, the *ohm* and the *volt*, will retain their present definitions; the ohm is a resistance equal to 10^9 absolute unities (C. G. S.), and the volt is an electromotive force equal to 10^8 absolute unities (C. G. S.). The practical unit of resistance (ohm) will be represented by a column of mercury of 1 square m.m. in section at the temperature of 0° C. An international commission will be charged with ascertaining for practice, by means of new experiments, the height of this column of mercury representing the ohm. The name *ampère* will be given to the current produced by the electromotor force of 1 volt in a circuit whose resistance is 1 ohm. *Coulomb* is the quantity of electricity defined by the condition that in the current of an ampère the section of the conductor is traversed by a coulomb per second. *Farad* is the capacity defined by the condition that a coulomb in a condenser, whose capacity is a farad, establishes a difference of potential of a volt between the armatures.

Application of Radiophony to Telegraphy. The Multiple-Inverse Electric Teleradiophone.—E. Mercadier.—This paper cannot be reproduced without the accompanying diagram.

A New Electro-Magnetic Pointer, destined for Experimental Researches.—G. Noel.—The author describes an instrument intended for physiological experiments.

Secondary Batteries.—J. Rousse.—In order to accumulate electricity for the production of light or motive power, the author has arranged secondary batteries, which differ from those of M. G. Planté. At the negative pole he uses a sheet of palladium, which, during the electrolysis, absorbs more than 900 times its volume of hydrogen. At the positive pole he uses a sheet of lead. The electrolysed liquid is sulphuric acid at 1-10th. This element is very powerful, even when of small dimensions. Another secondary element which has also given good results, is formed at the negative pole of a slender plate of sheet-iron. This plate absorbs more than 200 times its volume of hydrogen when electrolysed in a solution of ammonium sulphate. The positive pole is formed of a plate of lead, pure or covered with a stratum of litharge, or pure oxide, or all these substances mixed. These metallic plates are immersed in a solution containing 50 per cent of ammonium sulphate. Another arrangement is at the negative pole, sheet-iron; at the positive pole a cylinder of ferro-manganese. The electrolysed liquid contains 40 per cent ammonium sulphate.

A Manganese Battery, where the Salts are Utilised or Regenerated.—J. Rousse.—Instead of the zinc in a Bunsen element the author uses ferro-manganese. As the liquids, he uses sulphuric acid at 1-20th and concentrated nitric acid, or if a feeble current is required, instead of the latter, potassium permanganate. The salts produced are manganese sulphate and nitrate.

Levulose.—MM. Jungfleisch and Lefranc.—Not suitable for abstraction.

Verhandlungen des Vereins zur Beförderung des Gewerbfleisses. June, 1881.

Position of the Copper Trade in the Year 1880.—The total consumption of copper in Germany for the year

1880 is given as 406,116 cwts., and the total production as 204,480 cwts.

Part 7, 1881.

Development of the Synthesis of Indigo.—Prof. Liebermann.—A discourse delivered at the meeting of the Society, July 4, 1881. The author summarises the researches of Prof. Baeyer, and admits that from this quarter there is no immediate danger to the production of natural indigo.

Die Chemische Industrie.
Vol. 4, No. 4.

Preparation of Potassium Sulphate from the Crude Potassium Salts of Stassfurt.—Dr. H. Gruneberg.—A summary of patents relating to the potash manufacture.

Separation of Alumina from Ferric Oxide.—H. Beckmann.—The author shows that the caustic alkalies used for this purpose are contaminated with silica, alumina, and organic matter which render the separation uncertain. He proposes the use of baryta water, which, contrary to the earlier statement of Vauquelin, dissolves alumina completely, and has the advantage of not acting upon silica.—*Verein. Naturw. Braunschweig*, 1880.

Vol. 4, No. 5.

Synthetic Production of Nitric Acid.—Atmospheric air streams through a series of closed vessels, and is exposed to the action of the electric spark, whereby hyponitric acid is formed, and is carried by the current of air into an absorption-column traversed by potash lye. The air and the liquid flow in opposite directions, so that a moderately concentrated solution of potassium nitrate flows off below.—*Moniteur Indust.*, vii., p. 526.

Determination of the Value of Lead Peroxide.—H. Fleck.—A weighed quantity is placed in a small flask fitted with a gas-delivery tube, and decomposed with dilute hydrochloric acid. The chlorine evolved is passed into a solution of potassium iodide. When the escape of gas has ceased the solution is titrated with sodium hyposulphite, and the percentage of lead peroxide is calculated from the quantity of iodine. In rich samples the moisture should be determined specially.—*Repertorium Anal. Chem.*

Vol. 4, No. 6.

General Congress of German Manure Manufacturers, Dresden, May 23.—The first question discussed was the influence of recent experiments on manuring with precipitated phosphate and "Kladno-phosphate" (a by-product from dephosphorising iron-ores by Jacobi's patent) upon the consumption of superphosphate. The general opinion was that precipitated phosphate could not become a dangerous competitor, whilst the production of the Kladno-phosphate was likely to diminish in consequence of the introduction of the Thomas and Gilchrist process. The next questions considered relate merely to import duties. As to the value of Seltsam's process for extracting from bones by means of benzol, the general opinion was that the additional quantity of fat obtained was not great, and that the quality was objected to by purchasers. The question whether organic nitrogen is equal in value to the nitrogen in ammonia and nitrates remained undecided, as the respective experimental results varied according to soils, methods of cultivation, &c. In a long discussion on the use of ammonium citrate, it appeared that iron phosphate is much more soluble in an ammoniacal than in a neutral citrate solution, whilst Koninck and Thiriart have shown that recently-precipitated alumina phosphate is very readily soluble in ammonia. The citrate process was pronounced to be the foundation of a correct method of determining the value of superphosphates.

Vol. 4, No. 7.

This number is taken up with abstracts of patent specifications and extracts from other journals.

Vol. 4, No. 8.

Analysis of Sulphuric Anhydride and Fuming Sulphuric Acid.—O. Clar and J. Gaier.—The difficulties to be encountered here depend on inaccuracy in weighing substances so highly hygroscopic, and on losses in consequence of the violent reaction on diluting with water prior to titration. The authors, after criticising known methods, give a process which cannot be intelligibly described without the accompanying illustration.

Journal de Pharmacie et de Chimie.
July, 1881.

Pharmacologic Study of Atropine.—J. Regnauld and F. Valmont.—The atropine of medicine is a mixture in variable proportions of two isomeric alkaloids, atropine (of Ladenburg) and atropidine (hyoscyamine of Ladenburg).

Researches on Formic Ethers.—MM. Berthelot and Ogier.—These ethers, like the oxalic and the acetic ethers, are formed with absorption of heat.

Artificial Production of Vivianite.—J. Girardin.—Already noticed.

Transformation of Morphine into Codeine and Homologous Bases.—E. Grimaux.—From the *Comptes Rendus.*

Complex Function and the Constitution of Morphine.—P. Chastaing.—Already noticed.

Assay of Commercial Methylic Alcohols Used in the Denaturation of Ethylic Alcohol.—C. Bardy.—The wood-spirit used in France for admixture with alcohol for industrial purposes is required to contain 40 per cent of pure methylic alcohol. As an easy method of ascertaining its quality, the author proposes to determine its chief residual ingredient, aceton. The method which he proposes depends on the transformation of aceton into iodoform in presence of soda-lye and a solution of iodine in potassium iodide. His process will be described in a future number.

A Compound of Iodoform and Strychnin.—M. Lextrait.—The compound in question is very unstable, being decomposed by light. It is also decomposed by a temperature of 90°, by boiling-water, by ether and chloroform, and in part by alcohol. The author assigns to it the formula—$(C_{42}H_{22},N_2O_4)_3C_2HI_3$.

Determination of Salicylic Acid in Beverages.—A. Rémont.—Beer and cider are previously freed from carbonic acid by heating to 58° or 60°. Wine is concentrated to one-third of its volume by heating to from 70° to 80°. The liquid when cold is treated three times with its volume of ether washed with water. The agitation should not be too violent, lest the ether forms an emulsion. Each treatment with ether is followed by a decantation. The collected ethereal solutions are freed from ether first by distillation and then by spontaneous evaporation. The residue is weighed, and treated by its volume of chloroform, washed in water, and applied in three portions. The chloroformic solution is allowed to evaporate, and the residue is treated repeatedly with water till all acidity is removed, and the solution is then made up to 100 c.c. This solution, submitted to a colorimetric test in comparison with a freshly-prepared solution of salicylic acid, contained 0·2 grm. per litre.

On Sewage.—H. Bouley.—This paper contains the strange assertion that the sewage of London is treated by the irrigation system.

Journal für Praktische Chemie.
No. 12, 1881.

On Two New Nitro-phenols.—F. Fittica.—The two compounds obtained and examined by the author are respectively the fourth and the fifth mono-nitro-phenol,—a result not in harmony with the "benzol hypothesis."

Putrefaction Compounds of the Brain.—Florian Stockly.—The principal compounds obtained were skatol and paracresol, fatty acids from the acetic to the capronic inclusive, hydrocinnamic acid in considerable quantities, small quantities of pepton, and traces of leucine. If the products of putrefaction are examined at an earlier stage succinic acid is obtained, which after forty-eight hours is no longer to be found.

Chemical Examination of the Ambrosius-Spring at Marienbad, in Bohemia.—Dr. W. F. Gintl.—A very elaborate investigation, which shows that the character of the water in question has changed considerably since it was analysed by Dr. Raysky, in 1860.

On Isomalic Acid.—M. Schmœger.—The author has obtained the zinc and silver salts of this acid in the form of crystals. He does not consider it identical with the methyl-tartronic acid of Bœttinger.

Notes, by E. Drechsel:—

1. A Crystalline Guanine.—The author finds that guanine, contrary to the assertion of the text-books, is soluble in ammonia, and can be obtained from the solution in crystals.

2. A Modification of Pettenkofer's Reaction for the Biliary Acids.—The author uses, instead of concentrated sulphuric acid, syrupy solution of phosphoric acid, which he mixes with a concentrated solution of the alkaline salts of the biliary acids, adds a little sugar, and heats the whole in a small test-tube plunged into a flask of boiling water.

3. On Calomel.—Calomel readily dissolves in a solution of mercuric nitrate at a gentle heat, with formation of mercuric chloride and mercurous nitrate. Mercuric chloride is precipitated, however, by mercurous nitrate, except an excess of mercuric nitrate is likewise present.

Anthology of Modern Chemical Utterances.—H. Kolbe.—A selection of passages the *curiosa infelicitas* of which would greatly escape in translation.

No. 13, 1881.

Attempt at a Determination of the Reactionary Value of the Components of the Alcohols and Acids.—M. Menschutkin.—A bulky memoir, not susceptible of useful abstraction.

Contributions to the Chemistry of the Chrome-Ammonium Compounds (III. Xanthochrome Compounds).—The xantho-salts can only be prepared through the intervention of the roseo-salts. The author describes the preparation, composition, and reactions of xanthochrome chloride, xanthochrome bromide, the corresponding iodide, nitrate, sulphate, dithionate, chromate, bichromate, platinum chloride, mercury chloride, carbonate, and hydrate.

Anthology of Modern Chemical Declarations.—H. Kolbe.—A collection of illogical, ungrammatical, &c., passages from the writings of Lossen, Merz, Weith, and Wislicenus.

Gazzetta Chimica Italiana.
Anno 10, Fasc. 5 and 6.

Observations and Researches on Blood-Stains.—D. Vitali.—Attention has been recently called to a reaction discovered by Schœnbein—the blue colouration produced by a mixture of oil of turpentine and alcoholic tincture of the resin of guiacum, on the addition of a little blood or a very dilute solution of hæmoglobin. It is said that this reaction is preferable to any other, not excepting that founded on the formation of crystals of hæmine and on spectroscopic observation, and that none of the substances capable of simulating blood-spots give the same opaque blue colour. The author, however, shows that all substances capable of acting as direct or indirect oxidising agents are capable of producing the same reaction.

On the Neutral Cerium Tungstate.—Prof. A. Cossa and Mario Zecchini.—The authors determine the atomic weight of cerium = 138.

On Certain Derivatives from Natural and Synthetic Thymol.—E. Paterno and F. Canzoneri.—The authors examine the action of nitric ether on the methylic ether of nitro-thymol, that of dilute nitric acid upon the methylic ether of nitro-campho-thymol, and the composition of dibromo-oxymethyl-toluic acid.

On Sacchulmic Acid.—Fausto Sestini.—The author ascribes to this acid the formula $C_{11}H_{10}O_4$.

Experiments on Cumo-phenols.—Dr. P. Spica.—An account of the action of mono-chloracetic acid upon para-cumo-phenol in an alkaline solution, and upon ortho-cumo-phenol in presence of soda.

Sulphacids of Cymene.—Prof. P. Spica.—The author, in contradiction to numerous chemical authorities, shows the existence of two cymenic sulph-acids.

On a New Phenol.—Dr. G. Mazzara.—The phenol in question is obtained by melting the potassium salt of para-ethyl-methyl-benzol-sulphuric acid with potassa. Its composition is $C_9H_{12}O$.

Researches on Blood-Stains.—Dr. Dioscoride Vitali.—The author gives further details on the application of Schœnbein's test for the detection of blood.

MISCELLANEOUS.

Cantor Lectures.—The following are the subjects of the courses of the Society of Arts Cantor Lectures for the Session just about to commence:—First course, on "Some of the Industrial Uses of the Calcium Compounds," by Thomas Bolas, F.C.S. Second course, on "Recent Advances in Photography," by Captain Abney, R.E., F.R.S. Third course, on "Hydraulic Machinery," by Prof. John Perry. Fourth course, on "Book Illustration, Old and New," by J. Comyns Carr. In connection with Capt. Abney's lectures it is intended to arrange for an exhibition of photographic apparatus, processes, &c. These Lectures originated in 1863, with a bequest to the Society of Arts by the late Dr. Cantor. Since that date three or more courses have been given every Session, each course dealing with some application of Science or Art to Industry or Manufactures.

NOTES AND QUERIES.

*** Our Notes and Queries column was opened for the purpose of giving and obtaining information likely to be of use to our readers generally. We cannot undertake to let this column be the means of transmitting merely private information, or such trade notices as should legitimately come in the advertising columns.

Sulphuric Test for Anthracen.—I have been trying to ascertain for some little time the *modus operandi* of a test called Meister's sulphuric test for anthracen, obtained in the distillation of coal-tar. None of my friends here appear acquainted with it. Could any of your correspondents kindly enlighten me?—S. Baker, Jun.

MEETINGS FOR THE WEEK.

Saturday, Nov. 12th.—Physical, 3. "On Spirals in Crystals," by Lewis Wright. "On Integrating and other Appliances for the Measurement of Electrical and Mechanical Forces," by C. V. Boys.

Silicates of Soda and Potash in the state of Soluble Glass, or in CONCENTRATED SOLUTION of first quality, suited for the Manufacture of Soap and other purposes, supplied on best terms by W GOSSAGE and Sons, Soap Works, Widnes, Lancashire.
London Agents, COSTE and Co., 19 and 20, Water Lane, Tower Street, E.C., who hold stock ready for delivery

IRISH HILL BAUXITE (Alum Clay).

THE IRISH HILL MINING CO. are now, and always have been, the LARGEST PRODUCERS OF THIS CLAY, of Superior Quality, and supply the Manufacturers of Alum, Sulphate of Alumina, and Alum-Cake, of the United Kingdom, America, and the Continent, almost exclusively.

ANALYSIS BY JOHN PATTINSON, ESQ.

Supplies over 90 % of the Bauxite (Alum Clay) used.

	Dried at 212° F.		
	Gertrude (extra qual.)	1st Quality.	2nd Quality.
Alumina	59·00	53·83	52·00
Peroxide of Iron	0·47	1·57	4·57
Silica	18·00	8·67	12·00
Titanic Acid		5·80	6·20
Lime, Magnesia, Potash, Soda, and Sulphuric Acid	0·23	0·83	1·14
Combined Water	22·30	29·27	24·00
	100·00	99·97	99·91

Supplies over 90 % of the Bauxite (Alum Clay) used.

Our MINES, DRYING KILNS, and GRINDING MILLS are situated very close to the Shipping Ports of BELFAST and LARNE, and adjacent to Railways running alongside both Steamers and Sailing Vessels at both Ports, from either of which shipping is abundant and cheap, therefore we can guarantee Regular Delivery as Buyers require it, and are prepared to quote prices f.o.b. c.i.f., or delivered at any Port, in Bulk or Bags, Lump or Ground.

Vol. XLIV. No. 1146.

ON THE OCCURRENCE OF SELENIUM AND TELLURIUM IN JAPAN.*

By Professor EDWARD DIVERS, M.D.

At the Sulphuric Acid Works of the Imperial Japanese Mint, and at a private works, both in Osaka, the sulphur now employed comes from different parts of Japan, Kagoshima, Oïta, Hokkaido, &c. In some of the sulphuric acid made there I have found not inconsiderable quantities of selenium, and Mr. M. Shimosé, one of my pupils, has also found more than traces of tellurium. Arsenic is also present in quantity.

A former pupil of mine, Mr. Nakagawa, now a chemical engineer in the Imperial Mint, states that the flue deposits of the sulphur burners is rich in selenium.

I had hoped to have obtained by this time fuller particulars, but have been disappointed by not receiving in time supplies of acid and flue dust. I must therefore limit my communication to the announcement of the presence of these two elements in Japanese sulphuric acid, and of the probable occurrence of material quantities of selenium in Japan. A further communication will be published when particulars have been ascertained.

THE DIRECT PRODUCTION OF PHENOL FROM BENZENE.

By C. T. KINGZETT, F.I.C., F.C.S.

At a meeting of the New York Academy of Sciences on March 14th of this year, Dr. A. R. Leeds, of the Stevens Institute of Technology, made a communication† relating chiefly to peroxide of hydrogen, ozone, and benzene. Among other matters of interest therein referred to, he describes an experiment wherein 20 c.c. of benzene had been digested with 300 c.c. of a slightly acidulated 1·2 per cent solution of hydrogen peroxide during some days and under certain conditions as to temperature, &c. :—"At the end of this time the liquid had become yellow, and was found to contain, beside the colouring matter, oxalic acid and phenol." Benzene does not absorb oxygen when exposed to the air in sunlight or otherwise, and therefore it is unlike the terpenes and certain other classes of hydrocarbons in this respect. This observation was recorded by the writer some years ago,‡ and Dr. Leeds confirms it in his paper.

After reading Dr. Leeds's communication it occurred to me that it would be interesting to ascertain if phenol is produced by placing benzene in prolonged contact with air, water, and a hydrocarbon known to give rise to the formation of peroxide of hydrogen by aërial oxidation in the presence of water. Accordingly, I have conducted some few experiments to determine this question, and although the obtained results are chiefly negative in character, the matter is of sufficient interest to justify a brief description.

Experiment A.—100 c.c. benzene were mixed with 100 c.c. of Russian turpentine; 100 c.c. of water were added, and the mixture was maintained at 60° C. during some six or seven days, and exposed meanwhile to a current of air. Attached to the vessel containing this mixture was a wash-bottle charged with cold water, in order to condense, so far as practicable, such substances as might be volatilised in the oxidiser and carried over in the air-current. From time to time further quantities of benzene and turpentine were placed in the oxidiser. As the oxygen was absorbed the oil-mixture became dark yellow in colour and increased in density: the aqueous solution also became coloured. It was proved by actual determinations, which were made from day to day, that the presence of the benzene did not interfere with the production of the peroxide of hydrogen.* Thus, on the seventh day, 5 c.c. of the aqueous solution contained H_2O_2 equal to 12 c.c. N/10 $Na_2S_2O_3$ solution, and the oxidised oil-mixture was proved to contain a large amount of that organic peroxide which by contact with water gives rise to the peroxide of hydrogen.

On the third and seventh days the aqueous solutions contained in (both) the oxidiser and the wash-bottle were examined for phenol, which substance was not found present. An addition of excess of bromine water caused the liberation of oxygen gas, but yielded no precipitate of tribromo-phenol, nor did the solution give any of the other reactions characteristic of phenol.

On the seventh day the oil-mixture itself was tested for phenol, by agitating a part of it with caustic soda, separation of the alkaline extract, neutralisation of this with dilute sulphuric acid, and examination of the solution thus obtained. Phenol was not found present. After the seventh day, more benzene and turpentine were added to the oxidised oil-mixture, and the temperature raised to 100° C., a reflux condenser being attached to the oxidiser. The air-current was then kept up for several days, after which, however, the aqueous solution still contained some peroxide of hydrogen (100 c.c. = 10 c.c. N/10 thio-sulphate), but apparently no phenol. The oxidised oil was now of a very dark yellow colour and quite thick. The bulk of the aqueous solution was rendered strongly alkaline by dissolving caustic potash therein, and this solution was then well agitated with the oil-mixture. This treatment caused the whole mass to become almost black by the direct absorption of oxygen from the air, strongly reminding the observer of the behaviour of pyrogallic acid. After a shor time the alkaline lye was separated from the oil, and neutralised with dilute hydrochloric acid, filtered from a little tarry matter, and the resulting solution carefully examined for phenol and pyrogallic acid.

1. Treated with a great excess of bromine water it became milky, and in course of time deposited a slight amount of yellowish substance. This deposit presented characters distinct from those of tribromo-phenol, but almost identical with those of the similar or identical substance which is precipitated from an aqueous solution of thymol on addition of bromine water. It was readily soluble in absolute alcohol and in ether, and was reprecipitated from the alcoholic solution on the addition of *much* water.

2. With ammonia and calcic hypochlorite the produced reaction was not that of phenol, but resembled that given by a dilute solution of pyrogallic acid examined concurrently.

3. With ferrous sulphate it developed a greenish blue colour, like that which can be obtained by adding dilute acid to the pyrogallic blue obtained side by side.

4. With ferric chloride the solution was coloured reddish brown.

5. On addition of excess of caustic soda it darkened very much, and oxygen was absorbed from the air.

6. It reduced potassic permanganate just as acid pyrogallic solutions do.

Experiment B was practically a repetition of the first experiment, and identical results were obtained.

On this occasion it was observed that the substance which gives the slight precipitate with bromine water is lost—presumably by volatilisation—if the faintly alkaline

* Read before the British Association, York Meeting, Section B.

* *Journ. Chem. Soc.*, vol. xiii., p. 210, and Chemical News, vol. xxxii., p. 138.

solution be heated on the water-bath with the view of concentration.

On testing dilute solutions of thymol, pyrogallic acid, and phenol side by side with the product of the experiment, the results clearly confirmed the impressions made by the earlier observations. The behaviour with bromine water was exactly that of a dilute thymol solution, and the precipitate has precisely the same properties. The general behaviour towards reagents closely copied that of pyrogallic acid, but in no case was any reaction obtained clearly suggestive of phenol. It is quite true that neutral salts like chloride and sulphate of sodium do materially interfere with many of the reactions for phenol; but as regards the most important test—with bromine water—that is not the case, and except in the most attenuated solutions this reaction produces a bulky flocculent precipitate, quite distinct from the partly adhesive and finely-divided nature of the deposit which is obtained from thymol and the product of the experiment described above.

In Dr. Leeds's experiments a higher temperature was observed during the latter part of the time, since he saturated his water-bath with calcic chloride, but long before that period was reached his 1·2 per cent solution of hydric peroxide must have been largely decomposed, and as it would then probably not exceed in strength that of the peroxide of hydrogen present throughout my experiments, any phenol which was formed was produced in all probability in the earlier stages of his experiment. His tribromo-phenol weighed 0·25 grm., but no analysis of the product is given in the paper from which I have gathered this fact. The total weight of bromine water precipitate obtained in my observations was, I believe, considerably greater, but yet not sufficient to enable me to conduct any analyses.

I hope Dr. Leeds will be enabled to continue the study and afford some analytical information in support of the direct formation of phenol. I am rather of the opinion that in my experiments the benzene suffered no change, and it is certainly remarkable that benzene admits of oxidation by a 1·2 per cent solution of hydric peroxide.

It is not my intention to continue the investigation of the subject of the experiments herein described.

BREWING IN JAPAN.

By R. W. ATKINSON B.Sc. (Lond.).

The origin of the method of brewing used in Japan cannot be certainly known, but it is generally believed that it was brought over from Korea by some emigrants from that country. However that may be there is little doubt that it was employed in China at a period long anterior to that at which it became known in Japan, and as far as can be learnt, the process of manufacture was the same.

As in our brewing process the manufacture of Japanese *saké* is divided into two parts, the first of which in its aim corresponds with malting, the second with mashing and fermentation, but beyond this general resemblance the two industries have little in common. I will, therefore, divide this description into two parts, the first treating of the material which is used in place of malt, and for which I am compelled to employ the Japanese word "*koji*," the second describing the subsequent conversion of the rice-starch, first into sugar, and subsequently into alcohol, the product being called in Japanese *saké*.

I. Kōji Making.

This material, *koji*, is usually preserved in masses upon shallow wooden trays, and when examined will be seen to consist of grains of rice deprived of the embryo, and bound together by the interlacing threads of the mycelium of an air-fungus. A section taken through a single grain shows that the outer layers are loose and penetrated by the mycelial fibres, whilst in the centre the outlines of the cells can be faintly seen with very few grains of starch, which, indeed, have been gelatinised by a steaming process preparatory to the growth of the fungus. A comparison of the chemical composition of the koji with that of the rice from which it was produced, shows that the most important change is the conversion of the insoluble albumenoids of the rice into a soluble form, which is accompanied by the solution of much of the starch in the form of dextrose and dextrin, when the koji is treated with water.

	A. Whitened Rice (Dried at 100° C.).		B. Koji (Dried at 100° C
Insoluble in water—			
Starch	82·27	per cent	56·00
Cellulose	4·79	,,	4·20
Fat	0·49	,,	0·43
Ash..	0·46	,,	0·09
Albumenoids.. ..	7·50	,,	1·50
Soluble in water—			
Albumenoids.. ..	1·95	,,	8·34
Dextrose	1·91	,,	25·02
Dextrin			3·88
Ash..	0·63	,,	0·52
	100·00	,,	99·98
Water	12·70	,,	25·82

The percentage of starch calculated from the amounts of starch, dextrose, and dextrin present in the koji amounts to 82·4, a number nearly agreeing with that present in the original rice. Other analyses confirm these results, the proportions of starch, dextrose, and dextrin alone varying in the koji.

When the koji is treated with cold water, digested for some time, and filtered, a yellow solution is obtained which possesses the property of rendering thick starch-paste liquid within a very short time, five or seven minutes at 15° C., and half-a-minute to two minutes at a temperature of 45° C. This solution of koji contains dextrose and dextrin together with albumenoids derived from the rice, in quantities which vary according to the proportion of water used for solution, and according to the duration of the digestion. When the koji remains in contact with the water for a short time only, the specific rotatory power of the liquid is much higher than when the digestion is longer continued, and this is due to the circumstance that the albumenoid matters require a perceptible time before being degraded by the action of the water, so that the liquids resulting from short digestion contain a smaller proportion of nitrogenous matter, and hence the dextrose and dextrin exert a more energetic effect upon polarised light.

The effect of a higher temperature is to increase the amount of matter dissolved in a given time, and if the digestion be conducted at a temperature of 50° to 55° C. for three or four hours almost the whole of the starch may be brought into solution in the form of dextrose. The most favourable temperature appears to be 55° C.; above 60° C. solution is much less rapid, and is accompanied by a precipitation of a part of the albumenoid matter.

It is to the presence of this albumenoid matter that solution of koji owes the active properties for which it is prepared and used, and I have compared its action upon various carbohydrates with that of malt extract with this result, that whilst the latter effects the hydration of cane-sugar, dextrin, and starch, the former hydrates maltose in addition to the others, which malt-extract does not do. In this respect, therefore, the diastase of koji shows a marked difference from that of malt, and this property necessarily renders the nature of the products of its action upon starch-paste different, malt-extract producing as final products maltose and dextrin, whilst koji forms dextrose and dextrin, or if the action be long continued dextrose alone. The first product of the action upon starch-paste is, however, maltose, and it is only by the further action

of the solution that this undergoes hydration, but as the diastase of koji is very powerful the maltose may not be found unless care is taken to avoid using an excess of the active agent. The conversion of starch into dextrose and dextrin goes on even at 0° C., the rapidity of solution increasing until it attains a maximum at 55° C., above which it diminishes, and at some point near 70° C. becomes entirely inactive.

The points in which the extract of koji differs from that of malt are these:—1st in causing the hydration of maltose, and, 2nd, in the lower temperature at which its activity is destroyed, but a further difference lies in the essentially distinct mode of production of which I may now give a short sketch.

The grains of rice are in the first place deprived of the husk before being sent into the market by the farmer, and the koji maker further removes the testa from the grain by beating in a wooden mortar by which not only is the thin outer coating of the endosperm removed, but many of the grains are broken, and from all the embryo is detached. The broken grains, the testa, and the embryo are separated and used for various purposes, whilst the cleaned entire (except for the absence of embryo) grains alone are converted into koji. They are next steeped in water and washed thoroughly to remove the dust adhering to them, after which they are steamed till the starch is gelatinised, and the grains have become flexible and horny looking. This takes from half-an-hour to one hour, after which the steamed rice is thrown on to straw mats and cooled, the workmen turning it over all the time to keep the grains separate. When sufficiently cold (about 26° C.) the foreman mixes a small quantity of the spores of a mould with a little of the rice, and then scatters the mixture over the remainder, the men working the whole up thoroughly with the hands. In this state it is allowed to remain in the cool part of an underground chamber for about twenty-four hours, where it preserves nearly the same temperature as at mixing. In most cases, but not always, water is sprinkled over the heaps, which are then spread out on shallow wooden trays, and transferred to the innermost of the underground chambers, where the temperature is kept pretty constantly about 80° F., at least whilst work is actively going on. In these chambers the mixture of rice and spores remains for about thirty-six hours, during which time the spores throw out filaments of mycelium, and the temperature of the mixture on the trays gradually rises until it attains a maximum of about 106° F., some 20° to 25° F. above the temperature of the enclosure, carbonic acid at the same time being abundantly formed and oxygen absorbed. A slow circulation of air provides for the supply of oxygen and the removal of carbonic acid, the ventilation being effected merely by the warmer air rising up a square shaft at the end of the chamber to the air above. The chambers are in reality merely long low passages cut out in the clay about 15 or 20 feet below the level of the ground, and are about 50 feet long, 5 feet broad, and 4 to 5 feet high. As soon as the masses on the trays have become matted together by the threads of mycelium, and the temperature has risen to about 106° F., the workman spreads the material out in shallow layers to lower the temperature, that there may be no danger of it becoming spoilt, but after having cooled down several degrees he once more collects the mixture into heaps and permits the temperature to rise a second time to nearly the same point as at first. When the temperature has risen sufficiently a second time the rice, or koji, as it has now become, is again spread out, and left for the remainder of the time, during which it gradually cools down till it has the same temperature as the chamber.

The trays are removed and preserved in cool dry places until they are required for use. During this process the rice loses about 11 per cent of its weight calculated on the dry rice used, and it is by this species of combustion that the temperature of the chambers is kept up (for no external heat is applied), the carbonic acid and water liberated, and the oxygen used up. During the winter, when the production of koji is carried on most actively, the difference between the temperature of the chamber and that of the external air may be as much as 50° or 60° F., there being no greater variation in the chamber temperature than 4° or 5° F., whilst the temperature of the koji at times rises 25° F. above the temperature of the chamber. During the summer the amount of work diminishes, and there is then very little difference, sometimes none at all, between the outer and the inner temperatures, as a result of which the ventilation is much impaired and the growth of the fungus becomes weakened for want of the necessary oxygen. On this account the chambers are rarely used during the summer.

II. Mashing and Fermentation.

The koji thus prepared is used by the brewer for the purpose of bringing the starch of the rice into solution, and probably also because there are adherent to the grains of koji germs of the ferment, which subsequently convert the dextrose formed into alcohol and carbonic acid. The brewing operations are essentially two in number, the first being in order to obtain a quantity of vigorous ferment, and the second to allow the yeast prepared in the first process to effect the conversion into alcohol of the sugar already formed and that afterwards produced. The materials employed consist only of steamed rice, koji, and water, and although in different works the proportions vary slightly, those used at the works in Tokio may be given, as all the subsequent analyses refer to this mixture. In the first stage the proportions are the following, the quantities of steamed rice and koji referring to those bodies taken in the ordinary marketable condition of rice:—

Steamed rice	1·985 bushels
Koji	0·794 ,,
Water	15·880 gallons

This mixture is divided into several shallow vessels and thoroughly agitated: at first it forms a thick mass, but gradually, under the influence of the solution of koji, becomes thin and sweet-tasted. These operations are always carried out in the winter, and the mash at this period rarely has a temperature above 5° C., and generally rises very little above 0° C. After remaining in these shallow tubs for some time (several days) the mash is next collected in a single larger vessel, in which its temperature is raised by the introduction of closed wooden barrels filled with hot water. Almost immediately after heating fermentation sets in, and continues for several days, during which time the temperature rises to about 23° C. After being heated for a time, which varies in different breweries, the mash is returned to the shallow tubs and allowed to cool down. It then contains about 10 per cent of alcohol, but the object of this fermentation is not so much to produce alcohol as to obtain a ferment which in the second stage will cause the rapid conversion of dextrose into alcohol. The two following analyses show the composition of the mixture on the third and fifth days respectively before the heating had commenced.

	3rd day. Per cent.	5th day. Per cent.
Dextrose	7·35	12·25
Dextrin	5·12	5·69
Glycerin, ash, and albumenoids	trace	0·48
Fixed acid	0·017	0·019
Volatile acid	—	0·008
Water (by difference)	87·513	81·553
	100·000	100·000
Starch undissolved	20·43	15·46

The composition on the following days, after heating on the fifth day, is as follows.

	7th day. Per cent.	10th day. Per cent.	12th day. Per cent.	14th day. Per cent.
Alcohol	5·2	8·61	9·41	9·20
Dextrose	5·4	0·99	0·49	0·50
Dextrin	7·0	2·81	2·72	2·57
Glycerin, &c. ..	1·14	2·82	2·35	1·93
Fixed acid.. ..	0·31	0·24	0·31	0·30
Volatile acid ..	0·15	0·11	0·05	0·03
Water (by diff.)..	80·80	84·42	84·67	85·47
	100·00	100·00	100·00	100·00
Starch undissolved	10·68	12·46	11·55	12·05

The percentage of starch undissolved refers to the original weight of the materials used, the percentage in the original mixture before any change took place being 32·17, and is calculated by deducting from 32·17 the amount of starch equivalent to the alcohol, dextrose, and dextrin found in the liquid.

When the first stage is finished the mash is used like yeast, and mixed with fresh quantities of steamed rice, koji, and water in three portions, so that, including all additions, made the composition of the mash (supposing no change to have taken place) should be as follows:—

	Per cent.		lbs.
Dry rice.. ..	1450	=	34·7 (containing 29·15 starch)
Water	2724·7	=	65·3
	4174·7		100·0

The fresh quantities of koji are used for the purpose of effecting the solution of the additional quantities of starch, as the koji added during the first stage becomes quite exhausted. The addition of fresh food in the form of sugar causes the growth of the yeast present to take place vigorously, and the temperature of the mixture thus rises considerably, carbonic acid is given off explosively, and a fragrant odour spreads everywhere.

At the same time that the yeast is using up the sugar already formed, new quantities are being brought into solution by the action of the koji, and thus the two processes go on concurrently, the fermentation never being arrested by the presence of a large amount of sugar at any one time, and only stopping when the food is exhausted, or when the percentage of alcohol becomes so great that it kills the yeast. In this respect the Japanese brewing process differs from our beer-making; in the latter the activity of the diastase is destroyed before fermentation begins, so that, except by the direct addition of sugar, no increase in the amount of the latter can take place after the mashing is finished, and the total amount of alcohol formed cannot exceed that equivalent to the weight of sugar and dextrin in solution at the beginning of the fermentation.

The following are the analyses of the Japanese mash during the second stage:—

	17th day. Per cent.	19th day. Per cent.	21st day. Per cent.	24th day. Per cent.	28th day. Per cent.
Alcohol ..	5·80	9·44	11·83	12·41	13·23
Dextrose ..	2·06	1·16	0·27	0·27	—
Dextrin ..	3 89	2·74	1·42	0·47	0·41
Glycerin, &c.	0·043	1·09	1·98	1·68	1·99
Fixed acid..	0·015	0·03	0·058	0·086	0·107
Volatile acid	—	—	0·029	0·086	0·061

The alcohol steadily increases, whilst at no time is any considerable amount of sugar present; it is no doubt formed from the starch, but is as quickly used up by the ferment.

After this point is reached the mash is filtered, and the tuns rinsed out with water, which is added to the rest of the brew, a circumstance which explains the diminished percentage of alcohol in the filtered liquid, the composition of which was as follows:—

Composition of the Filtered Saké.

Alcohol	11·14 per cent
Dextrose	— ,,
Dextrin .. .. / Glycerin, &c...	1·992 ,,
Fixed acid	0·130 ,,
Volatile acid	0·020 ,,
Water	86·718 ,,
	100·000
Specific gravity	0·990

The insoluble residue retained 6 per cent of its weight of alcohol, which is recovered afterwards by distillation.

The analyses given below of various specimens of saké, produced in different breweries, show that there is no great variation in the composition of this liquid, and also that it differs markedly from beer in the very minute proportions of dextrose and dextrin which it contains.

The yield is not very good: in the process which I had the opportunity of thoroughly examining the quantity of alcohol obtained amounted only to 50 per cent of that theoretically obtainable from the starch, and the numbers given to me at Itami and Nishinomiya indicate a yield of 56·8 and 55·5 per cent respectively.

The fermentation appears to be spontaneous, and probably resembles the wine fermentation in the fact that the germs introduced are adherent to the materials employed.

The average size of the full-grown ferment is 0·0082 m.m. in diameter, and the different specimens do not vary very much from that average. Whether it is a variety of a known species, or whether it differs from those already known, I am not able to say, but it certainly differs from *Saccharomyces ellipsoidens* in its uniformly larger size, and from most of the other wine ferments in the regularity of its form, whilst it differs from the beer ferment both in its smaller size and in its capability of living in presence of 12 to 15 per cent of alcohol.

The fermented liquid after filtration is clarified by being allowed to stand in large wooden tuns for about fifteen days, after which the clear liquid is decanted and preserved in store vats. During the hot months of summer the germs of various forms of disease develop in the saké, and to destroy them the brewer has for 300 years been accustomed in the spring to heat his wine to 120° to 130° F. This at first sight looks like a "Pasteurising" process, but the essential feature of that process is omitted, for after heating the saké is poured back into the same vats, and no precautions are taken to destroy the ferments left in the store vats. Hence the necessity is felt of keeping a constant watch over the saké, and on an average it requires to be heated about once a month during the five hot months of the year. After being kept the liquid contains a smaller amount of alcohol, the dextrose has disappeared, and the amounts of fixed acid (lactic) and of butyric acid have increased, but there is in addition ammonia formed from the albumenoid matter, and also a volatile oil, the nature of which has not yet been ascertained, but which, even more than the butyric acid, contributes to produce the disgusting odour which such "turned" saké possesses.

Two kinds of ferment cells are present in great numbers in the diseased saké, one of which resembles the ferment of "turned" beer figured in Pasteur's "Etudes sur la Bière," plate I., fig. 1, and the other almost identical with the ferment found in putrid beer figured in the same plate.

By modifying the heating process used in such a way as to keep the liquid out of contact with air, and to preserve it in clean barrels completely full, there can be no doubt but that the brewing industry in Japan might become more extensively developed, and furnish a larger proportion to the Revenue than it does at present, without making the consumption of alcohol remarkable; and such a source of revenue is much needed to relieve the farming classes from much of the pressure to which at present they are subject, the farmers contributing rather more than two-thirds of the entire revenue.

II. Argento-antimonious Tartrate (Silver Emetic).

On one occasion when analysing antimonious chloride we noticed the formation of "silver emetic," and the observation led us to fear that this compound might be occluded by the argentic chloride or bromide, precipitated from a solution containing tartaric acid and antimony. This suspicion, thus excited, led us to make an investigation of the substance in question, with the following results:—

As stated in our former paper, this compound was originally obtained by Wallquist by precipitating nitrate of silver with tartar-emetic, and was analysed both by him and by Dumas and Piria. These chemists obtained respectively 27·31 and 28·05 per cent of oxide of silver. They appear, however, to have prepared the substance only in an amorphous form. As stated in the paper just cited, we first noticed the formation of crystals of the compound in a concentrated solution of antimonious chloride and tartaric acid, to which had been added an excess of argentic nitrate, and from the circumstances of their formation we were led to form a somewhat erroneous inference in regard to their relation to water. We find that the substance is far more soluble in this solvent than at first appeared. We have found from further investigation that one part of silver emetic dissolves completely in one hundred parts of boiling, and in somewhat less than five hundred parts of water at 15° C. In one determination made by evaporating a saturated solution, which had stood a long time at a temperature of 15°, we found that one thousand parts of water had dissolved 2·76 parts and in another 2·68 parts of the salt. There is obviously therefore no danger of the formation of this product in the precipitation of chlorine, bromine, or iodine from solutions of the antimony compounds of these elements in tartaric acid, unless the excess of silver nitrate is very large and the solutions very concentrated; and although we have most carefully looked for it in the precipitate we have never discovered it, except under the peculiar conditions described in our former paper, and our fear that it might be occluded by these precipitates was wholly unfounded.

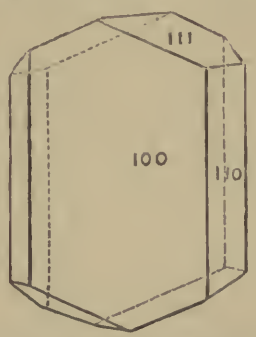
It is evident from the above experiments that the solubility of silver emetic in water, like that of cream of tartar and other salts of tartaric acid, is very greatly increased by heat, and we were easily able to obtain good crystals of the compound in large quantities by dissolving the precipitate, obtained as Wallquist describes, in boiling water, and allowing the solution to cool. The crystals are colourless and have a very brilliant, almost an adamantine, lustre.

From the reaction by which silver emetic is formed we should infer that the composition of the salt would be expressed by the symbol

$$Ag,SbO,H_2''''O_4''''(C_4H_2O_2).H_2O.$$

This compound would theoretically contain 26·34 per cent of silver and, as a mean of three analyses, we obtained for the amount of silver in the crystals 26·30 per cent, as previously stated.

The crystals of silver emetic rapidly blacken in the light, and are very easily decomposed by heat. This decomposition takes place at about 200° C. with a slight explosion. A very fine carbon dust is blown out of the crucible, and a residue is left behind, which under the microscope is seen to consist of spangles of metallic silver mixed with an amorphous powder. Almost the whole of



the powder dissolved easily in a solution of tartaric acid, and it evidently consisted of Sb_2O_3. In one experiment we weighed the silver emetic and the product, and found that 0·8460 grm. of the salt left 0·5304 grm. of residue. If the residue consisted solely of silver and Sb_2O_3, theory would require 0·5200 grm., and it can be seen from this how perfect the decomposition was. It is obvious, therefore, that were this compound occluded as we at first

* Presented to the American Academy of Arts and Sciences, May 11, 1881.

feared, it would have made itself evident on drying the precipitates.

Mr. W. H. Melville, assistant in this laboratory, has made the following crystallographic measurements of the crystals whose formation and reactions we have described.

Angles between Normals.

(111) ∧ (100) 70° 19½'
(111) ∧ (1̄11) 70° 17'
$a : b : c = 1 : 1{\cdot}386 : 0{\cdot}571.$

	I.	Measured.
100 ∧ 110	54° 12'	54° 19'
111 ∧ 110	54° 51'	54° 54'

The pinacoid planes were irregular, and the angles can only be regarded as approximate.

System Trimetric with Hemihedral Habit.

Observed planes + κ {111} {100} {110} {011} ?

In the following table the crystallographic ratios are compared with those of the acid tartrates of rubidium, cæsium, and potassium, formerly measured by us, and which have the same general form and hemihedral habit.

	Vertical.	Macro.	Brachy.
Acid tartrate of cæsium ..	0·661	1	0·694

Silver emetic	0·412	1	0·721

III. On the Solubility of Argentic Chloride in Water.

In our analyses of antimonious chloride we constantly noticed, while washing the precipitated chloride of silver with warm water, that although the water first decanted from the precipitate was perfectly clear, it became turbid when mixed with the successive washings; and on investigating the cause of this unexpected result, we found that it was due to the chloride of silver dissolved by the pure wash water, and re-precipitated by the excess of nitrate of silver in the filtrate. As the solvent action of the water used for washing the precipitate evidently produced a marked effect on our chlorine determination, we determined at once to investigate the extent of the influence.

This subject has already been studied by Stas, whose observations are summed up by Dr. John Percy,* in his recent volume on the Metallurgy of Silver, in the following words:—

"The solubility of the chloride is greatest when in the flaky state, as precipitated in the cold from a sufficiently dilute solution of silver; the solubility diminishes as the flakes shrink when left to themselves, or as they are rendered pulverulent by long agitation with water. Flaky or pulverulent chloride of silver, dissolved in water, pure or acidified by nitric acid, is precipitated by the addition of a salt of silver, or of hydrochloric acid, or of an alkaline chloride. . . . . The solution of the chloride is wholly effected by pure or acidified water, as the case may be, and is not caused by the soluble salt formed simultaneously with the chloride of silver. The presence of nitric acid in the water does not affect the solubility of flaky chloride of silver; but it increases the solubility of the pulverulent chloride in proportion to the quantity of acid present. The precipitation of the dissolved chloride is the exclusive result of its insolubility in the solution formed by adding an excess either of the silver salt or of the alkaline chloride."

So also in Liebig and Kopp (*Jahresbericht*, 1871, 339): —"According to Stas, the granular scaly and crystalline chloride is wholly insoluble in cold water: in boiling water the solubility is comparatively great, but decreases rapidly with the temperature."

In our own investigation of this subject we have at once confirmed and extended these observations of Stas, and our results may be of interest as showing that in the very familiar method of determining chlorine by precipitation with nitrate of silver, which is generally supposed to be extremely accurate, a sensible error may arise from the solubility of the chloride of silver in the hot distilled water used in washing the precipitate. It would be well for every analyst to make the following very striking experiment, which will enable him to appreciate the extent of the action in question.

Take from 5 to 10 c.c. of pure hydrochloric acid, and precipitate the chlorine in the usual way with nitrate of silver, avoiding a large excess. After pouring off the supernatant liquid and washing the precipitate once or twice with cold distilled water, pour upon the white flaky chloride of silver a comparatively large volume of boiling water. As soon as the precipitate settles, pour off the clear hot water, dividing the solution between two precipitating jars. To one of these add a few drops of a solution of nitrate of silver, and to the other a few drops of hydrochloric acid. In both cases a precipitate of chloride of silver will fall, and most chemists, certainly, will be surprised at the effect; for it is not a mere turbidness that results, but a well-defined precipitate, whose amount is easily estimated. Successive portions of boiling water poured upon the precipitate give the same reaction. In one experiment the reaction was still perceptible in the fourteenth wash-water. But under the action of the boiling water the precipitate becomes crystalline or granular, and the action lessens, until at last the water does not dissolve sufficient chloride of silver to cause even a cloudiness on the addition of nitrate of silver, as just described. Mr. G. M. Hyams, a student in this laboratory, washed two different portions of chloride of silver with boiling water until the action ceased, and then weighed and examined the residue. In the first experiment 1·4561 grms. of chloride of silver were washed with 66 litres of water. The chloride of silver was then collected, and found to weigh 1·2320 grms. Hence 0·2241 grm., corresponding to 15·39 per cent, had passed into solution. In the second experiment 60 litres of water were used, and 16·03 per cent of the chloride of silver originally precipitated were dissolved. These numbers, however, are only approximately accurate, for as the precipitate becomes granular it settles with less readiness, and there was necessarily some loss in filtering off so large a volume of liquid.

In the experiments above described the boiling water produced only a very slight decomposition of the chloride of silver. The precipitate, granulated by the washing, readily dissolved in aqua ammonia, leaving less than a milligramme of black powder, which was proved to be metallic silver.

The solvent power of water on freshly precipitated chloride of silver did not appear to be influenced by the presence of free nitric acid, even in large quantities. We tried the effect both of dropping the nitric acid on the precipitate before pouring on hot water, and also of previously adding nitric acid to the boiling wash-water. We used amounts of nitric acid ($\delta = 1{\cdot}355$) varying from 5 to 200 c.c. to the litre of water, but without finding any marked difference in the result.

The presence of a small amount of nitrate of silver in the water entirely prevented its solvent action, so far as we could discover. In order to determine the limit of the action, we added different quantities of nitrate of silver to the boiling water before pouring it on to the precipitated chloride of silver. With 1 centigramme of nitrate of silver to the litre of water there was a marked turbidness on subsequently adding an excess of the same reagent to the filtrate. With 2, 3, or even 4 centigrms. to the litre an opalescence could still be distinguished, although constantly diminishing with the increasing amount of the salt. With 5 centigrms. there was no opalescence, and we concluded that 1 decigrm. of nitrate of silver to the litre of boiling wash-water would certainly prevent all action.

A few drops of hydrochloric acid added to the wash-water greatly diminishes its solvent action on flaky chloride

* "Metallurgy of Silver and Gold," Part I., p. 60.

of silver, but does not wholly prevent it, as is evident from the fact shown in the table below, that hydrochloric acid does not precipitate chloride of silver from its solution in water nearly as effectually as nitrate of silver; and, as is well known, hydrochloric acid, if in any considerable excess, exerts a strong solvent action on the precipitated chloride.

As shown by Stas, the precipitation of chloride of silver, from its solution in hot water by the reagents we have named, depends solely on the change which the reagents produce in the solvent. That the action is an example of simple solution is shown by the fact that a considerable portion of the chloride of silver dissolved in boiling water is deposited when the solvent cools. This phenomenon is a striking one, and can easily be observed by pouring into a glass crystallising pan some of the clear solution obtained in the experiment described above. As the water cools it becomes cloudy, and deposits a granular powder, which adheres to the bottom of the glass. The grains are usually very small; but if the solution cools slowly the crystalline form can readily be distinguished under the high powers of a good microscope, and the little cubes present all the characteristics of the native crystals of chloride of silver. It is evident, therefore, that the granular condition of chloride of silver is a crystalline condition, and this experiment may elucidate the manner in which the native crystals are produced.

We have thus far only spoken of the solubility of chloride of silver in boiling water. As is evident from the crystallisation just described, the solubility rapidly diminishes as the temperature falls; but even at the ordinary temperature the solubility is distinctly marked. Lukewarm water poured on and off freshly precipitated chloride of silver becomes decidedly opalescent on the addition of nitrate of silver, and even if cold water is used the opalescence is perceptible.

In order to obtain an approximate measure of the effects we have described, Mr. Hyams precipitated about 15 grms. of chloride of silver, and, after thoroughly washing it, boiled the precipitate with a large volume of water in a glass flask. At the end of an hour he decanted through a filter about 1 litre of the boiling water, and, having divided the filtrate into two portions, he added to one portion nitrate of silver, and to the other hydrochloric acid. The precipitated chloride of silver was in each case collected and weighed. At the end of two hours' boiling, two other portions were filtered off and treated in a similar way. These determinations were then repeated with a fresh quantity of chloride of silver, and afterwards taking a third quantity of chloride of silver, the boiling water was simply poured on twice in succession, and the similar portions thus obtained treated as before. The results in every case were nearly the same as shown in the following table. In this table—

1 and 2 are results after 1 hour's boiling of 1st quantity.
3 and 4 " " 2 hours' " "
5 and 6 " " 1 hour's " 2nd q'tity, &c.
7 and 8 " " 2 hours' " " "
9 and 10 after simply pouring on boiling water.
11 and 12 " " "

No.	Weight of Water.	Weight of AgCl.	Weight of AgCl per litre.	Precipitant.
1	523·6 grms.	0·0011	0·0021	Nitrate of silver.
2	469·5	0·0004	0·0009	Hydrochloric acid.
3	115·0	0·0002	0·0017	Nitrate of silver.
4	402·1	0·0004	0·0010	Hydrochloric acid.
5	225·0	0·0004	0·0018	Nitrate of silver.
6	462·0	0·0004	0·0009	Hydrochloric acid.
7	696·4	0·0014	0·0020	Nitrate of silver.
8	825·4	0·0007	0·0008	Hydrochloric acid.
9	700·4	0·0014	0·0020	Nitrate of silver.
10	747·2	0·0007	0·0009	Hydrochloric acid.
11	520·9	0·0011	0·0021	Nitrate of silver.
12	287·5	0·0003	0·0010	Hydrochloric acid.

If we assume that the amount of chloride of silver precipitated by nitrate of silver under the conditions described above is a correct measure of the solubility of the chloride, it appears from the above determinations that about 2 m.grms of chloride of silver are dissolved by each litre of boiling water, and, further, that only about one-half of the amount thus dissolved is precipitated by hydrochloric acid.

In making chlorine determinations it is a very common practice to wash with very hot water, in order to secure the prompt settling of the chloride of silver, or to wash away any occluded material; and it was the chief object of this investigation to determine the extent to which the solubility of the chloride in distilled water might affect the result. For this purpose we made two series of determinations of the chlorine in chloride of antimony; in both cases precipitating with nitrate of silver the chlorine from a solution of the chloride of antimony in tartaric acid and water, with the usual precautions. But, while in the first series the precipitated chloride of silver was washed with boiling hot distilled water to about the 1-100,000th according to Bunsen's scheme, in the second series, although hot water was also used in washing, 1 decigrm. of nitrate of silver per litre was added to each successive portion of the wash-water poured upon the precipitate, until the last two portions, which were poured on cold. By this simple device the advantages of washing with hot water may be secured, while its solvent action is prevented. The results are given in the following table:—

First Series.

No.	Weight of $SbCl_3$ taken.	Weight of AgCl obtained.	Per cent of Cl calculated.
1	2·3856 grms.	4·4784 grms.	46·441
2	3·1300	5·8712	46·407
3	3·4207	6·4243	46·462
4	5·0031	9·3790	46·377
		Mean value	46·422
		Max. diff. from mean ..	0·047

Second Series.

No.	Weight of $SbCl_3$ taken.	Weight of AgCl obtained.	Per cent of Cl calculated.
1	3·4059 grms.	6·4188 grms.	46·624
2	3·6603	6·9014	46·643
3	2·4762	4·6658	46·617
4	2·5567	4·8212	46·651
		Mean value	46·634
		Max. diff. from mean ..	0·017

Difference between means of two series, 0·212

It is evident from these results that when great accuracy is required the solubility of chloride of silver may become a very serious source of error in determinations of chlorine, and in our first paper on the atomic weight of antimony this was the chief cause of the discrepancy between the analyses of chloride of antimony on the one hand, and the bromide, iodide, and sulphide of antimony—analyses of which closely agreed among themselves—on the other hand. It was shown in the paper just referred to that, although the greatest care was taken in purifying the material, the chloride of antimony used actually left behind, on evaporation, a sufficient amount of oxychloride to reduce the per cent of chlorine 0·116 (*loc. cit.*, p. 64). The mean results which we actually obtained from seventeen analyses of chloride of antimony was 46·620; and when to this we add 0·212 and 0·116, the sum is 46·948, which differs from 46·985—the theoretical value when Sb = 120. and Cl = 35·457—by only 0·037, or, if we take Cl = 35·5, by 0·072. In this estimate we leave out of the account the known solvent action on chloride of silver of the tartaric acid used to keep the antimony in solution. This must equally affect both of the series of determinations given above, and fully accounts for the small difference that re-

mains to be explained. This whole discussion, however, only serves to confirm the conclusion previously expressed, that chloride of antimony is a most unsuitable material for the basis of an atomic weight determination; and, having explained the anomaly to which we gave prominence in a previous paper, we shall here take leave of the subject. We have also studied the solubility of bromide of silver in water, but this is so small that we found it difficult to measure the amount. In water at the ordinary temperature, or even in tepid water, bromide of silver is practically insoluble. In boiling water it is perceptibly soluble, but not more so than is chloride of silver in water at the ordinary temperature. Hence the determination of bromine does not require the same precautions, and is susceptible of greater accuracy than that of chlorine; and on this account, as well as for other reasons which we have previously discussed, the atomic weight of antimony can be deduced from the analyses of the bromide of antimony with as great accuracy as can at present be reached in such determinations. In the seven determinations of the per cent of bromine in bromide of antimony, whose results are given beyond, the maximum difference from the mean value 66·6651 was only 0·0045, and Prof. Mallet, in his analyses of bromide of aluminum, has obtained with the same method a similar degree of accuracy.*

In conclusion, we would again express our obligations to Mr. G. M. Hyams, who has assisted us in the work of this investigation.

(To be continued.)

* *Phil. Trans.*, Part III., 1880, 1022.

PROCEEDINGS OF SOCIETIES.

CHEMICAL SOCIETY.

Thursday, November 3, 1881.

Dr. GILBERT, F.R.S., Vice-President, in the Chair.

DR. GILBERT mentioned that the President, Dr. Roscoe, was unavoidably absent, having been appointed by her Majesty on the Royal Commission on foreign technical instruction. The minutes of the previous meeting were read and confirmed. The following certificates were read for the first time:—C. Armitage, D. E. Anatole, C. H. Bothamley, J. Bingley, T. Farmer, R. P. Gardner, H. E. Head, W. B. Harrington, J. Innes, W. Jackson, R. V. Jackson, P. S. Looker, R. T. Mathews, K. D. Naegamvala, J. B. Orr, H. Ross, C. H. Sieber, C. H. Slaytor, R. Tervet, J. S. Topham, Rev. E. W. V. Volckxson, C. Wilkinson, J. Whitlock.

The SECRETARY then read a paper "*On Citraconic and Mesaconic Ethers, and Maleic and Fumaric Acids*," by W. H. PERKIN. It has been shown (*Journ. Chem. Soc.*, 1881, 409) that the differences existing between α- and β-coumaric acids are comparable to those between maleic and fumaric, and again between citraconic and mesaconic acids. Petri has pointed out a fresh point of resemblance between the two latter acids, and has found that as α-methyl-coumaric acid when distilled with phosphoric chloride yields the chloride of the β acid, so citraconic acid yields the chloride of mesaconic acid. A considerable divergence exists in the boiling-points, for, while the ethers of the α-coumaric acid boil at lower temperatures than those of the β acid, the ethers of maleic and citraconic acids boil at higher temperatures than those of fumaric and mesaconic acids. The author thought it desirable to compare some other physical properties. The methylic ethers of citraconic and mesaconic acids were first selected. The details of their preparation are given in the paper. The results obtained were:—Methylic citraconate boils at 212°, sp. gr. 1·1168, magnetic rotatory power 1·064; methylic mesaconate boils at 205°, sp. gr. 1·1254, mag. rot. power 1·154. The ethylic ethers gave ethylic citraconate boils 231·75°, sp. gr. 1·050, mag. rot. power 1·121; ethylic mesaconate boils 229°, sp. gr. 1·051, mag. rot. power 1·168. Dr. Gladstone has determined the refractive indices and finds the mesaconate in both cases more dispersive than the citraconate. The author endeavoured to prepare from fumaric acid an anhydride other than maleic acid, by the action of fumaric chloride on argentic oxalate, on argentic fumarate, on argentic carbonate, and by the action of acetylic chloride in the presence of acetic acid on fumaric acid, but in all these reactions maleic anhydride was alone obtained. So that it appears that there is but one anhydride for maleic and fumaric acids, one anhydride for citraconic and mesaconic acids, and one anhydride for α- and β-coumaric acids. The author then discusses the cause of the isomerism of these acids, and concludes that in the conversion of maleic acid, &c., into the corresponding isomerides, a contraction of the molecule takes place, attended with greater stability and diminished solubility. This conclusion is borne out by an examination of the aniline salts. The author then gives an account of a process for the direct preparation of maleic anhydride from malic acid. By heating malic acid with an excess of acetylic chloride in a water-bath, a transparent gummy fluid was obtained, which on distillation yielded a large quantity of pure maleic anhydride; the yield was from 40 to 48 per cent.

Mr. M. M. P. MUIR then communicated several papers. The first was "*On the Action of Potassium Cyanide on Bismuthous Nitrate.* By the above action Boedeker obtained a reddish brown salt, to which he gave the formula $Bi_2O_52H_2O$. In a previous paper the author prepared this puce coloured body, and came to the conclusion that it contained no water when dried at 150°, and that its composition was Bi_2O_7. Subsequent and more careful testing of this substance has convinced the author that it contains cyanogen, and that its formula is $Bi_7(CN)_6O_{15}$, or, perhaps, $2Bi(CN)_55Bi_2O_5$. This bismuth oxycyanide when dried at 140° to 150° is a reddish brown solid, somewhat resembling lead dioxide; it dissolves in hot strong nitric or sulphuric acid, producing dark red liquids. The author gives details as to the formation and reactions of this substance. By the action of hot concentrated aqueous potash on the oxycyanide Bi_4O_7 is formed. This compound, which the author designates bismutho-hypobismuthic oxide, is heavy, dark grey, and crystalline; it undergoes no alteration when exposed to air and light; dissolves readily in strong hot nitric acid, forming a purple liquid.

"*On the Atomic Weight of Bismuth*," by M. M. P. MUIR. Dumas, by the determination of the chlorine in bismuthous chloride, found the atomic weight of bismuth to be 210·44. Schneider, by converting known weights of bismuth into the nitrate, igniting, and weighing the oxide, came to the number 208·005. Re-calculating these numbers with the more recent atomic weights, we have Dumas's at. wt. 209·86, Schneider's at. wt. 207·5. The author has for some time been engaged in revising the atomic weight of bismuth, but states that his results so far are more negative than positive. He gives some results in the present paper obtained by the analysis of bismuthous chloride: determining the chloride volumetrically (full details of the method are given), he obtained a mean number 211·58; gravimetric analysis indicated 209·35; mean 210·46. The differences between the various numbers are, however, too considerable, and the author hopes to obtain better results by the synthesis of bismuthous iodide.

"*Additional Observations on the Halogen Salts of Bismuth*," by M. M. P. MUIR. The author has studied the effect of varying strengths of the haloid acids on Bi_2O_3. The reactions with the various acids resemble each other, but the actions with hydriodic and hydrofluoric acids are modified by the greater insolubility and stability towards water of the bismuthous iodide and fluoride, so that very dilute hydriodic acid must be used to ensure the formation of BiOI, whilst the Bi_2O_3 must be boiled

with HF to transform all the bismuthous oxide into the oxy-fluoride; probably, also, the formation of double salts, $BiF_3,3HF$ and $BiOF,2HF$, modifies the reaction.

"*Note on the Action of Sulphuric Acid on Zinc and Tin*," by M. M. P. MUIR and C. E. ROBBS. Strong sulphuric acid, $7H_2SO_4+2H_2O$, exerts no action on zinc until a high temperature is reached, when SO_2 is evolved, and some sulphur separates; more dilute (7 : 4) acts similarly; with acid still more dilute (1 : 1) no SO_2 is produced, but H_2S is evolved with the separation of sulphur. With weaker acids the action begins at a lower temperature, and hydrogen is the chief product of the reaction. Traces of sulphuretted hydrogen also come off, but no SO_2 and no S. The action of strong sulphuric on tin at ordinary temperatures is very slight, SO_2 being evolved and a little sulphur; as the temperature rises the action increases, and H_2S begins to appear. With acid 1 : 1 (molecules) H_2S is evolved at a lower temperature, and at 120° H, H_2S, SO_2, and S are formed simultaneously; more dilute acids have but little action until the boiling-point is reached, when H and H_2S are evolved; with $H_2SO_4:7H_2O$, H alone is formed.

"*On the Volumetric Estimation of Bismuth in the Form of Oxalate*," by M. M. P. MUIR and C. E. ROBBS. This is a modification of the process of Von Reiss (*Berichte*, 14, 1172) to adapt it for volumetric purposes. The reaction is $Bi_2O_3+4K_2C_2O_4H_2O=Bi_2(C_2O_4)K_2C_2O_4+3K_2O+4H_2O$. The bismuth oxide is dissolved in a minimum quantity of nitric acid, the solution freed from excess of nitric acid by evaporation, and a large excess of acetic acid added. An excess of standard potassium oxalate is added in a measuring flask and the double oxalate of bismuth and potassium allowed to settle. An aliquot portion of the clear solution is drawn off and titrated with permanganate.

"*Note on the Influence of Water on the Reaction between Potassium Iodide and Chlorine*," by M. M. P. MUIR and R. THRELFALL. This action is carefully studied, and also the effect of suddenly arresting the action, and then allowing it to proceed. Curves and tables accompany the paper. This apparently simple reaction seems to be in reality very complex.

"*Laboratory Notes*," by M. M. P. MUIR.

a. A lecture experiment showing the effect of (*a*) time, (*b*) temperature, (*c*) mass was exhibited by the author. Three beakers, containing respectively 100 c.c. of cold water, 100 c.c. of water at 90° to 100°, and 500 c.c. of cold water, are placed on a white surface; to each a few drops of a solution of BiI_3 in HI are added. In the 1st beaker brown BiI_3 is precipitated; in the 2nd, red crystalline BiOI; in the 3rd, a smaller quantity of BiOI. The brown BiI_3 in the 1st is slowly converted into BiOI, but the reverse change can be produced by pouring some strong HI.

b. The solution of manganese dioxide and manganese ores in hydrochloric acid. The author has confirmed the observation of Pickering (*Chem. Soc. Journ.*, 1880, 128) that potassium iodide facilitates this solution. The rapidity of the action was doubled by adding an excess of KI.

c. A new method of detecting tin in the presence of antimony. The stannic salt is reduced to stannous by boiling with copper turnings for ten minutes, after dissolving the mixed sulphides in strong hydrochloric acid. The stannous chloride is recognised by the reaction with mercuric chloride.

d. To detect the haloid acids in presence of nitrous and nitric acids. Test for HI by CS_2 and N_2O_3; if present remove by adding to neutral liquid $CuSO_4+FeSO_4$ and filtration; boil filtrate with KIIO to precipitate Cu and Fe, filter, and test as under:—

Test for HBr by CS_2 and Cl water; if present, remove by adding H_2SO_4, and then $KMnO_4$, until purple; boil ten minutes; filter, test filtrate for HCl by $AgNO_3$.

Test for HNO_2 by adding acetic acid and $FeSO_4$; if present remove by adding to a fresh portion much solid AmCl, and evaporating till liquid s thick; dilute, and test for HNO_3 by $FeSO_4$.

Test for HClO by adding one drop of indigo solution, and then dilute HCl until acid; do not warm. Instant decolourisation indicates HClO; slow bleaching, with evolution of red fumes, is due to HNO_2. Remove HClO by boiling with H_2SO_4 until Cl is no longer evolved; cool add indigo solution and H_2SO_3; bleaching indicates $HClO_3$.

Mr. WARINGTON suggested the addition of a little urea to get rid of any nitrites; on boiling for two minutes all nitrites would be decomposed, whilst the nitrates would be practically untouched.

"*On Suberone*," by R. S. DALE and C. SCHORLEMMER. The work in this paper, so the authors state, was carried out by Dr. A. Spiegel, the authors only furnishing the material. The object of the investigation was to establish the constitution of suberone. Suberone, $C_6H_{12}CO$, was combined with hydrocyanic acid, yielding the cyanhydrin, $C_7H_{12}(HO)CN$. By the action of hydrochloric acid the body $C_7H_{12}(HO)CO_2H$ was formed; this was subsequently transformed successively into $C_7H_{12}Cl,CO_2H$, $C_7H_{11}CO_2H$, $C_7H_{13}CO_2H$. This last substance, suberan-carboxylic acid, was boiled with nitric acid, when a bibasic acid, having the formula $C_8H_{12}O_4$ or $C_8H_{14}O_4$, was obtained; further examination had to be postponed, on account of the want of a further supply of the expensive suberone.

"*On Sulphonic Acids derived from Isodinaphthyl*," by WATSON SMITH and T. TAKAMATSU. The authors have prepared and investigated the following bodies:—Dinaphthyl $\beta\beta$ mono-sulphonic acid, $C_{10}H_7C_{10}H_6SO_3OH$, its calcium and barium salts; also barium $\beta\beta$ dinaphthyl-disulphonate—

$$\left.\begin{matrix} C_{10}H_6SO_3 \\ C_{10}H_6SO_3 \end{matrix}\right\rangle Ba,$$

an isomeride, and the lead salt of this acid. The lead salt of $\beta\beta$ dinaphthyl-tetra-sulphonic acid was also prepared.

"*On Phenyl-naphthalen*," by WATSON SMITH and T. TAKAMATSU. The chief object of the authors was to increase the yield of this body, which is obtained by exposing a mixture of bromobenzene and naphthalene to a high temperature (*Ber.*, xii., 1396, 2049). The authors give an account of their improved process. The phenyl-naphthalene was obtained in beautifully white plates, melting at 101° to 102°. A vapour density determination gave 7·08.

"*On Dimethyl-malonic Acid and Dimethyl-barbituric Acid*," by L. T. THORNE. By the action of methylic iodide on the di-silver derivative of barbituric acid, Conrad and Guthzeit obtained a dimethyl-barbituric acid, which, on saponification with potassic hydrate, &c., yielded dimethyl-malonic acid, fusing at 185°. Markownikoff, however, who first prepared this acid, by the action of potassic cyanide on bromiso-butyric acid, and decomposing the resulting product with HCl, gives its fusing-point as 170°. To explain this discrepancy the author has prepared dimethyl-malonic acid by saponifying ethylic-dimethyl-malonate with caustic potash, &c. The acid so prepared fused constantly at 186°, but sublimes before fusion. The author prepared the zinc salt which crystallises with one molecule of water. It is clear, therefore, that the acid obtained by Markownikoff could not have been pure. To remove all doubt the author prepared some dimethyl-barbituric acid by the action of dimethyl-malonic acid and urea. The acid so obtained agrees in all respects with that described by Conrad and Guthzeit. The first two hydrogen atoms substituted in barbituric acid in the formation of its salts are undoubtedly those contained in the CH_2 group of the malonyl radical, and not those attached to the two nitrogen atoms.

The Society then adjourned to November 17th, when the following papers will be read:—"Aluminium Alcohols, their Products of Decomposition by Heat," by Dr. Gladstone and Mr. Tribe. "The Chemical Action of Decomposing Vegetable Matter on the Rock-forming Sediment of the Carboniferous Period," by E. Wethered.

NOTICES OF BOOKS.

City and Guilds of London Institute for the Advancement of Technical Education. Programme of Technological Examinations 1881 *to* 1882. Gresham College, London, E.C.

This prospectus contains the general regulations of the Institute. It appears that in most of the subjects the examinations will be in two grades: a lower, ordinary, or "pass" examination, and a higher for honours. In each grade, however, there are two classes. The lower grade is intended principally for apprentices and journeymen, whilst the higher grade is designed for foremen and managers. Candidates may enter, however, for either, and there is neither limitation of age nor fee payable. The benefits of the scheme are not confined to London. If a local committee undertakes to carry out the examination according to the rules of the Institute, such examination will be held wherever a class for the needful instruction is formed and a sufficient number of candidates present themselves. The acceptable local committee may be either the committee of any art or science school connected with the Science and Art Department, or any School Board, or any Local Examination Board in connection with the Society of Arts. But in special cases a special local committee may be accepted. It must not be supposed that instruction must necessarily be given, or that candidates must present themselves in all or in even a large part of the subject.

Of the 32 branches in which examinations may be held, no fewer than 18 are to a greater or less degree dependent upon chemical science. To wit: Alkali manufacture, bread-making, brewing, distilling (including the very incongruous subjects of coal-tar distilling and the manufacture of spirit); sugar; fuel; colours and varnishes; oils, illuminating and lubricating; gas manufacture; iron and steel manufacture; paper; pottery and porcelain; glass; dyeing (silk and wool); bleaching, dyeing, and printing (calico and linen); tanning; photography and electro-metallurgy.

In certain cases each subject is distinctly two-fold. Thus the candidate in coal-tar distilling, which includes the manufacture of the coal-tar products, will not be examined in the manufacture of gin and whiskey, and *vice versa*; a candidate in bleaching, dyeing, &c., may at his option be examined in silk-dyeing, wool-dyeing, or in cotton-dyeing and printing. The division here is, however, much less natural than in case of distilling, since piece-goods to be dyed have now frequently a cotton warp with a woollen, worsted, or silk weft, and latterly even the yarns themselves are often a mixture of animal and vegetable fibres.

The syllabus before us gives under each head a list of the main heads upon which the questions will be founded, and a list of the works of reference which intending candidates may usefully study. There is a general proviso to which attention must be drawn. Before a full technological certificate can be obtained, the candidate who is not otherwise qualified (under Rule 33), will be required "to have passed the Science and Art Departments' examination for the full certificate in the ordinary grade in the elementary stage at least, and for the full certificate in the honours grade in the advanced stage at least in two of certain science subjects." Of these subjects a list is given under each section, and, we must say, they differ in a manner not to be explained. Thus, for the full certificate in wool- and silk-dyeing, the candidate must have passed in two of the following: Machine construction and drawing, theoretical mechanics, applied mechanics, light and heat, inorganic chemistry, and organic chemistry. If we turn to calico-dyeing and printing, we find, in addition to the above subjects, acoustics and elementary botany. The presence of acoustics in this list we can only account for by a clerical error, since its use to the dyer or tissue printer is about on a level with that of heraldry, Botany, too, can scarcely be pronounced to have any direct bearing on the subject.

According to Rule 33 above referred to, the certificate of the Science and Art Department will be dispensed with if the candidate has taken a degree in any British university, or can show a certificate from a professor at any one of a number of colleges specified that he has attended instruction in the requisite science subjects, and has passed a satisfactory examination.

It will at once strike the reader that there are not a few important chemical manufactures which have been so far omitted; such as soap, starch, artificial gums, chemical manures, glues and sizes, blood albumen, &c. Some of these will doubtless in course of time receive their due share of attention.

We have great hopes concerning the results of the activity of the City and Guilds of London Institute. Two possible evils should, we beg to suggest, be carefully avoided: We must remember what we want is a practical, not merely verbal, acquaintance with the different subjects. To this end the examinations should be as far as practicable directed, so as to test the working knowledge, and the resources of the candidate. Secondly, we must beware of a feverish and enthusiastic energy at the outset, succeeded before long by mere indifference and routinism. In all matters connected with higher education we must adopt for our motto "unhasting, unresting!"

CHEMICAL NOTICES FROM FOREIGN SOURCES.

Note.—All degrees of temperature are Centigrade, unless otherwise expressed.

Comptes Rendus Hebdomadaires des Séances, de l'Académie des Sciences. No. 15, October 10, 1881.

Sounds Produced in a Telephonic Circuit during Storms.—G. de Lalagade.—Referring to the recent memoir of M. Thury, the author mentions that he had observed the same phenomena, not merely during storms, near or remote, but sometimes, though less frequently, during cloudy weather in winter, and even occasionally on fine days almost free from clouds.

Galvanometer with Angular Deviations Proportional to the Intensities.—A. Gaiffe.—The instrument is a horizontal galvanometer graduated in milliwebers; its multiplier frame is of an elliptical form. Its deviations are regular under two angles of 35°, representing 35 milliwebers on each side of zero.

Biedermann's Central-Blatt für Agrikultur-Chemie, Vol. x., Heft 3.

Existence of Ozone in the Atmosphere.—E. Schœne.—From the *Berichte der Deutsch. Chem. Gesell.*

Researches on the Heat of the Ground.—Dr. von Liebenberg.—All air-dry soils at equal temperatures radiate heat equally. The author insists strongly on the injurious effect of any agency that lowers the temperature of the ground in spring, as reducing both the quantity and quality of the crop.

Manurial Experiments with Phosphoric Acid in Different Forms of Combination.—Dr. Fittbogen, Prof. Dietrich, F. Oldenburg, Dr. Birner.—The authors have compared the manurial action of superphosphates made from Mejillones Guano and from Lahn phosphorite with precipitated "Kladno-phosphate" (an aluminium phosphate) and with iron phosphate. The proportionate results for grain were:—Mejillones superphosphate 32, Lahn do. 12, precipitated phosphate 8, Kladno-phosphate 9, iron phosphate 10, whilst a check experiment without phosphoric acid gave 9. On doubling the doses,

the yield was approximately doubled in case of the Mejillones and the Lahn superphosphate, whilst with precipitated calcium phosphate, with Kladno and iron phosphate, there was little difference. The authors conclude that in sandy soils, such as were used in their experiments, only that part of the phosphoric acid which is soluble in water is utilised. Plants cannot, by the mere action of their roots, and without the co-operation of ground waters containing carbonic acid, extract any phosphoric acid from the insoluble phosphates.

Manurial Action of Gypsum on Lucerne.—V. Nanquette, Prof. Medicus, and M. Schell.—Gypsum has proved useful in the cultivation of lucerne, even on decidedly calcareous soils. (This agrees with the view of Prof. Ville.)

Comparative Manurial Experiments.—C. Nerger.—In the experiments tried a manuring, containing otherwise all the constituents of the crop (barley), but deficient in silica, gave the poorest results, being on a level with a plot totally unmanured.

Nutritive Value of Gelatin.—N. P. Oerum and Dr. Ditzel.—A dog weighing 11 kilos., was kept for three days fasting, and received then daily for 9 days 45 grms. gelatin and 200 c.c. water. The excretion of nitrogen in the urine during the fast was daily 2·385 grms., during the gelatin diet 7·105 grms. This latter quantity exceeded that present in the daily ration by 0·785 grm. Hence during the gelatin diet 1·600 grms. of the nitrogen of the system was economised, and accordingly the animal lost weight in a smaller proportion than when fasting. The experiment was repeated with an increase of the daily ration of gelatin to 50 grms., but the results were still in accordance with those of Voit that gelatin indeed economises albumenoids, but can never entirely cover the waste of albumenoids in the system, and has therefore a much lower dietetic value than albumen.

Lupin Disease in Sheep.—Dr. G. Liebscher and Prof. Kühn.—There exists a poison in lupins which produces a disease resembling jaundice. This poison is rendered harmless by steaming.

Determination of the Value of Cattle Foods.—J. König.—It is proposed to overlook the physiological value of the various articles and to be guided merely by the market prices. Hence the ratio of value between proteine, fat, and non-nitrogenous extractive matter, is assumed, not as constant, but as fluctuating from year to year.

Studies on Evaporation from Vegetables.—Dr. P. Sorauer.—Not susceptible of useful abstraction.

Researches on the Ripening of Cheese.—Dr. G. Musso, Dr. A. Menozzi, and N. Bignamini.—The quantity of true albumen suffers little change during ripening, but the double compounds of albumen with calcium phosphate are decomposed, yielding peptons and amides. Lactose undergoes both the mucous and the alcoholic fermentation.

Action of Diastase upon Starch Paste.—A. Herzfeld.—The final products are maltose and achroodextrin.

Society of Arts.—The first meeting of the One Hundred and Twenty-Eighth Session of the Society of Arts will be held on Wednesday, the 16th inst., when the Opening Address will be delivered by Sir Frederick J. Bramwell, F.R.S., Chairman of Council. Previous to Christmas, there will be four ordinary meetings in addition to the opening meeting. For these, the following arrangements have been made:—November 23, "The Storage of Electricity," by Prof. Sylvanus Thompson, D.Sc.; November 30, Discussion on the Society of Arts' Patent Bill; December 7, "The American System of Heating Towns by Steam," by Capt. Douglas Galton, C.B., F.R.S.; December 14, "Electric Lighting at the Paris Electtical Exhibition," by W. H. Preece, F.R.S.

NOTES AND QUERIES.

*** Our Notes and Queries column was opened for the purpose of giving and obtaining information likely to be of use to our readers generally. We cannot undertake to let this column be the means of transmitting merely private information, or such trade notices as should legitimately come in the advertising columns.

Sulphuric Acid Test for Anthracen.—S. Baker will find the recognised test for anthracen, described by Meister, Lucius, and Brüning, in CHEM. NEWS, vol. xxxiv., p. 167.—W. W. STAVELEY.

MEETINGS FOR THE WEEK

MONDAY, Nov. 14th.—Society of Chemical Industry, 7.30. Address, by Prof. Abel. "The want of Uniformity in Tables of Specific Gravity," by Dr. Messel.

THURSDAY, 17th.—Chemical, 8. "Aluminium Alcohols: their Products of Decomposition by Heat," by Dr. Gladstone and Mr. Tribe. "The Chemical Action of Decomposing Vegetable Matter on the Rock Forming Sediment of the Carboniferous Period," by E. Wethered.

CLARENDON PRESS LIST OF NEW AND RECENT BOOKS.

Second Edition, 2 vols., demy 8vo., cloth, £1 11s. 6d.,

ELECTRICITY AND MAGNETISM. By JAMES CLERK MAXWELL, M.A. Edited by W. D. NIVEN, M.A., Fellow of Trinity College, Cambridge.

Demy 8vo., cloth, 7s. 6d.,

AN ELEMENTARY TREATISE ON ELECTRICITY. By the late Prof. JAMES CLERK MAXWELL. Edited by W. GARNETT, M.A., formerly Fellow of St. John's College, Cambridge.

Large 4to, paper covers, 4s. 6d.,

TABLES OF QUALITATIVE ANALYSIS. Arranged by H. G. MADAN, M.A., F.C.S., Fellow of Queen's College, Oxford.

Third Edition, Revised and considerably enlarged, crown 8vo., cloth, 9s.,

EXERCISES in PRACTICAL CHEMISTRY. Vol. I. (ELEMENTARY EXERCISES.) By A. G. VERNON HARCOURT, M.A., F.R.S., Senior Student of Christchurch, and Lee's Reader in Chemistry; and H. G. MADAN, M.A., Fellow of Queen's College, Oxford.

"To the numerous classes formed throughout the country for the study of chemistry—with especial reference to the Science and Art and the University Examinations—we strongly recommend this little volume."—*Athenæum*.

Published for the University by HENRY FROWDE, 7, PATERNOSTER ROW, LONDON.

BERNERS COLLEGE of CHEMISTRY.

Instruction and preparation in CHEMISTRY and the EXPERIMENTAL SCIENCES under the direction of Professor E. V. GARDNER, F.A.S., M.S.A.

The Class Rooms are open from 11 to 5 a.m. and from 7 to 10 p.m daily.

Especial facilities or persons preparing for Government and other examinations.

Private Pupils will find every convenience.

Analyses, Assays, and Practical Investigations connected with Patents, &c., conducted.

Prospectuses and full particulars on application to Prof. Gardner at Berners College, 44, Berners-street W.

Water-Glass, or Soluble Silicates of Soda and Potash, in large or small quantities, and either solid or in solution, at ROBERT RUMNEY'S, Ardwick Chemical Works Manchester.

SOUTH LONDON SCHOOL OF CHEMISTRY.

VACATION ARRANGEMENTS.

Gentlemen can be privately instructed in any branch of Practical Chemistry during the months of July, August and September. Those desirous of working out any Research or Patent (with or without advice) can secure a Private Laboratory to themselves.—For terms apply to W. BAXTER, Secretary, South London Central Public Laboratory, Kennington Cross, S.E.

IRISH HILL BAUXITE (Alum Clay).

The IRISH HILL MINING CO. are now, and always have been, the LARGEST PRODUCERS OF THIS CLAY, of Superior Quality, and supply the Manufacturers of Alum, Sulphate of Alumina, and Alum-Cake, of the United Kingdom, America, and the Continent, almost exclusively.

ANALYSIS BY JOHN PATTINSON, ESQ.

Supplies over 90 % of the Bauxite (Alum Clay) used.

	Dried at 212° F.		
	Gertrude (extra qual.)	1st Quality.	2nd Quality.
Alumina	59·00	53·83	52·00
Peroxide of Iron	0·47	1·57	4·57
Silica	18·00	8·67	12·00
Titanic Acid		5·80	6·20
Lime, Magnesia, Potash, Soda, and Sulphuric Acid	0·23	0·83	1·14
Combined Water	22·30	29·27	24·00
	100·00	99·97	99·91

Supplies over 90 % of the Bauxite (Alum Clay) used.

Our MINES, DRYING KILNS, and GRINDING MILLS are situated very close to the Shipping Ports of BELFAST and LARNE, and adjacent to Railways running alongside both Steamers and Sailing Vessels at both Ports, from either of which shipping is abundant and cheap, therefore we can guarantee Regular Delivery as Buyers require it, and are prepared to quote prices f.o.b. c.i.f., or delivered at any Port, in Bulk or Bags, Lump or Ground.

ON THE OXIDES OF MANGANESE.*

By V. H. VELEY. B.A.

Part I.—Historical.

The oxides of manganese, though known to possess the peculiar property of clarifying crude glass, were not distinguished in earlier times by name (*Lapis Magnes*) from magnetic oxide of iron,† or some white mineral used medicinally.‡ But at a later period these compounds were designated specially by the titles of Magnesium nigrum or Magnesia vitrariorum. However, it was only at the end of last century that the researches of Pott (1740) and Kaim and Winterl§ (1770) established that oxide of iron was not a necessary constituent of the ores of manganese. Their properties and reactions were more completely studied by Scheele‖ (1774), who to some extent traced out the analogy between the so-called manganese and the metallic oxides. In connection with these experiments, Seven Ruiman¶ observed that black manganese, when heated in an assay furnace, was changed to a brownish red colour, without thereby becoming essentially altered in its properties. It does not, however, appear that this phenomenon attracted any attention until John** (1807) not only isolated the metal, but described and analysed three separate oxides—black oxide, or the natural product; green oxide, obtained by the oxidation of the metal in water; and brown oxide, by heating the two former oxides in the air. To these three oxides Berzelius and Arfvedson†† (1813-1817) added a fourth or less oxygenated black oxide, and these results were subsequently confirmed by Forchammer‡‡ (1820-1821), Berthier§§ (1821), and Turner‖‖ (1828). Berthier assigned to the free oxides their present formula, MnO, Mn_2O_3, Mn_3O_4, and MnO_2, and considered the two intermediate oxides to be compounded of the basic monoxide, MnO, with the acidic dioxide, MnO_2. Three distinct hydrates of the dioxide were also analysed, viz., $4MnO_2H_2O$(Berthier), $2MnO_2H_2O$ (Berthier), and MnO_2H_2O (Forchammer). It appears thus far that chemical enquiry satisfactorily established:—1. That manganese forms with oxygen a series of definite oxides (other than those present in manganic and permanganic acids); 2. that manganese dioxide forms a series of hydrates.

But the particular conditions under which these several oxides are formed were not defined until 1859, when Schneider,¶¶ in the course of his determination of the atomic weight of manganese, observed that all its oxides, when heated strongly in a current of oxygen, were converted into the oxide Mn_2O_3. A few years later Dittmar,*** starting with the two facts ascertained,—that the oxides when heated in air were converted into the red oxide Mn_3O_4, and when heated in oxygen into the sesquioxide Mn_2O_3—investigated the question as to whether various mixtures of oxygen and nitrogen oxides are formed intermediate in composition between Mn_2O_3 and Mn_3O_4. It was, however, found that when the tension of oxygen was between 0 and 0·21 atmosphere the red oxide was formed, but with oxygen tension between 0·26 and 1 atmosphere the sesqui or black oxide was formed.

In no case was an oxide intermediate in composition between Mn_2O_3 and Mn_3O_4 formed; either a small quantity of the brown oxide was found mixed with the black, or *vice versa*. At about the same time Görgeu* (1862) and Rammelsberg described a series of derivatives of a manganous acid, $H_2O,5MnO_2$, in which the hydrogen is replaceable by potassium, calcium, or manganese itself. The manganese manganate was isolated by passing a current of chlorine through water in which manganese carbonate was suspended.

Within the last few years the action of reducing agents—as hydrogen, carbonic oxide, and carbon—has been made the subject of elaborate researches by Wright.† The main points established in connection with the present discussion seem to be the following:—1. When the higher oxides are heated only to moderate temperature in air, oxides intermediate between Mn_3O_4 and Mn_2O_3 are formed; 2. When the oxides are heated in hydrogen there are two definite stages of reduction, the one corresponding to the formation of Mn_3O_4, the other to the formation of MnO. (Wright also confirmed and extended an observation of Fresenius,‡ that the oxides of manganese, when prepared by methods in which the fixed alkalies take part, are always contaminated by appreciable quantities of the alkali combined with the oxides. This fact unfortunately renders at least doubtful conclusions derived from several researches of these oxides.)

Experiments by Pickering§ indicate that oxide containing a relatively large quantity of so-called available oxygen lost oxygen, while those containing a smaller quantity absorbed oxygen when heated in air to 100°, and both these "reactions increase in extent up to 200° to 250°." This loss or gain of oxygen seems to be dependent not altogether on the original amount of available oxygen, but also on the amount of water, combined or uncombined, present in the oxides.

Part II.—Experimental.

It seemed desirable to the author to study the higher oxides of manganese prepared so as to avoid contamination with alkalies, with regard to the changes which such oxides undergo when heated to moderate temperatures in various gases rendered as pure and dry as possible. The starting-point of the research was a hydrate of the oxide Mn_6O_{11}, isolated by Görgeu (*vide supra*).

Change in Air.—The hydrated oxide was heated in a current of air at temperatures ranging from 60° to 200° C. It was found that the oxide underwent two distinct changes—first, a loss of water of hydration; second, an absorption of oxygen, these changes between 130° to 150° being concomitant, and possibly dependent one on another. Thus, a hydrate of the oxide Mn_6O_{11} was converted into a hydrate of an oxide, $Mn_{12}O_{23}$. It was also observed that at certain temperatures the oxide neither lost water nor gained oxygen, owing to the production of a hydrated oxide stable at those temperatures. (For the experimental evidence on which these views are based the author must refer to a paper published in the *Journal of the Chemical Society*, 1880, 581-592.)

Change in Oxygen.—On repeating the experiments with oxygen substituted for air similar changes were observed, but, according to expectation, the absorption of oxygen begun at a lower temperature and the oxidation was more

complete. An oxide of composition expressible by a formula $Mn_{23}O_{45}xH_2O$ was obtained.

Change in Nitrogen.—In nitrogen the only change observable was a loss of water of hydration; the relation of manganese monoxide to oxygen was the same after as before the experiments. It thus appears that the changes in nitrogen at low temperatures is totally different from that in high temperatures (Dittmar, *vide supra*), in which is involved a loss of available oxygen.

Change in Hydrogen.—The author's results confirmed the former experiments of Wright: there were the two distinct changes of loss of water of hydration, and loss of available oxygen. At 200° a hydrate of an oxide approximating in composition to Mn_3O_4 was formed. The oxides and their hydrates are tabulated below, but in order to facilitate comparison and to show their mutual relations they are represented as peroxidised derivatives of a protoxide of molecular formula $Mn_{24}O_{24}$.

	$Mn_{24}O_{44}8H_2O$	$Mn_{24}O_{45}8H_2O$ (?)	
	$Mn_{24}O_{44}6H_2O$		
	$Mn_{24}O_{444}H_2O$	$Mn_{24}O_{463}H_2O$	
$Mn_{24}O_{323}H_2O$	$Mn_{24}O_{442}H_2O$	$Mn_{24}O_{462}H_2O$	$Mn_{24}O_{472}H_2O$

The author hopes shortly to bring forward further account of his experiments on these oxides.

With regard to the constitution of these bodies, it seems interesting to examine as to how far they can be regarded as true chemical entities. They must be either heterogeneous mixtures, or homogeneous mixtures, a so-called molecular compound, or, lastly, chemical compounds or entities. Their thorough uniform appearance under the microscope proves that these bodies are not heterogeneous mixtures. Again, although it is at least possible that a homogeneous mixture of two bodies might be prepared, of which one formed a series of definite hydrates, yet it is quite improbable that the relative quantities of water combined with the same weight of the mixture would bear any simple arithmetical proportion one to another. But the quantities of water combined with the same weight of one of the oxides were in the relation 1 : 2 : 3 : 4. It is generally received and promulgated in the text-books that all the manganese oxides are molecular combinations of the monoxide and the dioxide in various proportions. This view is based on an observation of Forchammer,* that the sesquioxide Mn_2O_3, when treated with nitric or sulphuric acid, is separated into the monoxide, which dissolves as manganous nitrate or sulphate, and the dioxide which remains undissolved. But it has never been established, and indeed is quite improbable, that by this reaction there is an exact and quantitative separation of the two oxides.

This view has also been furthered by the general tendency, since Kekulé's memoirs on molecular compounds, to reduce the formula of all inorganic non-volatile compounds to their simplest possible terms. But these hydrated oxides—not only at the temperature of their formation, but also at ordinary temperatures—are even more stable than the monoxide, which readily absorbs oxygen, or the dioxide which readily loses oxygen. If, then, the monoxide and dioxide be regarded as chemical entities, so equally these higher oxides must be regarded in the same light, if stability be considered to be the criterion of true chemical combination. The probability of the existence of these series of oxides and hydrates was further corroborated by a repetition of the experiments in which were obtained oxides of the same and not approximate composition which at the same temperature underwent the same cycle of changes. It is still of course an open question how far the formulæ above express the real molecular constitution of these oxides. There is some evidence in favour of regarding the molecules of the metallic oxides as complex,† and therefore the molecule of the oxide Mn_6O_{11} might be constituted as $Mn_{12}O_{22}$ or $Mn_{24}O_{44}$.* On the one hand, the fact of the oxide $Mn_{12}O_{22}$ forming hydrates containing 4, 3, 2, and 1 molecule of water of hydration, and in that it is converted, when heated in air, to an oxide $Mn_{12}O_{23}$, seems rather to point to these oxides as oxidised derivative of a monoxide expressible by a formula $Mn_{12}O_{12}$. On the other hand, the formation of an oxide $Mn_{24}O_{47}$ would seem to support the supposition that these oxides are derived from a monoxide of formula $Mn_{24}O_{24}$. At present the formula $Mn_{12}O_{12}$ seems to be supported by the greater preponderance of evidence.

The author proposes to carry on researches on oxides of other metals, and hopes thereby to arrive at a more intimate knowledge of their constitution.

(Note.—Since this paper was written, a series of researches on the hydrated oxides of tin and manganese has been published by Van Bemmelen, in which the author arrives at the conclusion that the affinity of the water molecules cannot be differentiated from so-called chemical affinity, inasmuch as these hydrated oxides decompose aqueous solutions of such stable compounds as potassium sulphate, chloride, or nitrate.)

† Abstract of a Paper read before the British Association, York, 1881.

THE BLOWING WELLS NEAR NORTHALLERTON.†

By T. FAIRLEY, F.R.S.E.

The term "blowing wells" has been applied because at certain times strong currents of air blow out from the shafts of the wells, while at other times equally strong currents blow into them. An examination of the sandstone rock in which the wells are sunk shows the fissures through which the air passes. It is also observed that an out-current prevails while the barometer is falling, an in-current while it is rising, and that when the barometer remains stationary for any length of time, the current slackens, and at length becomes perfectly still.

Having proved by analysis that the gas passing in these powerful currents was really atmospheric air, it seemed to me that the only possible explanation of the phenomena is the existence of large cavities in the strata communicating by fissures with the shaft of the wells, of course above the water-level. Applying the well-known law of the relation of the volume of gases to pressure, in virtue of which an increased pressure (indicated by a rise of the barometer) causes the volume of air in any confined space to become less, and a diminished pressure (indicated by a fall of the barometer) causes the volume to become greater than before, I thought it possible by measuring the air passing out or in during a period of fall or rise of the barometer, and by carefully observing the barometric changes, to obtain data by which the volume of these cavities might have become known approximately.

At present three of these wells are known in the district:—At Solberge, three and a half miles southward from Northallerton; another at Langton, about four miles W.N.W. from Northallerton, these two wells being about five miles apart, situated on the rising ground separating the valleys of the Wiske and the Swale. The third well is at Ornhams, about two miles south from Boroughbridge.

(The analysis of the air from the well at Solberge did not show any excess of carbonic acid.)

At Solberge, the residence of Mr. John Hutton, a large number of experiments have been made, and I am indebted to that gentleman's kindness in continuing the observations of the instruments in my absence, and in rendering all the assistance in his power.

A small vane anemometer from Mr. Davis, optician, of Leeds, was used in the first series of experiments to measure the linear velocity of the current, and the sectional area of the large pipe leading from the well in which the anemometer was placed being known it was easy to obtain the total volume of air passing. Selecting those periods of rise or fall of the barometer which lasted so long that the current due to them had apparently time to expend itself, results were obtained giving the total capacity of the cavity as about 11 millions of cubic feet. Afterwards experiments were made, using very large dry gas meters. Two of the largest meters at liberty at the time in the stock of the Leeds Corporation were connected with the shaft of the well, one to register the out-current, the other the air-current. The force and magnitude of the current was, however, so great that these meters were soon thrown out of gear. I am indebted to Messrs. Glover and Son, the meter manufacturers, of London, for the loan of two very large meters, capable of passing 3000 cubic feet per hour. Even these after a time were found to be insufficient. The results actually obtained with them give a total capacity of 10 millions of cubic feet. A chamber 217 feet in length, breadth, and height would have practically the same capacity.

The rocks in the district are red sandstone, under which is magnesian limestone. The latter comes to the surface near Ripon on the south, and near Darlington on the north, and in both cases numerous "pot-holes" show its cavernous character. It is probable that the cavities connected with these wells occur in the limestone communicating by fissures in the sandstone. I have visited and enquired about many other wells in the district sunk in the same sandstone, but the three I have mentioned are the only ones showing air- or gas-currents.

The waters in these wells were analysed, and were hard waters similar to those found in limestone districts. The red sandstone from Solberge contains 7 per cent of carbonates of lime and magnesia. The air-currents are very powerful, producing a loud hissing noise in passing through crevices. A buzzer formed of some inverted bottles, placed over a pipe from the well at Solberge, could be heard at a distance of a mile from the well. It is likely that there are other wells in the county of this character, and if so I hope that this paper may lead to their being recognised and reported.

Analysis of Water from the Blowing Well at Solberge, Northallerton. Sent by J. Hutton, Esq., June 12th, 1879. The water contains in grains per gallon:—

Chloride of sodium	4·1
Sulphate of lime	6·36
Carbonate of lime	16·24
Carbonate of magnesia	11·36
Oxide of iron and alumina	0·03
Silica	0·21
Organic matter, loss, &c. (by diff.)	0·34
Total solids by evaporation	38·64

Colour of the water in two-foot tube, very slight green tint. Hardness of the water before boiling 32·6°, after 8·4°, giving temporary hardness 24·2°, permanent 8·4°, total 32·6°.

Analysis of Sandstone taken near the Water-level from the Blowing Well at Solberge, near Northallerton, April*, 1880.

The stone when fresh is soft and friable. Strong hydrochloric acid applied to the stone disintegrates it with effervescence. An analysis of the stone, after partial drying by free exposure to the air, gave the following numbers:—

Moisture	1·25	by diff. 1·27
Silica	87·72	
Peroxide of iron (traces of alumina)	3·96	
Lime*	3·58	98·73
Magnesia*	0·32	
Carbonic acid*	3·15	
Sulphuric acid	trace	
Loss	0·02	
	100·00	100·00

* These give 7·05 per cent of carbonates of lime and magnesia.

* Fifteen yards below the surface, adjacent to one of the fissures through which air was passing.

REPORT OF THE COMMITTEE ON PHOTOMETRIC STANDARDS.

THE Committee on photometric standards was appointed by the Board of Trade to examine and report upon the different standards which have been proposed by Mr. A. G. Vernon Harcourt, by Messrs. T. W. Keates and W. Sugg, and by Mr. J. Methven, and also the standard which is now used for testing the illuminating power of coal-gas. It was shown by preliminary experiments that standard candles are not uniform in their illuminating power; the causes and range of their variations were therefore experimented upon. In 115 determinations a maximum variation of 22·7 per cent in illuminating power was found between two pairs of candles; all these experiments were made by one observer, working with one apparatus, and as uniformly as possible.

The lamp devised by Messrs. Keates and Sugg is intended to give the light of 16 standard candles when burning pure sperm oil with a two-inch flame from a circular wick. As a rule the light emitted was constant, but occasionally it was subject to sudden variations; therefore the Committee think that it falls short of the requirements of a standard of light.

Mr. Methven's system is exceedingly simple, but still it is not considered by the Committee to be sufficiently exact for the work required of it. The system consists in allowing only a particular part of a 3-inch coal-gas flame to pass to the photometer, the coal-gas used at the testing burner being the same as that tested.

With regard to Mr. Harcourt's standard air-gas flame, the Committee say it is exact and trustworthy as compared with the sperm candle. The extreme difference obtained by two observers in 19 different observations by Mr. Harcourt's method was 0·3 candle, or 1·8 per cent. They recommend that in official documents the light furnished by coal-gas should still be expressed in standard candles, and also that the use of the sperm candle should be discontinued, and for the future Mr. Harcourt's air-gas flame (as defined in the appendix to the report) should be employed instead.

The number of grains of sperm burnt per hour in a standard candle has undergone many alterations, and has been the subject of many discussions. In 1849 the Great Central Gas Consumers Company decided upon 131·5 grs. per hour. In 1852, Prof. Graham and Dr. Leeson recommended that this should be changed to 140 grs. In 1860, the standard consumption of sperm was fixed at 120 grs. per hour; this is the present standard. It is here stated that only two London firms at present make sperm candles of the kind prescribed by the Acts, namely Messrs. Langton and Bicknell, of Newington Butts, and Mr. T. G. Miller, of Westminster. Mr. Miller states in a letter written to the Committee that, in his opinion, the irregularity with which the candles burn is due to irregularity in the plaiting of the wick.

The Committee have made a large number of experiments on the consumption of sperm by candles having

different wicks, having from 18 to 23 threads in them. The results of four comparisons between candles from different packets of Miller's 21-thread candles, each comparison being the mean of 20 observations at intervals of one minute, show that the ratio between the illuminating power of two pairs of candles frequently alters by 6 or 7 per cent in less than one minute. In six instances the ratio altered more than 10 per cent within a minute.

The Committee find that candles are open to very grave objections when used as a standard source of light. They mention very aptly that, beyond the custom of candle makers, there is nothing in the Parliamentary definition of the present standard candle to limit the diameter of the candle.

The following is a description of Mr. Methven's standard burner, which consists of a Sugg's London Argand, burning coal-gas with a 3-inch flame, having in front a screen with a slit cut in it:—

"In front of the burner, between it and the photometer disc, is fixed a brass screen, with provision similar to that of an ordinary candle holder, for fixing it at the end of the photometer bar. The tube on which the burner is fixed is provided with a T-piece and union joint, to which can be attached a flexible tube from the ordinary service to the photometer, supplied with an ordinary micrometer cock and governor, to facilitate the adjustment of the height of the flame. The end of the tube is fixed on a stand, so that the whole may be lifted off the end of the bar at any time. A hole about one inch in height and one-quarter of an inch in width is cut in the screen, which will be found sufficient to allow an amount of light to pass through it equal in illuminating power to that given by two standard sperm candles." The principle of Mr. Methven's standard depends on the possibility of finding corresponding portions of the flames of gases of varying qualities consumed so as to effect perfect combustion in similar burners, which shall be equal in illuminating power.

Experiments were made with different gases, such as pure Cannel gas, and Cannel diluted with varying quantities of common gas. The result of these experiments showed that while the light from the 37 candle gas was nearly equal to that from the 16¾ candle gas, with intermediate qualities of gas, the burner gave more light, the slit being in the same position throughout.

Mr. Vernon Harcourt's standard air-gas flame is produced by burning a mixture of air, with that portion of American petroleum which after repeated rectifications distils at a temperature of about 50° C. It is almost entirely composed of pentane; the proportion used is 576 volumes of air to one of pentane, measuring the liquid at 60° F.; the diameter of the burner is a quarter of an inch, and the height of the flame is brought to 2¾ inches. Several experiments on illuminated power were tried with samples of air-gas made on different days, and the results were found to be very concordant, the greatest difference between two observers being 0·2 of a candle. Other experiments were tried to find the effect of making a too rich or a too poor air-gas, and it was found that, taking the illuminating power of the normal mixture to be 100 candles, if 2·9 cubic feet of air were taken instead of 3, the illuminated power was equal to 100·53 candles, and if 3·1 cubic feet of air were taken to the same quantity of pentane, the light emitted was equal to 99·65 candles. The error in the volume of air being at least ten times greater than that likely to be made by any operator, it will be seen that the light will not be subject to much variation in intensity. All the experiments made with the air-gas flame being very satisfactory, the Committee have judged it to be the best standard for comparison.

Researches on the Formation of Starch Granules.—A. F. W. Schimper.—In the stems of many plants the starch granules do not arise at arbitrary points in the chlorophyl grain, but exclusively close under its surface.—*Biedermann's Central-Blatt.*

ANALYSIS OF SOIL FROM CUTTACK, BENGAL.

By C. J. H. WARDEN, Bengal Medical Staff, Chemical Examiner to Government.

The soil to which the following analysis refers was stated to have been obtained from the District of Cuttack, where the waters of the Orissa Canals are used for irrigation. The sample consisted of portions of earth taken from the surface, and from depths varying between 8 inches and 1 foot below the surface.

The soil was of a light fawn colour, and contained abundance of sand, but was free from stones or gravel. Particles of mica were visible, as well as a few small fragments of vegetable fibre. The specific gravity was 2·5, and it was found capable of holding 39·8 per cent of moisture. 100 parts contained:—

Ferric oxide, Fe_2O_3	5·7498
Aluminic oxide, Al_2O_3	6·1355
Calcic ,, CaO	0·3197
Magnesic ,, MgO	0·2350
Manganese	traces
Potassic oxide, K_2O	0·0768
Sodic ,, Na_2O	0·0497
Silicic oxide and sand, SiO_2	82·8100
Sulphuric anhydride, SO_3	0·0038
Phosphoric ,, P_2O_5	0·0013
Carbonic ,, CO_2	0·2513
Chlorine, Cl	0·0012
Nitrogen, N	0·2864
Non-nitrogenous organic matter	1·4489
Moisture	1·8143
	99·1837

The reaction was neutral; nitrates could not be detected. The whole of the iron was in the ferric condition.

Medical College, Calcutta, Sept. 6, 1881.

UPON THE

ADULTERATION OF FOOD, DRINK, AND DRUGS, FROM THE CHEMIST'S STANDPOINT;

AND UPON

THE ATTITUDE OF CHEMISTS IN THE MATTER OF APPOINTMENT OF "GOVERNMENT ANALYSTS."

By ALBERT R. LEEDS.

(Abstract).

The subject of adulteration had not received that amount of attention from the chemists which its nature and amount, as at present practised in the United States, properly demanded. And in neglecting to assume control of the investigation of the subject, and of the information and education of the public mind as to the actual facts, they had left the field in the possession of scientific demagogues and pseudo chemists who, for the past four years, had been sending out through the daily press an unlimited amount of sensational literature, either in part or altogether false. The investigations as to the facts had been mainly fragmentary and sporadic in their character, instituted from time to time by various Boards of Health, but without much outcome in the arrest and prosecution of the offenders. But this period of education had now gone by, and the time had come when the various States were about to pass laws upon adulteration. Some laws had been already enacted, and grave blunders had been committed. The experience in England had shown how difficult it was to secure wise and efficient legislation, and it was very important for chemists in America to avail

themselves of that experience, and to control and shape the laws now under consideration in the legislatures of the various States. Moreover, the duty of the public analyst required public training and accurate knowledge of certain topics not ordinarily studied by chemists. Finally the analysts could not properly perform their labours without the aid of suitably qualified inspectors, and as yet these two professions did not exist in the country and would have to be in a sense created.

Dr. Leeds, who had been commissioned by the State of New Jersey to investigate the facts concerning adulteration, as a basis for future State legislation, then gave a brief *resumé* of the results of his labours up to date. He had analysed a very large number of samples, and without claiming that the facts were universally true for the whole country, yet the examinations of so many articles of each kind, purchased at random from dealers in various parts of New Jersey and in the City of New York, might justly be regarded as representing a reasonably close approximation to the true facts in the case.

In regard to teas, three classes of adulterated samples had been found. The smallest class contained an amount of mineral matter in excess of that which should be present from facing materials alone, or from impurities which could properly be derived from the processes of preparation for the market. The largest class consisted of teas adulterated with exhausted leaves. Finally, in some samples foreign leaves were present in such numbers as to denote intentional adulteration. But the percentage of adulterated teas was much smaller than was anticipated (10 per cent), a majority of the teas being of inferior grade, their prices ranging from thirty to fifty cents per pound. Nearly all the coffees examined, both whole and ground, were pure; the adulterant in the other cases being chicory. The essences of coffee sometimes contained scarcely any coffee—one sample was composed almost entirely of chicory, caramel, and liquorice.

The manufacture of mixed sugars, containing both cane sugar and glucose, is now largely carried on in the United States, the product being sold under the name of "new process" sugar by the manufacturers. This fact had given rise to a popular belief that almost all varieties of sugar were more or less adulterated. Such was not found to be the case, most of the white sugars, purchased at random, being found pure; and of the brown sugars, which were the more adulterated, certain samples furnished by dealers as in their belief adulterated, were found to contain no more inverted sugar than might properly be present in a sugar of a low grade. A similar remark applies to the syrups. Even the lowest priced syrups were found, with few exceptions, to contain no more glucose than was to be expected in a non-adulterated article. No free sulphuric acid, or excess of lime, was present in any case.

The specimens of flour examined were uniformly pure, no other meal or alum being found in any instance. In bread, however, sufficient samples showing the employment of alum were obtained to demonstrate its occasional use by bakers. Cream of tartar was found to be extensively adulterated, the adulterants being sulphate of lime, acid phosphate of lime, and starch. The first-named substance was likewise present in some samples of bicarbonate of soda.

Some of the manufacturers of the baking powders now so extensively sold use only bicarbonate of soda, cream of tartar, and starch. Others employ either partly or altogether, in the place of the cream of tartar, alum or acid phosphate of lime, or a mixture of these two salts. Of the condiments and spices very few were pure, though in no instance was any injurious metallic adulterant detected.

Many of the samples of vinegar contained a much lower percentage of acetic acid than should have been present, but in no case were mineral acids present, and in only one instance a metallic substance—lead in traces. Some of the so-called white wine vinegars had all the characters of ordinary cider vinegar, decolourised by filtration through animal charcoal. None of the green pickles examined were free from copper—one pickle containing 15 milligrms. —although the pickles prepared by the use of brine, and those imported, with the Crosse and Blackwell label, were found unexceptionable. The employment of tin cans in the preservation of vegetables is reprehensible, both tin and lead being present in the canned tomatoes examined. The skimming and watering of milk was still very extensively practised in New York and New Jersey, although stringent laws had been passed for its repression.

Condensed milk varied remarkably in composition, the percentage of water ranging from 25·5 to 59 per cent, and of fat from 3 to 11 per cent.—*Journal of the American Chemical Society.*

IV. Additional Experiments on the Atomic Weight of Antimony.

In our previous paper on this subject, we gave our reasons for the opinion, since fully confirmed, that the bromide of antimony is the most suitable compound of this element as yet known for determining its atomic weight; and the results of fifteen analyses of five different preparations of the bromide were published, which gave for the atomic weight in question the mean value 120·00, with an extreme variation between 119·4 and 120·4 for all the fifteen analyses, and between 119·6 and 120·3 for the six determinations in which we placed most confidence. The antimonious bromide used in these determinations was purified first by fractional distillation, and secondly by crystallisation from a solution in sulphide of carbon. In the crystallised product thus obtained, the bromine was determined gravimetrically as bromide of silver in the usual way. Although it seemed at the time that the results were as accordant as the analytical process would yield under the unfavourable conditions, which the presence of a large amount of tartaric acid in the solution of the bromide of antimony necessarily involved; yet it was obvious that the agreement was far from that which was desirable in the determination of an atomic weight, and our chief confidence in the accuracy of the mean value—independently of its remarkable agreement with previous results—was based on the fact that the known sources of error tended to balance each other. Hence our conclusions were stated with great caution, and the hope was expressed that, after a thorough investigation of the subject, we might be able "to return to the problem with such definite knowledge of the relations involved as will enable us to obtain at once more sharp and decisive results then are now possible."

In our previous paper, we described a simple apparatus which we devised for subliming iodide of antimony; and in a note to the paper we stated that we were applying the same process to the preparation of bromide of antimony, and that it promised excellent results. Our expectations in this respect have been fully realised, and the product leaves nothing to be desired, either as regards the beauty or the constancy of the preparation. The fine acicular crystals are perfectly colourless, and have a most brilliant silky lustre. With ordinary precautions, they can be kept indefinitely without change, and it is easy therefore to determine the weight of the material analysed to the tenth of a milligramme.

The material used in the following determinations was first prepared as described in our previous paper. It was then repeatedly distilled from a small glass retort, rejecting at each distillation the first and the last portion. Lastly,

* Presented to the American Academy of Arts and Sciences, May 11, 1881.

it was twice sublimed in a slow current of absolutely dry carbonic dioxide. As it was only possible to sublime a few grammes at a time in the apparatus we used, and as the several procucts were not mixed, each of the portions analysed was the yield of a separate sublimation, and the agreement of the results is therefore in itself a proof of the constancy of the preparation. In the first set of analyses, the bromine was determined gravimetrically by precipitation with nitrate of silver, as before described. The bromide of antimony was first dissolved in a concentrated solution of tartaric adid, using about 5 grms. of the crystallised acid to 1 grm. of bromide, and the solution was then diluted with from 250 to 500 cubic-centimetres of water. To this solution was slowly added, under constant agitation, a solution of nitrate of silver in slight excess of the amount required for complete precipitation. The amount of crystallised nitrate of silver required was always carefully weighed out, allowing 1 decigramme in excess of theory for every litre of the solution of bromide of antimony made as above described. The nitrate of silver was then dissolved in a considerable volume of water, and the bromide of silver was precipitated from a cold solution, care being taken to prevent the formation of lumps which invariably result if the solutions are warm or concentrated, and which greatly interfere with the washing of the precipitate. The precipitate was washed by decantation 5 times, pouring on in each case a volume of lukewarm distilled water equal to that of the original solution, and after the precipitate had settled, drawing off the wash-water with the inverse filter (see *Proceedings of the American Academy of Arts and Sciences*, vol. xii., page 124.) Lastly, the precipitate was transferred to a porcelain crucible and dried at from 120° to 130°.

The bromide of silver weighed was always tested, sometimes by dissolving the material in strong aqua ammonia, and at other times by heating it to the melting point. Had there been the least occlusion of silver emetic, or any other possible product, there would have been an insoluble residue or a loss of weight; and, since the bromide of silver always gave a perfectly clear solution, and the loss of weight on melting never exceeded a few tenths of a milligramme, we were assured that our product was perfectly pure.

Of the five determinations whose results are given below, the first three were made under my direction by Mr. G. De N. Hough; the last two were made with my own hands.

ANALYSES OF ANTIMONIOUS BROMIDE.

Determination of Bromine.

Wt. of $SbBr_3$ taken in Grammes.	Wt. of AgBr obtained.	P.c. of Br. Br=80 Ag=108.	Difference from Mean.	Value of Sb.	Diff. from Mean.

Mean value		66·6679		119·996	
Theory Sb. 120 require		66·667			

The mean value of the percentage of bromine deduced from the fifteen analyses previously made (see *Proceedings of the American Academy of Arts and Sciences*, vol. xii., page 54) was 66·666, which differs only by an inappreciable quantity from the mean of the above results. At the same time the results are much sharper, the maximum difference from the mean value having been reduced to less than one-fifth of the previous amount, and to only 0·00025 of the quantity estimated, giving with certainty the atomic weight of antimony within one one-thousandth of its value. It must be remembered, moreover, that, although these last results were obtained with the same compound as before, the material was prepared in a wholly different way. The material first used was purified by repeated crystallisation from sulphide of carbon,—that last used by repeated fractional distillation and sublimation.

Hoping to reduce the limit of error to a still greater degree, we* were led to devise a volumetric method of testing the atomic weight of antimony, which, while it had all the advantages of the gravimetric method previously employed, is free from its sources of error. The method has also this great advantage, that it brings the question of the atomic weight of antimony down to a definite issue.

If the atomic weight of antimony were 122·00, it would require 1·7900 grms. of pure silver to precipitate the bromine from a solution of 2·0000 grms. of antimony bromide, while if the atomic weight of antimony were 120·00, it would require 1·8000 grms. of silver. Now it is easy to estimate volumetrically 1-100th of this difference with certainty. We therefore prepared with great care a button of *pure*† metallic silver, which we annealed, and rolled out to a thin ribbon. We then weighed out from 2 to 4 grms. of bromide of antimony, prepared by sublimation as described above, and dissolved this salt in an aqueous solution of tartaric acid, which we then transferred to a litre flask, and diluted to about 500 c.c. We next very accurately weighed out a quantity of silver, slightly less than that which calculation showed was required for complete precipitation. This silver was dissolved in nitric acid, and the solution having been evaporated to dryness over a water-bath, the silver salt was washed into the flask containing the bromide of antimony. As soon as the supernatant liquid had cleared, the small additional amount of a normal silver solution required to produce complete precipitation was run in from a burette, and measured with the usual precautions. We used no extraneous indicator, because it was important not to introduce any possibly new disturbing element into the experiment, and in the titration of bromine with silver, the normal and familiar phenomena, which mark the close of the process, furnish a very sharp indication. The details of one of the determinations were as follows:—

The weight of the bromide of antimony used amounted to 2·5032 grms. To precipitate the bromine from the solution of this material, 2·2404 grms. of silver would be required if Sb=122·00, and 2·2529 if Sb=120·00. We weighed out, with as much accuracy as if we were adjusting a weight, the smaller of these two quantities of metallic silver, and after dissolving the pure metal in pure nitric acid, evaporating the solution to dryness, and re-dissolving in water, we gradually added the whole of this silver solution to the litre flask containing the solution of bromide of antimony, in the manner described above. It was then found that 12·4 c.c. of a standard silver solution (1 grm. of silver to the litre) were required to complete the precipitation. It will be seen that the weights of the bromide of antimony and silver used could be thus determined with the most absolute precision, and we have the greatest confidence in these values to the

* Since publishing our "preliminary notice," our attention has been called to the fact that a similar process was used by Profesor J. W. Mallet of the University of Virginia in his investigation of the atomic weight of lithium, as it has since been used by him in his admirable work on the atomic weight of aluminum.

† A quantity of silver which had been reduced from chloride and bromide of silver, obtained as a product of previous analytical processes, was dissolved in nitric acid, and precipitated as chloride by hydrochloric acid. The precipitate was first boiled in *aqua regia*, and then thoroughly washed, after which the chloride was reduced by boiling with caustic soda and inverted sugar, and the precipitate, again washed, having been transferred to a porcelain crucible and dried, was heated to a low red heat in a muffle until the grains were sintered together. The sintered mass was melted on a block of prepared coke before a gas blowpipe, and while cooling was covered with a reducing flame in order to prevent the occlusion of oxygen gas. The metallic button was next rolled out into a ribbon between steel rollers; and, after the ribbon had been annealed in a muffle, the surface was etched with dilute nitric acid, and afterwards scoured with sand. The metal thus prepared was preserved under distilled water. The oxygen occluded by the metal thus prepared must have been, if any, exceedingly small in amount; but, even allowing the average quantity found by Dumas in metal which had been melted in the air under ordinary circumstances, we calculated that this amount would only affect the third decimal place in the atomic weight of antimony; and it seemed therefore unnecessary to take so inappreciable an effect into consideration. Moreover, the great purity of our material was subsequently made evident.

one-tenth of a milligrm. Moreover, it will be noticed that the volumetric method is only used to estimate the difference in the atomic weight which has been in question, and that, if the method were only accurate to the one-tenth of the quantity to be measured, it would give us the value of the atomic weight within two-tenths of a unit, while if, as we had reason to believe, the process was accurate within 1 per cent, it would fix the atomic weight within 2-100ths of a unit.

By the method just described, the following results were obtained. The letters *a* and *b* indicate different preparations:—

	Wt. of $SbBr_3$ taken.	Total Wt. of Ag used.	Per cent of Br. Ag=108 Br=80.	Corresponding value of Sb.
a 1.	2·5032	2·2528	66·6643	120·01
a 2.	2·0567	1·8509	66·6620	120·02
a 3.	2·6512	2·3860	66·6644	120·01
b 4.	3·3053	2·9749	66·6696	119·98
b 5.	2·7495	2·4745	66·6653	120·01
Mean value,			66·6651	120·01
Theory Sb. 120 requires			66·6666	
,, Sb. 122 ,,			66·2983	

The extreme variation from the mean in these determinations is less than one ten-thousandth of the quantity directly estimated, and corresponds to less than two ten-thousandths of the total value in the atomic weight of antimony. We have thus reached the extreme limit of accuracy with determinations on this scale. By using very much larger amounts of material, it is possible that we might still further diminish the limits of experimental error; but when we consider the further causes of error incident to handling so large an amount of material, it seems doubtful whether any advantage would really be gained. At all events such determinations would require an expenditure of labour and skill which is not demanded in the present condition of chemistry.

While making the first three volumetric determinations, it became obvious that the mode of experimenting was highly favourable to the accurate estimation of the amount of bromide of silver formed; and, were we to repeat this investigation we should adopt the same mode of precipitating bromine in all cases. The rotatory motion given to the liquid mass in the stoppered flask in order to hasten the "clearing up," after each fresh addition of the silver solution, tends very greatly to granulate and thoroughly wash the precipitate. In the last two determinations, therefore, we collected and weighed the bromide of silver formed, and this weight gave us a most important control over the whole work. In the previous work we assume that the ratio of Ag : Br = 108 : 80, and find that on this assumption Br : Sb = 80 : 120. But if we both determine the amount of silver required to precipitate a given weight of antimonious bromide, and also at the same time the weight of argentic bromide formed, it is obvious that we fix at once the ratio of three atomic weights (Ag : Br : Sb) independently of any assumption whatsoever. This, so far as we know, is a new feature in investigations of this kind, and evidently vastly diminishes the possibilities of error, and enhances the value of the result. We give in full the two determinaiions which were made in this way:—(See Table, next column).

Bringing, now, these results together, we have two additional gravimetric determinations of the atomic weight of antimony.

	Weight of $SbBr_3$ taken.	Wght. of AgBr determined.	Per cent Bromine Ag=108 Br=80.	Corresponding value of Sb.
b 6.	3·3053	5·1782	66·665	120·01
b 7.	2·7495	4·3076	66·667	120·00
Mean value			66·666	120·00

It is now obvious that these gravimetric determinations, taken in connection with the corresponding volumetric

results, give us the most conclusive evidence of the purity, both of the metallic silver used, and also of the bromine in the bromide of antimony, which is the basis of this atomic weight investigation. By comparing *b* 6 and *b* 7 with *b* 4 and *b* 5 respectively, we obtain the following data:—

Grms.		Grms.	
1. 2·9749	of silver gave	5·1782	bromide of silver.
2. 2·4745	,, ,,	4·3076	,, ,,

Hence it follows that, as shown by these experiments, the proportions of the silver to the bromine were respectively:—

1.	108·00	silver to	79·99	bromine
2.	108·00	,, ,,	80·01	,,
Mean value..	108·00	,, ,,	80·00	,,

This is the ratio of the atomic weight of silver to that of bromine, and corresponds to the second decimal place with the determinations of Stas as well as with those of Dumas.

We have now furnished as evidence of the atomic weight of antimony—

1. The mean of fifteen analyses of bromide of antimony purified by crystallisation from sulphide of carbon, with an extreme variation between 119·4 and 120·4 for all the fifteen analyses.

2. The mean of five analyses of bromide of antimony purified by distillation and sublimation, with an extreme variation between 119·90 and 120·08.

3. The mean of five volumetric analyses of bromide of antimony, also purified by distillation and sublimation, with an extreme variation between 119·98 and 120·02.

4. Two gravimetric determinations of the bromine in two of the portions of bromide of antimony used in the volumetric analyses, but still essentially distinct determinations, which gave almost identical results.

Bringing these several means together as of equal value, we have :—

		P.cnt. of Br.	Value of Sb.
1.	Mean of 15 determinations ..	66·666	120·00
2.	,, 5 ,, ..	66·668	119·99
3.	,, 5 ,, ..	66·665	120·01
4.	,, 2 ,, ..	66·666	120·00
	Final mean value	66·666+	120·00

Furthermore, we have shown by the last two determinations that the ratio of the atomic weight of the silver to that of the bromine used in our experiments was 108·00 to 80·00, and hence that the ratio of the atomic weights of bromine, silver, and antimony must be—

Ag : Br : Sb = 108·00 : 80·00 : 120·00,

with a probable error not exceeding 0·01 in any case. Of course our experiments only serve to fix the ratio between these three quantities, and any considerations which may lead chemists to change the value of one of the quantities must affect the other two in the same proportion. If with Stas we take Ag = 107·66, then Br = 79·75, and Sb = 119·63 ; and in this connection the fact should be recalled that the ratio of Ag to Br, according to Stas, is essentially identical with that given above, and the same as that found both by Dumas and by Marignac. Of all the ratios between the atomic weights, it is the one in regard to which there is the greatest certainty, and it is with this very well-established relation that we have connected the atomic weight of antimony.

Entirely in harmony with the above results are our experiments on the synthesis of sulphide of antimony, in which we found as a mean of thirteen experiments Sb = 119·94 when S = 32 ; and the same is equally true of our analyses of iodide of antimony, which gave as a mean of seven determinations Sb = 119·98 when I = 127·00. But although these results formed important stages in our investigation, they now add but little to the evidence of the far more accordant results since obtained. When compared with these later results they show, however, to what a great extent error may be eliminated by the repetitions of an imperfect process.

Lastly, the anomaly which the analysis of antimonious chloride first presented has been explained by finding, first, that the material employed contained a constant amount of oxychloride ; and, secondly, that the water used in washing the precipitate exerted a definite solvent action on the chloride of silver estimated.

Having thus solved the problem we undertook as far as is at present practicable, we must now take leave of the subject, regretting only that our investigation should have been the occasion of any controversy. In addition to the recognition we made in our previous paper, we would here express our obligations to Mr. G. De N. Hough and Mr. G. M. Hyams, who have greatly aided us in the experimental work during the latter part of this investigation.

(To be continued.)

Action of the Treatment of Cream with Oxygen upon the Quality of Butter.—Prof. L. B. Arnold.—The fatty matter of milk improves in aroma by a short action of the oxygen of pure air. A more prolonged action is hurtful. The butter from milk which has been excluded from oxygen does not keep as well as that from milk which has been exposed to the air.—*Biedermann's Centralblatt.*

PROCEEDINGS OF SOCIETIES.

PHYSICAL SOCIETY.

Saturday, November 12th, 1881.

Professor FULLER, Vice-President, in the Chair.

MR. W. D. NIVEN was elected a Member.

Mr. LEWIS WRIGHT then read a paper "*On some Spirals observed in Crystals, illustrating the relation of their Optic Axes.*" After remarking that the relation of the axes in uni-axial and bi-axial crystals had always been an interesting subject, he observed that if we took any uni-axial and a single axis of any bi-axial which had little or no axial dispersion, and polarised and analysed each circularly, we ultimately got similar phenomena. This is illustrated by calcite and a single axis of sugar, each giving when thus treated unbroken circular rings. From this it might be hastily inferred that a single axis of a bi-axial resembled in character the axis of a uni-axial ; but this was not the view of those who framed the theory of double refraction in crystals. Fresnel finally framed the conception of three elasticities in three rectangular directions. If all were equal there was no double refraction ; if only two were equal there was a single optic axis in the direction of the third ; and if all were unequal there were two optic axes. According to this theory the axis of the calcite did *not* resemble in character a single axis of the sugar or other bi-axial, but was a limiting case in which *both* such axes coincided. This was illustrated by the beautiful experiment of Professor Mitscherlich, applying heat to a crystal of selenite, and thereby altering the respective elasticities. The two axes gradually approached until they coincided and the crystal became uni-axial, after which, on heating the crystal still more, the axes re-opened in a direction at right angles to the former, thus proving Fresnel's theory. It was desirable to illustrate the point—that the axis of a uni-axial did retain, or still embraced within itself in some visible form, characteristics of the two axes thus brought into coincidence. Sir George Airey had discovered the double spiral in quartz. Uni-axial calcite showed a doule spiral, and bi-axial gave a single spiral. Mr. Wright repeated Professor Mitscherlich's experiment, on this additional basis of analysis, the spirals being first shown perpendicularly above each other. Gradually they approached until they resembled those of the calcite, and finally opened out again horizontally. All through there was a double spiral, and a single one could only be got by separating a single axis : the fluid would represent the axial properties of the quartz and the crystal the other properties, and the two ought to give similar spirals. In fact the fluid should replace the quartz successfully in all these experiments. By means of a column of oil of lemons 200 millimetres in length, and crystals of calcite, sugar, topaz, and nitre, Mr. Wright showed this to be the case. Finally, he demonstrated that the same phenomena held good through all the ordinary analogies with, or artificial substitutes for, natural crystals, the figures being produced with a circular chilled glass in parallel light, and also with an artificial uni-axial crystal made of crossed mica films, after Norremberg, and an artificial quartz made of superimposed mica films, after Reusch, in convergent light. All the figures were projected by the electric camera, to a size 8 feet in diameter. All Mr. Wright's experiments went to illustrate the truth of Fresnel's theory.

Mr. C. V. BOYS then read a paper "*On the Prevention of the Bursting of Water-pipes.*" Mr. Powell had proposed the use of pipes of elliptical or other round section, and Mr. Mangnall, of Manchester, had independently hit on the same idea. Such a pipe would become rounder in section when the water froze and expanded. A round pipe tends to become thinner at its weak parts on expanding under the pressure. With an elliptical pipe the force

required to alter the shape of its section is greater as the section is more circular, therefore the effect produced by a change of shape at any place makes that place stronger. A round pipe is in a state of unstable, and an elliptical pipe in a state of stable, equilibrium, and changes its form uniformly from end to end. Hence, if a portion only of such a pipe is exposed in the cold the whole is effective, and it will require a proportionally greater number of frosts to make the pipe round. Inspection would show if the pipes were becoming round, and then they could be squeezed back to their original shape. Mr. Boys had demonstrated these inferences by experiment with Mr. Powell. Messrs. Powell, Rigby, and Co., of Piccadilly, made these pipes.

Mr. J. Macfarlane Gray drew attention to some apparent discrepancies in the constants employed by Regnault in his work on the Physical Properties of Steam.

NOTICES OF BOOKS.

Description of the Chemical Laboratories at the Owens College, Manchester. By H. E. Roscoe, F.R.S. Third Edition. Manchester: J. E. Cornish.

From this summary it appears that there are in the College two large laboratories, each 70 ft. long, 30 broad, and 29 high. One of these is occupied by the first year's or qualitative students, and contains sixty working places. The second laboratory, for the advanced or quantitative students, contains ten blocks, of four working benches each. The ventilation arrangements are two-fold, general and special, both worked by means of the furnace chimney. The general ventilation is so successful that when a hundred students are at work in the two rooms, the air remains pure. The special ventilation relates to the evaporation niches and sulphuretted hydrogen closets. The large niches aspirate 100 cubic feet of air per minute, and the smaller ones 12 cubic feet per minute. The action is so good that no smell nor escape of vapours into the laboratory can take place, even when sulphuric acid is evaporated in quantity. The sulphuretted hydrogen closets vent into a horizontal flue, running underneath the floor, and thence passing into the chimney.

These two large laboratories are on the ground floor, which contains, in addition, a special room for organic analysis, two balance rooms, a room for gas analysis, a library, a lecture theatre for organic chemistry, Professor Schorlemmer's private room, and a store and reagent room. The first floor contains Professor Roscoe's private room, private balance room, and private laboratory.

The basment contains, in addition, a laboratory for medical and evening students, fitted with work-places for fifty; a special metallurgical laboratory provided with furnaces, a store room, class room, lavatory and cloak room, a spectroscopic room, photographic room, a dark room for photometry, three preparation rooms, and a boiler house. There is also a lecture theatre, capable of accommodating 380 persons with a small laboratory for the lecturer's use immediately behind the platform, and a store room for diagrams at the opposite end.

The Owens College, in addition to eminent and zealous professors, now possesses appliances and facilities for research admirably arranged and second to few, if any, in Europe. We may reasonably hope that the results will be in proportion to the opportunities afforded.

A Treatise on Chemistry. By H. E. Roscoe, F.R.S., and C. Schorlemmer, F.R.S., Professors of Chemistry in the Victoria University, Owens College, Manchester. Vol. III. The Chemistry of the Hydrocarbons and their Derivatives. London: Macmillan and Co.

With this volume Professors Roscoe and Schorlemmer enter upon the organic portion of their great work in such a manner that this division will equal, if not exceed, the inorganic portion in value. The volume begins very appropriately with a history of organic chemistry from the earliest traditions of antiquity down to the present day. The authors trace the successive rise and fall of theories and the various definitions given of organic compounds, adopting finally the one given on the title-page. They call attention to the fact that Lavoisier did not, as is sometimes asserted, recognise organic chemistry as a special branch of the science or define it as the chemistry of compound radicles. On the contrary, he arranged all acids together, dividing them into the three classes of mineral, vegetable, and animal. Yet on the opposite page we read that—"Agreeing with the views of Lavoisier, Berzelius explained the difference between these two great divisions by stating that whilst in organic nature every oxidised compound contains a *simple radical*, organic bodies consist of oxides of *compound radicals*."

The section on the ultimate analysis of organic bodies is very elaborate. The authors describe and illustrate the determination of hydrogen and carbon by the methods of Lavoiser, Berthollet, Gay-Lussac, Berzelius, and Liebig with its modifications; the determination of nitrogen according to Will and Varrentrapp; the "relative" methods of Liebig and of Bunsen; the absolute method of Dumas and of Simpson. Processes for the determination of other elements are then described, as well as processes for ascertaining vapour-densities, including that used by Victor Meyer in his recent investigations. After explaining the determination of molecular formulæ, the authors pass to the main or descriptive portion of their work, beginning with the hydrocarbons of the paraffin series; the compounds of the monad alcohol radicles; the alcohols and their derivatives; synthesis of the primary alcohols and the fatty acids; the secondary and tertiary alcohols; the methyl, formyl, and ethyl groups, and compounds containing higher numbers of carbon atoms from three to twenty-four.

As in the organic portion of the work, the illustrations, both of laboratory apparatus and of plant or appliances on a larger scale are numerous, admirably executed, and well selected. Footnotes in abundance refer the reader to the original memoirs, &c., for fuller information, so that the work in some measure serves as a general key to the literature of organic chemistry. The index is admirable, extending over twenty-five pages, and being at once full and accurate. Thr whole work, if completed on its present scale, will, as a systematic treatise on modern chemistry, have no superior in any language.

CHEMICAL NOTICES FROM FOREIGN SOURCES.

Note.—All degrees of temperature are Centigrade, unless otherwise expressed.

Comptes Rendus Hebdomadaires des Séances, de l'Académie des Sciences. No. 16, October 17, 1881.

An Experimental Peculiarity Relative to the Equipotential Law followed by Nobili's Rings.—Ad. Guébhard.—The author refers to the fact that on placing above a metallic plate, forming the bottom of an electrolytic vessel, points of any number attached to the conductors of a battery of strong tension, the coloured rings which take their rise always correspond in a striking manner to the equipotential systems which take their rise on applying directly, upon an isolated plate, poles of signs contrary to the former. Hence a natural assimilation of the phenomenon of dynamic efflux to a simple phenomenon of static induction, and the necessity, theoretically, of considering the liquid as an almost absolute insulator, in which the passage or efflux of the elec-

tricity can take place only by following the minimum traject from the point to the plate. This latter fact, little in accord with the original figures of Nobili and with current ideas concerning electrolysis, has been verified experimentally by the author, who has studied, under strongly concentrated illumination, the liquid currents from one electrode to the other, rendered visible either by the transportation of material particles, or by the disengagements of gases which accompany them. These latter are produced in great abundance in the double tartrate of antimonyl and potassium, between the positive plate and the negative electrode. Myriads of microscopic bubbles move in dense files along the plate till in close vicinity to the electrode, and then rise suddenly with an abrupt curve, following its surface to the upper surface of the liquid. What can these trajectories be but lines of force of the electric efflux? Kirchhoff has shown long ago that the quantity of electricity which traverses each element of a conductor of finite dimensions must be proportional to the potential and not to the elementary density of the electricity. A direct application of the law of Faraday leads, then, to the law just pointed out.

Crystalline Copper Sulphide (Cupreine) formed from Antique Medals at the Thermal Springs of Flines-les-Roches, Department of the North.—M. Daubrée.—The water in question forms a pool of about 300 metres in diameter. In ancient times this water was an object of worship, and numerous bronze coins and statuettes, both Gaulish and Roman, appear to have been thrown into it as offerings. Upon these there has been formed by the action of the water, an incrustation of that kind of chalcosine described by Breithaupt as cupreine. The water contains neither free sulphur nor sulphides, but merely sulphates, which are reduced by the organic matter.

Currents produced by Atmospheric Electricity, and the Telluric Currents.—J. Landerer.—The author observed since June, 1876, the currents produced in a telegraphic wire stretched between two houses to the length of 288 metres. Some of these currents are produced by the condensation of watery vapour. They may be recognised by means of a telephone, but scarcely, or not at all, by a sensitive galvanometer. The sound they produce in the telephone is like the creaking of tin. Other currents are produced by the discharge, more or less remote, of the electricity of the clouds; the sound is a continued crackling. On the approach of tempests the sound resembles that produced by a jet of steam. So called sheet lightning produces a very distinct effect. These currents have a well-marked action upon the galvanometer. There are, lastly, currents produced by the wind; they are without action upon the telephone, but they act strongly upon the galvanometer. Their intensity is a function of the strength of the wind. There are intervals of repose in which none of these currents are manifested. Telluric currents act both upon the galvanometer and the telephone. They are distinguished from atmospheric currents by the regularity and continuity of their action, during long intervals.

Action of Sulphur upon Alkaline Sulphides in very Dilute Solutions.—M. Filhol.—Sulphur acting upon sodium mono-sulphide, even in very dilute solutions, gives rise to the formation of a poly-sulphide, without the production of a notable quantity of poly-sulphide. It is, however, more rational to admit that the mono-sulphide, which was decomposed under the influence of water into hydrosulphate and hydrate, is reconstituted in presence of sulphur, and gives rise to the production of a poly-sulphide.

A New Base of the Cinchonaceæ.—M. Arnaud.—The base in question, which the author names cinchonamine, differs from hydro-cinchonine, both chemically and physically. It is represented by the formula $C_{19}H_{24}N_2O$.

A New Series of Bases derived from Morphine.—E. Grimaux.—There is a general reaction which renders it possible to obtain the homologues of codeine, containing new alcoholic groups, not in the phenolic oxyhydrile of morphia, but in the hydrocarbonated radical of the morphia itself. Metho-codeine is thus an isomer of codethyline.

Dissociation of Ammonium Carbamate.—R. Engel and R. Moitessier.—The authors have shown that chloral hydrate, butyl-chloral hydrate, and chloral alcoholate, do not exist in the state of vapour, their supposed vapour being merely a mixture of the vapours of their components. They have now subjected ammonium carbamate to an examination from the same point of view.

Justus Liebig's Annalen der Chemie,
Band 208, Hefts 1 and 2.

Benzarsenic Acids and their Derivatives.—W. La Coste.—We have here an account of benzarsenic acid, para-benzarsenic acid, arseno-benzoic acid, the potassium calcium, silver benzarsenates, benzarsenic methyl-ether, benzarsen-iodide, benzarsenious acid and its calcium and silver salts, benzarsenious chloride, dibenzarsenic acid and its derivatives, para-ditolyl-arsenious chloride, para-tolyl-arsenoxide, para-ditolyl-arsenic acid, silver ditolyl-arsenate, para-dibenzarsenic acid, methyl-dibenzarsenate, dibenzarseniodide, dibenzarsenious acid and its calcium salt, tribenzarsenic acid, tri-tolyl-arsen-dichloride, potassium and calcium tri-benzarsenates, tri-benzarsenious acid with its sodium and silver salts. The author's experiments on the oxidation of dimethyl-arsenic and ethyl-arsenic acid were only partially successful.

Researches on the Non-Saturated Acids (Fifth Part).—Rudolph Fittig.—These researches comprise a memoir on pyroterebic acid, by Carl Geisler; further communications on the lacton of isocapronic acid, by Jul. Bredt; on the lacton of normal capronic acid, by R. Fittig and E. Hjelt; on the terpenylic and teracrylic acids, and on hepto-lacton, by R. Fittig and O. Krafft; on allyl-acetic acid and valero-lacton, by A. Messerschmidt; on a simple preparation of and on the constitution of valero-lacton, by L. Wolff; on the constitution of the lactons, and on their formation from the addition-products of the non-saturated acids, by R. Fittig.

The Condensations of the Pyruvic Acids.—C. Böttinger.—The author examines the behaviour of pyruvic acid when heated with water and a quantity of barium hydrate sufficient to neutralise the acid; its behaviour when boiled with water and an excess of the hydrate; and lastly, its behaviour on treatment with ammonia.

Sodium Hyposulphite (Hydrosulphite of Schützenberger).—Aug. Bernthsen.—The author contests experimentally the formula proposed by Schützenberger, and assigns to it the composition $NaSO_2$.

Separation and Determination of Arsenic.—Emil Fischer.—The separation of arsenic from a given mixture with other metals by distillation with ferrous chloride, and its subsequent determination with solution of iodine, offers so great advantages that scarcely any of the older methods will be used when the determination of this element alone is required. If the substance in question is already dissolved, the whole operation may be completed in four hours. The process is especially adapted for chemico-legal cases.

Alkaloids of Belladonna Root and of Datura Seed.—Ernst Schmidt.—An account of very elaborate researches on atropine, daturine, and hyoscyamine.

Certain Derivatives of Phthalic Acid.—O. Miller.—Not susceptible of useful abstraction.

Band 208, Heft 3.

Communications from the University Laboratory of Halle.—These consist of a memoir on methyl-crotonic acid and angelicic acid, and a paper on the double calcium salt of methyl-crotonic acid and of isobutyl-formic acid,

both by Ernst Schmidt; and on a paper on the substituted glycolic acids, by Dr. M. Senff.

Anhydro-Compounds.—H. Hübner.—This is the first portion of a treatise extending over more than fifty pages, and incapable of useful abstraction.

Communications from the Chemical Laboratory of the University of Moscow.—These communications comprise a memoir on tetrylen-dicarbonic acid (homoitaconic acid), by W. Markownikoff and A. Krestownikoff; and an account of dichlor-hydrine and its oxidation-products, by W. Markownikoff.

Lycopodine, the First Alkaloid of the Vascular Cryptogams.—Karl Bœdeker.—The alkaloid in question is obtained from *Lycopodium complanatum*, known as being richer in alumina than any other plant. Its composition is expressed by the formula $C_{32}H_{52}N_2O_3$. It melts at 114° to 115°, dissolves easily in alcohol, chloroform, benzol, amylic alcohol, ether, and water. Its taste is bitter. The very dilute aqueous solution is rendered turbid, and coloured brownish red by iodine water.

Gazzetta Chimica Italiana.
Anno 10, Fasc. 5 and 6.

Hippurates of Isobutyl and Normal Butyl.—G. Campani and D. Bizzarri.—The hippurate of isobutyl forms minute prismatic crystals with a rhombic base, transparent, iridescent when examined by polarised light, of a bitter persistent flavour, insoluble in water, soluble in alcohol, ether, benzol, and chloroform, from which liquids it is easily deposited on evaporation in prismatic crystals. It melts between 45° and 46° to a perfectly homogeneous liquid. The hippurate of normal butyl crystallises much less readily than its isomer. It melts between 40° and 41°.

Composition of the Ash of the Stem, Leaves, and Fruit of the Orange, the Mandarin Orange (Citrus Deliciosa), and Citrus Bigaradia. — Dr. Leonardo Ricciardi.—Not capable of useful abstraction.

A New Cumo-phenol.—M. Fileti.—In this preliminary communication the author states that he has obtained the new compound by the action of nitrous acid upon the cumidine obtained from amido-cuminic acid.

Preparation of Camphoric Acid and of Camphoric Anhydride.—Pietro Maissen.—The author takes as his raw material, residues from the preparation of borneol by Baubigny's method, consisting of a mixture of borneol and of unaltered camphor.

Galvanic Polarisation produced by Metallic Deposits.—Prof. D. Macaluso.—This paper does not admit of useful abridgment.

Bulletin de la Société Chimique de Paris,
Tome 36, No. 3.

Alcoholate of Chloral.—M. Berthelot.—The author has undertaken the thermic study of this compound, and especially the measurement of the heat liberated by the union of alcohol and chloral, giving rise to this compound in the solid, liquid, and gaseous states.

The Evaporation of Glycerin.—G. Couttolenc.—Aqueous glycerin loses its water, after having been heated for five hours in the water-bath to about 90°. The evaporation of the glycerin then continues very regularly at the rate of about 0·00317 grm. per hour and per square centimetre of surface.

Acrolein Bromide (Aldehyd Dibromo-propionic). MM. Grimaux and Adam.—Not suitable for useful abstraction.

Determination of the Dry Extract Left in Wine.—L. de Saint-Martin.—M. Gautier has recently proposed a new method, which consists in evaporating 5 c.c. of the wine in question *in vacuo*, at first over sulphuric acid, and ultimately over phosphoric anhydride. The author, having compared this process with the old method, concludes that the inaccuracy of the latter has been much exaggerated, and that under certain conditions it gives good results. The process of evaporation *in vacuo* is also not free from objections. He proposes to determine the dry extract of wine by evaporating it in a current of highly rarefied dry air at a temperature not exceeding 50°. He finds this method very useful for determining the solid matter in samples of milk, urine, &c.

Formation of a Carbo-glucosic Acid. —P. Schützenberger.—The author heats to 100° for some hours a solution of inverted sugar along with hydrocyanic acid in a closed vessel. The liquid is decolourised by filtration over animal charcoal, and after expulsion of the excess of hydrocyanic acid, it is found to have lost its rotatory power and all action upon cupro-potassic liquid. It contains the ammoniacal salt of a carbo-glucosic acid, $C_7H_{13}O_8$.

Russian Chemical Society.— Session of Jan. 8/20, 1881.—M. A. Krakan.

M. Gustavson described the hydrocarbons yielded at common temperatures by the petroleum of America and of the Caucasus under the influence of aluminium bromide.

MM. Beilstein and Kourbatoff observe that the hydrocarbons C_n H_{2n}, contained in Caucasian petroleum, do not resist the action of nitric acid, bromine, and sulphuric acid. The saturated hydrocarbons of American petroleum are slowly oxidised by nitric acid.

M. Schirokoff gave a description of the characteristic properties of diethyl- and dipropyl-lactic acids and of their salts.

M. Saytzeff gave the result of new researches on the calcium and barium salts of the diethyl- and methyl-propyl-lactic acids.

M. Przybytek, on studying the oxidation of glycerin by nitric acid, has not hitherto observed the formation of any body belonging to the glucose series, which, however, he considers as probable.

M. Louguinine described his researches on the combination-heats of some bodies of the fatty series.

Moniteur Scientifique, Quesneville.
August, 1881.

Anthracic Vaccination.—The recent successful experiments of M. Pasteur and his principle of the attenuation of the contagious virus were the subject of a warm debate at the session of the Academy of Medicine, on June 24th.

The Ptomaines.—P. Brouardel and E. Bouty.—The ptomaines may be distinguished from the natural alkaloids by their power of instantly reducing potassium ferricyanide and silver bromide. It appears that in certain diseases, especially of the septic class, alkaloids resembling the ptomaines may be produced during life.

Colouring-matters.—Dr. W. Weyl.—A list of German patents relating to colouring-matters.

MEETINGS FOR THE WEEK.

MONDAY, Nov. 21st.—Medical, 8.30.
TUESDAY, 22nd.—Institute of Civil Engineers, 8.
—— Royal Medical and Chirurgical, 8.30.
WEDNESDAY, 23rd.—Society of Arts, 8.
THURSDAY, 24th.—Royal, 4.30.
—— Philosophical Club, 6.30.
FRIDAY, 25th.—Quekett Microscopical Club.
SATURDAY, 26th.—Physical, 3.

SILICATE OF SODA, Solid and in Solutions of Various Degrees of Concentration: the finest quality obtainable, and especially adapted for the use of Soap Makers and other Consumers.—JOSEPH CROSFIELD and SONS, Soap Makers, &c., Warrington.
London Agent—H. B. CLARKE Great Tower Street, E.C.

IRISH HILL BAUXITE (Alum Clay).

THE IRISH HILL MINING CO. are now, and always have been, the LARGEST PRODUCERS OF THIS CLAY, of Superior Quality, and supply the Manufacturers of Alum, Sulphate of Alumina, and Alum-Cake, of the United Kingdom, America, and the Continent, almost exclusively.

ANALYSIS BY JOHN PATTINSON, ESQ.

Supplies over 90 % of the Bauxite (Alum Clay) used.

	Dried at 212° F.		
	Gertrude (extra qual.)	1st Quality.	2nd Quality.
Alumina	59·00	53·83	52·00
Peroxide of Iron	0·47	1·57	4·57
Silica	18·00	8·67	12·00
Titanic Acid		5·80	6·20
Lime, Magnesia, Potash, Soda, and Sulphuric Acid	0·23	0·83	1·14
Combined Water	22·30	29·27	24·00
	100·00	99·97	99·91

Supplies over 90 % of the Bauxite (Alum Clay) used.

Our MINES, DRYING KILNS, and GRINDING MILLS are situated very close to the Shipping Ports of BELFAST and LARNE, and adjacent to Railways running alongside both Steamers and Sailing Vessels at both Ports, from either of which shipping is abundant and cheap, therefore we can guarantee Regular Delivery as Buyers require it, and are prepared to quote prices f.o.b. c.i.f., or delivered at any Port, in Bulk or Bags, Lump or Ground.

ON THE ACTION OF THE OXIDES OF NITROGEN ON GLASS AT A HIGH TEMPERATURE.

By THOS. M. MORGAN.

Several attempts were made to determine the nitrogen in organic nitro-derivatives by heating the substance in sealed tubes of hard glass containing oxygen, and in presence also of a little mercury to effect the reduction of any oxides of nitrogen which might be formed, but in all cases the nitrogen obtained was considerably less than the quantity theoretically present in the substance analysed. The source of this deficiency was eventually traced to the action which the oxides of nitrogen exerted on the alkali of the glass, and also on the mercury. For when some of the tubes which had been subjected to a temperature not above dull redness were washed with a little water, the washings could always be shown to contain a nitrate and a soluble salt of mercury; others, the temperature of which had been higher, contained nitrates and nitrites, but no soluble mercury salt.

For the purpose of showing more conclusively that the glass was thus attacked, and in order also to investigate the extent of the action, the following experiment was performed. A tube of hard glass, 50 c.c. capacity, was cleaned until the evaporated washings left no appreciable residue. A quantity of oxygen was next introduced, and then so much nitric oxide that the tube was filled with red fumes; after which it was heated to dull redness for two hours. When cold it was still full of red fumes, and when these were withdrawn it was washed as before, and the evaporated washings left a residue of 0·0038 of a grm., consisting of nitrates and nitrites. The same experiment was repeated three times on the same tube, the second residue was 0·0044 of a grm., and the third 0·0022. Another tube gave 0·0048.

As might be expected, this action is much more energetic at a high than at a low temperature, and it appears to be very slight until the heat approaches redness. In the analysis of such nitrogenous compounds as have the nitrogen in combination with oxygen, a certain deficiency of nitrogen, varying with the temperature employed, may therefore be expected.

Victoria College, Jersey.

NOTE ON THE REVERSAL OF THE SPECTRUM OF CYANOGEN.*

By G. D. LIVEING, M.A., F.R.S., Professor of Chemistry, and J. DEWAR, M.A., F.R.S., Jacksonian Professor, University of Cambridge.

In the course of many observations on the reversal of lines of metallic spectra, we have frequently noticed dark shaded bands which appeared to be the reversals of bands ascribed to the oxides or chlorides of sundry metals; more particularly we have seen them when experimenting with compounds of the alkaline earths, and we have repeatedly obtained a reversal of the green magnesium-hydrogen series; but, until recently, we have never seen any reversal of the shaded bands of the spectrum of cyanogen, though our attention has been constantly directed to this spectrum. Quite lately, however, we have obtained photographs which show the reversal of the violet and ultra-violet bands of this spectrum; and the fact is perhaps of sufficient interest, especially in connexion with the question of the occurrence of these bands amongst the Fraunhofer lines, to warrant the publication of this note. We have not yet succeeded in determining precisely the conditions under which the reversal can be produced at will. The most complete reversals of these bands were obtained by the use of the arc of a Siemens' machine, in a crucible of magnesia, fed with a considerable quantity of cyanide of titanium. The photographs in this case show a very complete reversal of the five bands near L, and of the two strong bands near N, and a less complete reversal of the six bands, beginning at about wave-length 4215. No other metallic cyanides have given, when introduced into the crucible, any such reversal; nor does a stream of cyanogen, led in through a perforated carbon, produce the effect. Various other nitrogenous compounds have been tried, but the only one which has given us anything like the effect of the titanic cyanide is borate of ammonia. Some photographs taken immediately after the introduction of borate of ammonia show distinctly the reversal of the group of bands near L. In one case when metallic magnesium had been put into the crucible, the photograph shows a reversal of only that part of the series which is nearest to the magnesium group, indicating that the reversal is due to the bright background supplied by the expanded magnesium lines. There can be little doubt that the greater stability of titanic cyanide and boron nitride than of other nitrogenous compounds, has some influence upon the result; and the difficulty in producing the reversal at will is in securing an absorbent stratum of sufficiently high temperature and at the same time a sufficiently luminous background. The circumstances which secure the former condition almost always produce in the arc a still more intense radiation of just those rays which are absorbed, without that expansion of the lines which shows out the absorption in the case of so many metallic spectra. The photographs are, however, conclusive evidence that it is possible to secure both conditions.

* Read before the Royal Society, November 17, 1881.

ON MANGANESE NODULES AND THEIR OCCURRENCE ON THE SEA-BOTTOM.*

By J. Y. BUCHANAN.

The specimens exhibited consist of two nodules from the South Pacific and of several from Loch Fyne in Scotland, a number of manganiferous worm tubes, and two samples of the mud in which these tubes and nodules are found in Loch Fyne. I have, besides, some very curious specimens of cobalt nodules from New Caledonia, which I owe to the kindness of my friend Prof. Liversidge, of the University of Sydney. These have recently come into my hands only within the last few days, and I exhibit them as curiosities which may have an interest for some of the members present.

My method of dredging for mud consists in anchoring the vessel by a dredge in the form of a Trotman's anchor, which carries a frame instead of a bar, connecting the flukes. To this frame is laced a bag, which receives the mud which would otherwise drop off the anchor on heaving up. This method has proved successful in two ways. First, by keeping the vessel stationary, while the anchor is down, and so admitting of temperature observations being made, and water samples being collected without having to resort to troublesome manœuvres, and second, by bringing up a large specimen of the mud taken, not from the soft surface layer, as is the case with the flat dredge, but from the underlying and stiffer material.

My first and best haul of manganese nodules, however, was brought up on an ordinary kedge anchor and adhering

* Read before the British Association, York Meeting, Section B.

to its flukes. A portion of this mud is exhibited. It is from the deepest part of Loch Fyne, between Tarbert and Skate Island. It was described in *Nature* of Oct. 10, 1878. I have never succeeded in getting mud so rich in nodules again. Part of it when sifted was found to consist of 30 per cent manganese nodules, 7·5 per cent shells, and 62·5 per cent of sandy clay. I doubt very much if even the richest bottom in the Pacific contains a like proportion. The other two samples of nodule bearing mud are from as nearly as possible the same locality, but, though they contain plenty of nodules, these nodules are of a smaller average size, and are present in much smaller proportion to the rest of the mud. Of the nodules collected on the first occasion in 1878, the average weight was 1·7 grms.; of those collected last July, the average weight, after eliminating all that passed through a sieve of four meshes to the inch, was only 0·42 grm., and the proportion of nodules to mud would certainly not be more than 5 per cent. The whole of the mud which came up on this occasion was sifted, with the exception of a small sample, dried as it was; the nodules were then sorted by sieves of different degrees of fineness. The bulk of them were retained by a ¼-inch mesh. The nodules so retained weighed 307 grms., and numbered 726, and it is remarkable that besides these nodules there was nothing on the sieve but a few fragments of shell and *two pebbles*. This affords very strong evidence that the nodules are formed *in situ*, and cannot have been washed into their present position, as in that case they would certainly have been accompanied by pebbles.

Hitherto the deep portion of Loch Fyne above alluded to is the only locality in Scottish waters where I have found the oxide of manganese occurring as nodules. It is, however, widely distributed as incrusting shell and as worm tubes, notably in the channel between Garvelloch Island and the Island of Scarba, and in Loch Sumart. Similarly, during the cruise of the *Challenger*, besides the many localities where the nodules abounded, it was constantly found encrusting shells in calcareous bottoms which were devoid of nodules.

The Loch Fyne nodules resemble the oceanic ones in nearly every particular. They are comparatively soft when first brought up, and become harder when exposed to the air. Heated in the closed tube they give off water charged with ammonia and empyreumatic products. When treated with hydrochloric acid the soluble constituents are removed, and what remains behind includes the insoluble constituents of the surrounding mud. Many of the Loch Fyne nodules have soft kernels, which are richer in oxide of manganese than the rinds.

A considerable number of determinations have been made both of the available oxygen and of the manganese, and if the manganese found be united to the whole of the available oxygen the resulting formula varies between $MnO_{1·5}$ and $MnO_{1·6}$. Taking the soft kernel alone and separated from the sandy rind, the formula is $MnO_{1·75}$. The rind alone had the formula $MnO_{1·5}$. In some oceanic nodules which were examined the formula varied from $MnO_{1·90}$ to $MnO_{1·95}$.

Some of the mud which contained the Loch Fyne nodules was examined. It contained 0·71 per cent of MnO and a hardly-distinguishable trace of extra oxygen.

If we express the available oxygen in terms of its equivalent MnO_2, we have in oceanic nodules from 22 to 32 per cent, in Loch Fyne ones from 13 to 22, and in the kernel treated separately 33 per cent of MnO_2.

The insoluble residue varies in oceanic nodules from 16 to 30 per cent, and in the Loch Fyne ones from 28 to 33 per cent, both containing from 83 to 88 per cent of silica.

Oceanic nodules appear to contain more nickel and cobalt than the Loch Fyne ones, while the latter contain distinct traces of copper, which does not appear to be so common in the oceanic ones.

With regard to the method of formation of these nodules, and the deposition of higher oxides, not only of manganese, but of iron, on the sea-bottom, it is perhaps unwise at the present moment to speak positively, but I think there is enough known to enable us to indicate a probable process of production.

All the nodules without exception contain residues of organic matter; where the oxide of manganese is not aggregated into nodules it is found encrusting animal remains, as shells, worm-tubes, &c. Whether in the form of nodules or incrustations the black matter contains all the recognisable sand and other matter of the surrounding mud; moreover they are certainly formed *in situ*, and not brought from a distance. The mud in Loch Fyne at any rate contains manganese in the form of protoxide, and no doubt as silicates; it also contains oxides of iron, which are present in all manganese nodules and incrustations: indeed in the same dredgeful we can pick out all gradations of nodules from these which contain almost exclusively MnO_2 with only traces of Fe_2O_3 to those which contain Fe_2O_3 without any MnO_2.

The formation of the sesquioxide of iron nodules has gone on under my own eyes. In July, 1879, I dredged from the bottom of the Sound of Jura, in 70 to 80 fathoms, a large mass of very stiff blue clay, as stiff as the best brick-making clay. Throughout the mass there were disseminated patches and pockets of blackish blue matter, which proved to be sulphide of iron, hydrochloric acid liberating sulphuretted hydrogen in abundance. This was dried in the usual way in plates on the cylinder covers of the engine, and when dry not a trace of sulphide was to be found, every black patch being now represented by a reddish brown one, even in the centre of large and compact masses. Now, what has here taken place in a very short time under the combined action of air, moisture, and heat takes place as surely, but more slowly, in the surface layer of the mud at the bottom; and in point of fact, not only in our shallow seas, but even in the deepest water of the ocean, we find the surface layer of the mud almost invariably of a different colour from the underlying mass, the top being red, while below the mud is grey. I believe, then, that for the formation of the nodules we have to look to the organic world as a necessary, though indirect, assistant. The decomposition of animal matter in presence of the sulphates of the sea-water reduce these to sulphides, which in their turn react on the iron and manganese minerals (principally silicates) in the mud forming sulphides of these metals. As the organic matter gets exhausted these sulphides are oxidised to oxides by the oxygen of the water, forming concretions or incrustations of the ochreous oxides, which naturally also enclose the other and unaltered constituents of the mud.

In conclusion, I cannot help thinking that the shell-producing animals of the sea obtain the lime from the sea-water in this way, the lime being assimilated from the dissolved sulphates in the form of sulphide in the interior of the animal, and transformed into carbonate on the outside.

LONDON WATER SUPPLY.

REPORT ON THE COMPOSITION AND QUALITY OF DAILY SAMPLES OF THE WATER SUPPLIED TO LONDON, FOR THE MONTH ENDING OCTOBER 31ST, 1881.

By WILLIAM CROOKES, F.R.S.

WILLIAM ODLING, M.B., F.R.S., F.R.C.P., Professor of Chemistry at the University of Oxford;

and C. MEYMOTT TIDY, M.B., F.C.S., Professor of Chemistry and of Forensic Medicine at the London Hospital; Medical Officer of Health for Islington.

To the RIGHT HONOURABLE THE PRESIDENT OF THE LOCAL GOVERNMENT BOARD.

November 5th, 1881.

SIR,—We lay before you, in the following tables, the results of our analyses of the 182 samples of water, collected by us during the month of October, on the days

and at the times indicated, from the mains of the seven London water companies taking their supply from the Thames and the Lea.

Of these 182 samples, three were noted as "very slightly turbid." The remaining 179 samples were bright, clear, and efficiently filtered.

In Table I. we have recorded the analyses in detail of samples, one taken daily from October 1st to October 31st inclusive. The purity of the water in respect of organic matter has been determined by the Oxygen and the Combustion processes, and the results of our analyses by these methods are stated in columns XIV. to XVIII.

We have recorded in Table II. the tint of the several samples of water as determined by the colour-meter described in a previous report.

Of the 26 samples supplied by the New River Company, the whole were found to be well filtered, clear, and bright.

Of the 26 samples from the mains of the East London Company, the whole were found to be well filtered, clear, and bright,

Of the 26 samples from the mains of the Chelsea Water Company, the whole were found to be well filtered, clear, and bright.

Of the 26 samples from the mains of the West Middlesex Company, the whole were found to be well filtered, clear, and bright.

Of the 26 samples from the mains of the Lambeth Water Company, the whole, excepting two which were recorded as "very slightly turbid," were found to be well filtered, clear, and bright.

Of the 26 samples from the mains of the Grand Junction Company, the whole, excepting one which was "very slightly turbid," were found to be well filtered, clear, and bright.

Of the 26 samples from the mains of the Southwark and Vauxhall Company, the whole were found to be well filtered, clear, and bright.

In Table III. we have recorded the oxygen required to oxidise the organic matter, and the quantities of free oxygen present in the whole of the samples collected.

As regards general appearance, the waters during the past month were clear, and afforded evidence of efficient filtration. Chemically, they were pure, and showed a freedom from all matters, mineral or organic, in any degree harmful. Dietetically they were of good quality, and perfectly wholesome for use as drinking waters.

We have the honour to remain, Sir,

Your obedient Servants,

William Crookes,
William Odling,
C. Meymott Tidy.

CONTRIBUTIONS FROM THE CHEMICAL LABORATORY OF HARVARD COLLEGE.*

By JOSIAH PARSONS COOKE, Director.

(Continued from p. 248.)

V. The Boiling Point of Iodide of Antimony, and a New Form of Air Thermometer.

In continuation of our investigations on the Haloid Compounds of Antimony, the boiling-point of antimonious iodide has been determined by Mr. W. Z. Bennett, at the time a student in this laboratory. The observations were made with Regnault's air thermometer, but it was found possible to simplify very greatly the details of the process without seriously impairing the accuracy of the result. For temperatures above the range of a mercury thermometer's measurements, accurate to one degree centigrade, are all that the uncertain conditions of most problems permit, and all, therefore, that the circumstances demand. As used by Regnault, the air thermometer is capable of measuring such temperatures accurately to the one-tenth of a degree, and by multiplying observations possibly to the one-hundredth of a degree. In his admirable investigation of the boiling-point of sulphur at different temperatures, the observations of temperature are undoubtedly accurate to this extent; but Regnault's own discussion of these observations plainly indicates that there must have been unknown or accidental causes influencing his experiments, which render the results uncertain to at least one degree; and the boiling-point of sulphur is still in doubt to this extent. It should be added, however that there are only a very few boiling-points which are known more accurately; for, even when within the range of a mercury thermometer, an observation of a boiling-point, to be accurate to a tenth of a centigrade degree, requires an attention to circumstances which is seldom bestowed on such observations.

The glass thermometer-bulb used in our experiments is represented in the accompanying figure (Fig. 1) of one-half the actual size in its linear dimensions. The longer stem was made of thermometer tube, and a shorter stem was added to the opposite end of the bulb in order to facilitate the cleaning, drying, filling, or emptying of the interior, all of which was easily accomplished by the aid of a Bunsen pump. The shorter stem was of course sealed after the bulb had been dried and made ready for use, and before it was immersed in the medium whose temperature was to be measured. After an equilibrium had been established at this unknown temperature, T'°, the protruding end of the longer stem was sealed, and at the same time the height of the barometer, H, was noted. The bulb was then taken to a room of uniform temperature provided in the laboratory for gas analysis, and, after being mounted on a convenient support, the end of the stem was broken off under mercury, and the apparatus left to itself for a time to secure a perfect equilibrium of temperature. This temperature, T°, was then observed, by means of a standard thermometer hanging near the bulb; also the height, h, to which the mercury had risen in the bulb, was measured by a cathetometer; and in addition the height, H', of a barometer (hanging in the same room) was noted. Closing now the open stem with the finger, the bulb was quickly inverted and the containing mercury drawn out into a tarred vessel and weighed (nipping off the extreme end of the shorter stem for the purpose). This gave the weight, w. Lastly, the bulb and stem having been completely filled with mercury by suction, the weight W, corresponding to their total capacity was obtained in a similar way. The required temperature could now be calculated by means of the well known law of Charles:—

$$T'^{\circ}+273{\cdot}2^{\circ}=(T^{\circ}+273{\cdot}2^{\circ})\,\frac{W}{W-w}\cdot\frac{H}{H'-h}\,[1+(T^{\circ}-T'^{\circ})k]$$

It will be noted that as the mercury columns, including the heights of the barometer, were all measured at the same constant temperature; and, as we are dealing with relative values only, no reductions are necessary. Moreover, an error of one-tenth of a millimetre in the value of—

$$\frac{H}{H'-h}$$

would make, in determining the boiling-point of sulphur (448°), a difference of only one eighth of a degree, so that measurements of these heights are sufficiently close, if accurate, to one-half a millimetre, and might even be made with a common rule. The most uncertain element in the formula is the expansion of glass; but if the bulbs are made of flint glass (lead glass) tubing, such as is used in this neighbourhood for ornamental ware, the mean coefficient of expansion will vary very little from 0·000025, if the temperature does not exceed that at which the glass begins to soften. The rate of expansion of flint glass is not only less than that of crown, but it is also more constant, and increases very slowly with the temperature. Flint

* Presented to the American Academy of Arts and Sciences, May 11

glass is therefore better adapted for the use we are describing. The expansion of the glass used in our experiments was carefully determined, and found to have the value given above, within two or three tenths of a unit in the last place. A difference of one unit in this place would make a difference of one-third of a degree in the boiling-point of sulphur.

In order to test the accuracy of this method, Mr. Bennett made four determinations of the boiling-point of sulphur under different barometric conditions, which in the following table are compared with the results of Regnault, reduced to the corresponding pressures:—

Barometer. Height at 0°.	Boiling-point of Sulphur. Bennett.	Regnault.	Diff.
758·8	447·4	447·3	+0·1
763·9	448·2	447·7	+0·5
769·6	448·2	448·1	+0·1
776·7	448·2	448·7	−0·5

Regnault made eight observations on the maximum tension of sulphur vapour at temperatures varying from 387·64° to 554·03°, and from a discussion of these deduced the constants of an exponential formula, by which he calculated a table of maximum tensions for every ten degrees between the extreme limits, and also plotted a corresponding curve. It so happens, however, that the only two observations within the range of ordinary atmospheric pressure fall outside, and on the same side, of this assumed curve. These observations are the ones usually taken as indicating the boiling-point of sulphur; and Victor Meyer, in one of his methods of determining the density of the vapours of substances which have a high boiling-point, assumes a value for the boiling-point of sulphur (at the mean atmospheric pressure at Zurich), which he obtains by simple interpolation from the two observations just referred to.* In like manner we have calculated the above values corresponding to the pressures at which Mr. Bennett's results were obtained on the basis of the same two obervations; but, instead of simply interpolating by the first differences, we have assumed that the variation between the two observed values would follow the law indicated by the general curve, which Regnault gives as the best expression for all his observations. But according as we take the two observations, or the whole, we obtain values for the boiling-point of sulphur differing by more than a degree; and hence, as we have already said, there is still an uncertainty in regard to the boiling-point to this extent. As is evident, Mr. Bennett's observations confirm very closely the interpretation of Regnault's results, adopted by both Victor Meyer and by ourselves.

After the accuracy of our method had been thus placed beyond doubt within the limits required, Mr. Bennett made three determinations of the boiling-point of antimonious iodide, with the following results:—

Barometer. Height at 0°.	Boiling-point of SbT_3.
758·1 millimetres	400·4°
758·4 ,,	400·9
759·3 ,,	400·9

Probably only a small part of the difference between these observations depends on the variations of pressure. We only regard the method as accurate to whole degrees, and 401° is evidently the boiling-point of antimonious iodide at the normal pressure of the air within half a degree on either side.

The method we have here described we can most confidently recommend as a most efficient and accurate means of determining high temperatures in chemical laboratories. It requires no expensive apparatus, and no more delicate manipulation than most processes of gas analysis. Indeed, this method is most readily associated with Bunsen's method of gas analysis; and, in a laboratory provided with a room fitted for that work, the observation of temperature we have described can be made in a very short time.

In connection with these experiments we were led to devise a very simple and inexpensive form of differential air thermometer, that can be used almost as readily as a mercury thermometer, and which will measure either high or low temperatures with all the accuracy that is usually required. The instrument is represented by Fig. 2 of one-

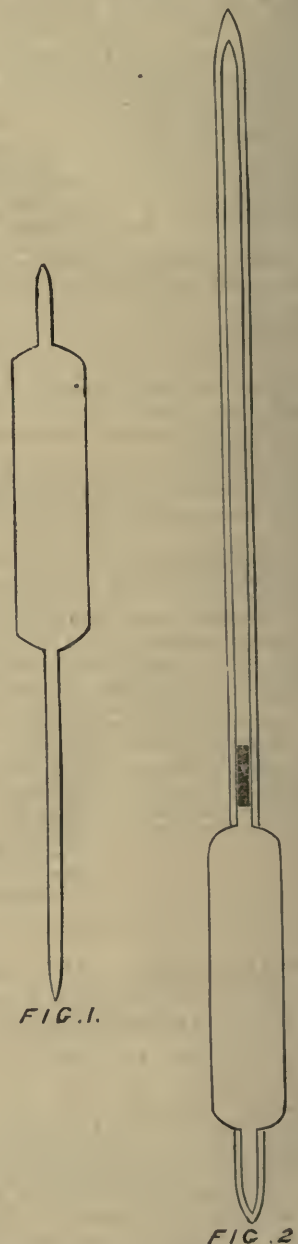

FIG. 1.

FIG. 2

half its linear dimensions. The long stem is made of "barometer tubing," a little over a millimetre in diameter, and by careful calibration is arbitrarily divided into parts of equal capacity, making, we will say, two hundred divisions on the length of the stem. While the instrument is still open at both ends it is easy to determine, first, the weight of mercury which fills the bulb up to the first divi-

* Fresenius's *Zeitschrift*, xvi., 482.

sion of the stem; and, secondly, the weight of a column of mercury covering an observed number of divisions of the stem. These constants being known, and the interior of the instrument having been most carefully dried, for which the two openings offer great facilities, a short column of very pure mercury is introduced, and brought into the position represented in the figure. The two ends are now hermetically closed with a blowpipe, and the instrument is made. It can be used either in a vertical or horizontal position, although the zero point of the scale is slightly different in the two cases, owing to the weight of the short mercury column. Of course this column remains immovable so long as the temperature of the two ends remains the same; but when the bulb is heated, the column, which we will call the index, moves up the stem, which becomes a closed monometer. If the instrument is to be used for measuring low temperatures, the index should be placed about one-third way up the stem before closing the open ends. The theory of the instrument is the same in either case, but in our description we will assume that the index has been set for high temperatures, as shown in our figure.

As the instrument is a differential thermometer, its accuracy depends on keeping the steam at a *constant* and *known* temperature; and from this constant temperature the observed temperatures are deduced. When the thermometer is held in a horizontal position, and the stem can be protected from the neighbouring sources of heat, it is sufficient to place a standard mercury thermometer at the side of the stem; but it is always better, and generally necessary, when the stem is in a vertical position over the source of heat, to surround the stem with a jacket, through which circulates a stream of water of known temperature. This temperature we will call the temperature of reference, and represent by T°. In order now to determine the value in Centigrade degrees of the division of the instrument, we place it in the position in which we propose to use it, and when the two ends are at the same temperature we observe the position of the two ends of the index on the graduate scale. We can now easily find from the weights obtained before closing the instrument, first the weight of mercury which would fill the bulb and stem up to the index, which we call W; and, secondly, the small weight of mercury which would fill one division of the stem, which we will call w. We have also, by observation, the number of division on the stem above the index. This number, which we count from the closed end of the stem, we will represent by N.

Assume, now, that the bulb and stem up to the index is immersed in a medium which has the temperature, T'. The index moves, and in its new position let N' represent the number of division on the stem above the index. We can now easily deduce the following values:—

$\frac{N}{N'}$ = the ratio of the tension of the confined air at T'° and T°.

N − N' = the number of division through which the index moved.

$$\frac{W+(N-N')w}{W} =$$

the ratio of the volumes of the air in the bulb at T° and T'°, independent of the expansion of the glass.

$$\frac{W+(N-N')w}{W}(1+[T-T']k) =$$

same ratio, allowing for expansion of glass.

Then, as we can easily deduce from the laws of Mariotte and Charles:—

$$T'^{c}+273=\frac{N}{N'}(T^{\circ}+273)\frac{W+(N-N')w}{W}(1+[T^{\circ}-T'^{\circ}]k)$$

With this formula it is now easy to compute the values for each division of our arbitrary scale. We cannot, however, depend absolutely on the result, as there are several causes which will differ with each instrument, and of which we can take no account. It is therefore best to observe, with the instrument, two or three well-established boiling-points, which will give us fixed points by which we can correct the table, and we shall then have an instrument whose precision is fully equal to that of a mercury thermometer.

It is, of course, very desirable that the temperature of reference T° should be always the same and as invariable as possible. This is best accomplished, as above suggested, by maintaining a circulation of water through a glass jacket surrounding the stem of the instrument and enclosing also a small mercury thermometer, which is best tied to the stem. By selecting the temperature of reference a little higher than the highest temperature of the water supplied by the laboratory hydrants, it is easy to maintain the required temperature within a degree by regulating the flow. The instrument may then be adjusted to the tubulature of a retort and used in fractional distillations.

(To be continued.)

PROCEEDINGS OF SOCIETIES.

CHEMICAL SOCIETY.

Thursday, November 17, 1881.

Dr. Gilbert, F.R.S., Vice-President, in the Chair.

The following certificates were read for the first time:—G. W. H. Clements, A. B. Griffiths, W. F. Reid, D. B. Steuart, C. A. Still, J. W. G. Stevens, B. E. Smith.

It was announced that a ballot for the election of Fellows would take place at the next meeting of the Society, December 1.

The Chairman then called on Dr. Gladstone to read a paper entitled "*Aluminium Alcohols* (*Part II. Their Products of Decomposition by Heat*), by J. H. Gladstone and A. Tribe. The authors recently described the formation of alcohols (*Journ. Chem. Soc.*, 1876 and 1881), in which basic hydrogen is replaced by aluminium. The present paper contains the results of their investigation of the products of decomposition by heat of these bodies. Ethyl Series:—Aluminic ethylate may be distilled *in vacuo*, but is almost wholly broken up near its boiling-point under the ordinary pressure of the atmosphere into alumina, ethene, and alcohol; a similar decomposition takes place with aluminic amylate. Phenyl Series:—If similar reactions take place in this series, simple ethers, $(C_n H_{2n-7})_2O$, and hydrocarbons, $C_6H_4C_7H_6$, &c., would be obtained. Aluminium Phenylate.—About 500 grms. of this compound were heated in a flask with a wide bent tube attached. It melted, and after some free phenol had passed over, a somewhat viscid yellowish brown liquid distilled. The residue consisted of charcoal, tarry matter, and alumina. The distillate was re-distilled, and then fractionated into three portions. The first portion, 52 grms., was principally phenol. The second, 160 grms., after purification, boiled at 249°; it was a colourless liquid, sp. gr. 1·0904, and had the composition $C_{12}H_{10}O$ (phenyl-ether). It solidified to a mass of colourless prismatic needles when immersed in a freezing mixture. The third fraction, 34 grms., a viscid brown liquid, containing grains of a yellow solid, was distilled many times; a colourless liquid was finally obtained, boiling at 280°, and condensing to a nearly white solid. This was purified by re-crystallisation from alcohol, when it melted at 97°, and sublimed slowly a little below this temperature. From its analysis and vapour-density its formula is probably $C_{13}H_{10}O$. Three bodies of this formula are known—fluorene alcohol, diphenyl-ketone, and its isomer. The present body does not correspond in its properties with either of these three. It is probably a phenyl-ketone. It appears, therefore, that half of the phenylate was resolved by heat into phenyl-ether and alumina, that a small quantity of a compound,

$C_{13}H_{10}O$, was formed, and that about a quarter of the phenylate was resolved probably as follows:—

$$(C_6H_5O)_6Al_2 = Al_2O_3 + 3C_6H_6O + 3C_6H_4.$$

No evidence of the existence of the hydrocarbon C_6H_4 was obtained. In a similar way, the authors have examined the action of heat on aluminium para-cresylate. As compared to the decomposition of the phenylate, a smaller quantity of the ether and a larger quantity of a body, $C_{15}H_{14}O$, were obtained. The hypothetical hydrocarbon, C_7H_6, was not found. Aluminium thymolate is readily resolved by heat into aluminium meta-cresylate and propylene, the meta-cresylate being in its turn resolved into alumina, meta-cresol, meta-cresyl-ether, and a pearly compound, $C_{15}H_{14}O$, which is apparently isomeric with the body of the same formula obtained from the para-cresylate. Two substances of the formula $C_{15}H_{14}O$ (para-ditolyl and dibenzyl-ketones) are known, but their properties do not agree with either of these substances. The authors are inclined to consider these bodies as ketones, and provisionally as para- and meta-cresyl-ketones. Aluminium β-naphthylate.—The principal product of the decomposition is β-naphthyl ether—

$$(C_{10}H_7O)_6Al_2 = Al_2O_3 + 3\left.\begin{matrix}C_{10}H_7\\C_{10}H_7\end{matrix}\right\}O.$$

Aluminium α-naphthylate.—This body requires a higher temperature than the β compound to effect its decomposition. The principal product formed has the formula $C_{20}H_{14}$, and resembles in physical properties the β-β-dinaphthyl of Watson Smith. It is doubtful whether an ether is formed at all by the splitting up of the α body.

Mr. E. Wethered read a paper entitled "*On the Chemical Action of Decomposing Vegetable Matter on the Rock-forming Sediment of the Carboniferous Period.*" The carboniferous rocks of the West of England above the limestone consist of an alternation of arenaceous and argillaceous strata with seams of coal. The arenaceous strata are of two types—the millstone and the Pennant grit. In almost every case the argillaceous strata immediately follow seams of coal, and in the exceptions where a grit occupies this position it becomes, in contact with carbonaceous matter, more or less argillaceous. In this paper the author endeavours to show that the argillaceous rocks, as compared with the Pennant grit, have been originated by the action of certain products of decomposition, given off from decomposing vegetable matter, on the original sediments of which the rocks have been built up. The author then compares analyses of several samples of Pennant grit with analyses of argillaceous strata, and shows that the principal difference between the two is in the alumina; while the Pennant grit contains 2 to 5 per cent of Al_2O_3, the argillaceous strata contain 9 to 16 per cent. In cases where a grit overlies seams of coal, it approaches, as it comes in contact with the carboniferous matter, in its characters, the argillaceous rocks. Thus the Doxall grit of the Bristol district, away from the coal, contains 5·5 per cent; close to the coal, 8·5 per cent of Al_2O_3. As another instance, the Great Vein stone, from the same district, away from the coal, contains 4·46 per cent Al_2O_3; close to the coal, 11·2 per cent. As a third example, two beds of Pennant grit were chosen, exactly similar, except that one contained stratified layers of carbonaceous matter, which were absent in the other. The bed free from carbonaceous matter contained 2·26 per cent, the other 7·11 per cent Al_2O_3. In every case, the grit becomes more argillaceous as it comes into contact with carbonaceous matter. The author has taken care that the samples compared should be of the same degree of fineness of grain, and is disposed to attribute this difference in chemical composition to the action of carbonic acid given off by the decomposing vegetation on the freshly-formed deposits of inorganic sediment. The carbonic acid would decompose all silicates, except the silicate of alumina, the bases forming soluble carbonates, and thus the alumina would increase in proportion to the whole, and the deposit become more argillaceous. The argillaceous rocks are also characterised by containing small quantities of sulphur, phosphorus, and manganese. The presence of these elements is attributed by the author to the power which plants have of secreting certain inorganic substances.

Prof. Church suggested that the increase in the alumina might be due to lycopodiaceous vegetation, as it was well known that the ashes of these plants contained much alumina.

Mr. Wethered could not agree with Prof. Church, because there are no remains of such plants in the argillaceous rocks, and because the alumina always increased whenever the grits came into contact with carbonaceous matter.

The Secretary then read a paper "*On α- and β-Amylam*," by C. O'Sullivan. Finely-ground skinless barley was treated with alcohol (sp. gr. 0·9 at 40°) as long as anything was dissolved. The residue was freed from alcohol, and treated with water at 35° to 38° for several hours. This extraction was repeated until nothing further was dissolved. The solution was filtered, evaporated, and precipitated with alcohol. The precipitate, which was white and stringy, was washed with alcohol, and dried. The powdered precipitate was extracted with cold water, and the crumby residue treated with cold dilute hydrochloric acid, washed, and then dissolved in boiling water, the solution filtered, and precipitated with alcohol containing 3 to 4 per cent hydrochloric acid. The precipitate was washed and dried, purified by re-solution and re-precipitation, and finally analysed after it had been proved by fractional precipitation that it contained but one substance. It has the formula $C_6H_{10}O_5$. A 1 per cent solution has rotatory power $[\alpha] = -24$; is almost insoluble in cold, and gelatinises in hot, water. It does not reduce alkaline copper solution. When boiled with 5 per cent sulphuric acid it is converted into dextrose without the formation of any intermediate products. This substance is distinct from Lippmann's lævulam, and is named by the author α amylam. The cold water extract of the crumby residue mentioned above was treated in a manner somewhat similar to that just described, and furnished β-amylam. It has the formula $C_6H_{10}O_5$; is soluble in cold water; has for 1 per cent solution $[\alpha] = -73$; and yields a birotatory modification (1 per cent sol. $\alpha = -144$). By the action of sulphuric acid it is converted into a dextrose, which resembles ordinary dextrose in cupric oxide, reducing power, and opticity, but has less tendency to crystallise. Barley contains about 2 per cent of α-amylam, and 0·3 per cent β-amylam. Wheat and rye contain 2 to 2·5 per cent of β-amylam, and not more than 0·1 per cent of the α body. Malted cereals do not contain these bodies.

Dr. Gilbert suggested that more or less perfect maturation of the grains might affect the quantities of these carbohydrates.

Dr. Armstrong drew attention to the paper as the result of a very large number of experiments. The author had established very clearly that these carbohydrates were converted directly into dextrose, when heated with dilute sulphuric acid, and thus differed most materially from ordinary starch.

"*On the 'Steeping' of Barley*," by E. J. Mills and J. Pettigrew. The authors have investigated carefully the action of distilled water, and of water containing known quantities of calcium sulphate and calcium carbonate on barley. The temperatures varied from 4° to 11°. The general results obtained are that water in which barley has been steeped contains at least two albumenoid bodies, one of which is thrown down by meta-phosphate (a quantity of sodic meta-phosphate is covered with acetified water and occasionally shaken; the clear liquid over the undissolved salt is the reagent) in the cold, the other only on boiling. The first of these is almost wholly kept back within the grain by a gypsum solution, and to a less extent by a chalk solution. The general effect of a calcic solution is to keep back the nitrogenous matter within the grain, but to increase the total amount of matter extracted. The authors examined the Burton water from Lichfield, which is in

much demand for steeping, and attribute its value to the nitrates it contains, which stimulate the germination. On the whole, the authors recommend for steeping a water containing 0·1 per cent of gypsum, and a small quantity of calcic nitrate. They suggest that with soft waters just enough water should be used to saturate the grain and no more.

"*On the Action of Oxides on Salts (Part IV. Potassic Chlorate and Ferric Oxide)*," by E. J. Mills and G. Donald. The authors give details as to the preparation of the two substances. The experiments consisted in heating a known weight (5 grms.) of the chlorate with varying quantities of ferric oxide to about 195° for about four hours. The oxygen expelled gave a measure of the reaction which had taken place. The authors conclude that this case of chemical change presents nothing unusual or peculiar in its features, and that the entire course of the action of ferric oxide upon potassic chlorate is strictly analogous to the first stage of the action of that oxide on potassic carbonate: from the carbonate an oxide of carbon is expelled, from the chlorate an oxide of oxygen. The name Catalysis therefore ceases to have any reason for its existence.

In a supplementary note E. J. Mills and John Stevenson have examined the action of manganese dioxide upon potassium chlorate, which also resembles the ordinary behavious of an oxide towards a salt.

The Society then adjourned to December 1, when a ballot for the election of Fellows will be held, and a paper by Dr. Armstrong, entitled "Researches on the Laws of Substitution in the Naphthalene Series," will be read.

NOTICES OF BOOKS.

The Student's Hand-book of Chemistry, with Tables and Chemical Calculations. By H. Leicester Greville, F.I.C., F.C.S. Edinburgh: E. and S. Livingstone.

The author of this work begins his preface with the very truthful remark that "in the presence of so many good manuals on chemistry the appearance of another may seem unnecessary." He ventures, however, to hope that his book will be of use to the student. Such a result is, of course, by no means impossible. But as far as all other subjects are concerned, the very first question asked by a publisher concerning a work proposed to be brought out is, what new and distinctive ground does it cover? As regards elementary works on chemistry, this rule, it seems, does not apply. Such manuals can scarcely do other than reproduce each other, with some very slight differences in arrangement, in wording, and in extent. The most noteworthy feature of the present volume is that it is non-examinational. The author includes in his scheme the whole of chemistry, physiological and analytical.

Adolph Strecker's Short Text-book of Organic Chemistry. By Dr. J. Wislicenus, Professor of Chemistry in the University of Würzburg. Translated and Edited, with extensive additions, by W. R. Hodgkinson, Ph.D., and A. J. Greenaway, F.I.C. London: Kegan Paul, Trench, and Co.

We have here a case of compound authorship in which the respective shares of the original author, of the German editor, and of the English translators are not easily traced. Strecker, it appears, died suddenly in 1871, as he was about beginning a sixth edition of the work. The revision of the book, and its adaptation to the present state of knowledge, fell to the lot of Prof. Wislicenus, who is not unknown in this country, especially to the readers of Kolbe's *Journal für Praktische Chemie*. Messrs. Hodgkinson and Greenaway have made alterations chiefly in the section dealing with the hydrocarbon compounds, and as regards the naphthalene compounds they have introduced the symbols of Reverdin and Noelting. The classification adopted in the volume before us is substantially as follows:—Cyanogen compounds: guanidin; derivatives of carbonic acid and carbon disulphide; the ethans or paraffins; their mono-, di-, tri-, and tetra-substitution derivatives; the respective derivatives of the pentavalent, hexavalent, and heptavalent hydrocarbon nucleus; the derivatives of the hydrocarbon nuclei, $C_nH_{2n}-6$; the aromatic compounds; homologues of benzene; the aromatic alcohols, aldehyds, ketones, and glycols; acids and their substitution products; further simple benzene derivatives; compounds of conjugated benzene nuclei; compounds containing condensed benzene nuclei; organic compounds of unknown constitution, and protein compounds. In an appendix are given the refraction equivalents of organic compounds, and an account of the diazo colours, the latter by Mr. R. Meldola—a high authority on the subject.

The descriptions of the various substances are brief, as may naturally be expected when the whole vast field of organic chemistry has to be surveyed in something less than 800 pages, but general accuracy is unmistakable. As regards theoretical questions, we notice that the authors adhere to the hypothesis of Kekulé concerning the benzol—or, as they write it, benzene—nucleus. Something concerning the views of Prof. Wislicenus may be gathered from the following passage in his preface:—"In the present state of our science we cannot neglect the frequent use of structural formulæ based on the valency of the chemical elements. Their partial uncertainty, and in many points tangible shortcomings, need not prevent their use to some extent in a text-book, though their use requires care. With regard to the manner of uniting the constitutional formula, no dogmatic adherence to any single method will be adopted, so that the formula of one and the same substance may be found varyingly written in different places. With every one of these systems of formulæ there is the danger of substituting a concrete image in place of an idea. These images we certainly cannot do without, but we must keep the idea lying behind such an image as far as possible pure and also mobile, seeing that in comparison with older views we have in it relative and not absolute truth."

We are far from regarding this passage as a model of scientific English, and if some portions of it do not read better in the original German we fear they may possibly be immortalised in Prof. Kolbe's *Chemische Blumenlese*.

We notice "maclurine"—an objectionable name—used instead of moreine, and on page 726 we find "phlorogulein" written for "phloroglucin,"—the only typographical error we have met with in the volume. There is a copious table of contents, and the index is full and accurate wherever we have tested it. As a fairly complete compendium of organic chemistry in the space of a single volume there was room for this work in our scientific literature, and we have no doubt but that it will be found useful.

Elementary Treatise on Natural Philosophy. By A. Privat Deschanel. Translated and Edited, with extensive modifications, by J. D. Everett, F.R.S. Sixth Edition. London: Blackie and Son.

We have on a former occasion had the pleasure of examining an earlier edition of this work, and we then felt bound to record our high opinion of its value and merits. Since that time it has undergone certain not unimportant modifications, and has received the additions necessary to render it a faithful summary of physical science up to the date of publication. Many of our readers may possibly take exception to the term "Natural Philosophy" in the title. That term has never been in use in France, and in England it is more and more falling into disuse, whilst in German the signification of "Naturphilosophie" is something totally different. But though we should certainly have preferred the title "Elementary Treatise on

Physics" had the work been now making its first appearance in an English guise, yet we can well understand the translator's unwillingness to alter the name of a book which has already passed through five editions, and has won the approval of competent authorities.

The original purpose of the treatise, as stated in the author's preface, was to assist young men in qualifying themselves for University Degrees. For this object it is well adapted. But it is also well suited for the purposes of private study and self-instruction. It is likewise to be recommended to that ever-increasing class who, without undertaking the formal study of any department of physical science, may wish to make themselves acquainted with any physical subject which is attracting public attention. Such persons will find it particularly adapted to their wants from the clearness of the language, the sparing use made of algebra, and the number and excellence of the illustrations.

The general classification adopted by the author is as follows:—Dynamics (including mechanics, hydrostatics, and pneumatics); thermics; electricity, including magnetism; acoustics, and optics. We may here remark that no agreement has yet been reached on the arrangement of the branches of physics. Save that all place dynamics at the beginning, nearly every treatise adopts a different order.

As regards the alterations made in the present edition, it appears that Part I., treating on dynamics, has been rewritten. All accurate statements of quantities are now given on the centimetre-gramme-second system. Part II. (thermics) has been re-arranged and enriched with much additional matter, such as an account of Dine's hygrometer and Symon's "Snowdon rain-gauge"; a notice of Guthrie's results on the freezing of brine; recent results on the conductivity of rocks and of water; a description of the modern gas-engine, &c. Part III., treating on electricity and magnetism, has also received extensive additions, among which rank descriptions of Planté's secondary battery, of Wheatstone's bridge and conjugate branches, of the magneto-electric machines of Siemens and Gramme, of the telephone, microphone, and induction balance, &c. Though the whole forms a bulky volume, it must be remembered that a full account of every subject included in the range of physical science would require far greater space, and this accordingly the author and the editor have not attempted.

CORRESPONDENCE.

SYMBOLICAL NOTATION.

To the Editor of the Chemical News.

Sir,—I shall be much obliged if you or any of your readers will explain to me how Kekulé's defence of his symbol for the benzene ring (viz., that the double linkings are not fixed in position, but oscillate) can be made to apply to naphthalene. The generally received symbol for naphthalene is—

Now it will be seen that the double and single linkings cannot be made to vibrate backwards and forwards at the same time in both rings, without one of the carbon atoms having five affinities saturated, and as carbon atoms are supposed to have only four each, this is impossible.

There do not seem to be any well-founded objections to the symbol—

analogous to the benzene one,—

but I have never seen this given in any book.—I am, &c.,

Alfred Pagan.

St. John's College, Cambridge,
October 11, 1881.

CHEMICAL NOTICES FROM FOREIGN SOURCES.

Note.—All degrees of temperature are Centigrade, unless otherwise expressed.

Comptes Rendus Hebdomadaires des Séances, de l'Académie des Sciences. No. 17, October 24, 1881.

Detonation of Acetylen, Cyanogen, and of the Endothermic Compounds in General.—M. Berthelot.—Gases whose formation is attended with the absorption of heat, such as acetylen, cyanogen, arsenic hydride, which do not detonate on mere heating, may be brought to explode under the influence of a sudden and very violent shock, such as that which results from the detonation of mercury fulminate. This shock, indeed, only acts upon a certain layer of gaseous molecules, to which it communicates an enormous *vis viva*. By this shock the molecular edifice loses the relative stability, which is due to an especial structure.

General Determination of the Tension and the Volume of Saturated Vapours.—R. Clausius.—A mathematical paper, not admitting of useful abridgment.

An Apparatus for Determining without Pain to the Patient the Position of a Projectile of Lead or other Metal in the Human Body.—A. Graham Bell.—This memoir requires the two accompanying illustrations.

Electrolysis of Water.—D. Tommasi.—According to the author a zinc-copper or zinc-carbon element plunged into dilute sulphuric acid does not decompose water if the two electrodes are of platinum. In order that the electrolysis of water may take place, the positive electrode must be formed of a metal which, under the influence of the voltaic current is able to combine with the oxygen of the water.

A Compass of Proportion, for the Measurement of Resistances.—J. Carpentier.—Suppose, at the surface of a sphere, of which the vertical diameter is taken as polar axis, two identical circuits are arranged so as to follow the circumference of two meridians. A current passing by one of these circles exerts upon a magnetic pole, situate at the centre of the sphere, a force normal to the plane of this circle, and proportional to its own intensity. Another current, traversing the second circle,

determines at the centre of the sphere a second force perpendicular to the former. These two forces acting simultaneously combine; the direction of the resultant depends merely on the ratio of the two intensities, and this ratio of magnitude of one of the components to the other will be exactly measured by the trigonometric tangent of the angle α, formed by the resultant and the second component. Let us suppose a wire without torsion extended along the polar axis of the sphere, and fixed upon this wire, perpendicularly, in its middle, a very short magnetic needle. This needle thus suspended in the centre of the sphere will be free to turn in the plane of the equator. Under the double action of the currents it will take the direction of the resultant of the forces. Nothing will be easier than to measure the angle α above defined.

A New Hydrate of Carbon.—E. Morelle.—The author has examined bergenite, a crystalline principle, obtained from *Bergenia sibirica*, and which he finds to be a pentatomic alcohol.

Moniteur Scientifique, Quesneville.
August, 1881.

Venomous Matters produced by Man and the Higher Animals.—A. Gautier.—The author has extracted from normal human urine a well-characterised and highly poisonous alkaloid. In the venom of the *Trigonocephalus* and of *Naja tripudians* (the Cobra), he has detected two alkaloids. In that of the cobra he has also found a second principle, still more poisonous, but not basic.

Researches on Conquinamine.—A. C. Oudemans.—From the *Archives Neerlandaises*, vol. 15.

Alkaloid extracted from Pituree.—Prof. Liversidge.—Translated from the English original.

Report presented by M. Vincent on a Communication from the French Celluloid Company.—From the *Bulletin de la Société d'Encouragement.*

Certain New Methods of Desulphurising Alkaline Solutions.—Scheurer Kestner.—The means employed for removing sodium sulphide from the lixivium of the black ash are precipitation of the sulphur as a metallic sulphide by the addition of metallic salts or oxides; the use of neutral alkaline salts, the property of which is to free the solution from a certain quantity of iron sulphide, and lastly oxidation-methods. Total desulphuration is generally effected by oxidation, set up by a current of air forced through the liquid. Hargreaves, in 1866, called attention to the oxidation of the liquid by means of a current of steam. Pauli has improved upon this process, and adds to the liquids to be oxidised a small quantity of manganese dioxide. This addition accelerates the oxidation in the proportion of 1·7 : 1. When air is used as an oxidising agent the liquid should be heated to about 75°. This oxidation ceases with the formation of sodium hyposulphite. If manganese is added, a portion of the hyposulphite is transformed into sulphate, but never the whole. If it is required to obtain solutions free from the lower oxides of sulphur, oxidation by electrolysis is preferable, as patented by Merle. The sodium sulphide is transformed into sodium sulphate without passing through the intermediate stages.

Journal de Pharmacie et de Chimie.
August, 1881.

Researches on Nitrogen Sulphide.—MM. Berthelot and Vieille.—From the *Comptes Rendus.*

Determination of Gluten in Flour.—MM. Bénard and J. Girardin.—The authors find that the length of time between the preparation of the paste and the extraction of the gluten decidedly affects the results.

Assay of Commercial Wood-Spirit intended for the "Denaturation" of Ethylic Alcohol.—C. Bardy.—For the assay of a commercial methylene the author takes, by means of a pipette, 5 c.c. of the sample in question, and introduces them into a flask holding 50 c.c., which is then immediately filled with water up to the mark. The flask is then closed with the finger and shaken vigorously. 10 c.c. of this liquid are then taken with a pipette, and let flow into a litre flask, which is then filled with water up to the mark, closed with the palm of the hand, and shaken well. A solution of methylene at 1-1000th is thus obtained. To make the assay, the author takes 5 c.c. of this dilute liquid with a pipette, pours it into a test-tube (graduated at 5, 15, and 30 c.c.). He adds a standard solution of soda (sp. gr. 1·080) up to the mark 15 c.c., and then introduces half a c.c. of the standard solution of iodine (a solution of 254 grms. iodide to 385 grms. potassium iodide, and made up with water to 1 litre). He closes the tube with the thumb, and reverses it *once* to mix the liquids. There is instantly produced a milky turbidity, due to the formation of iodoform. The tube is then filled up with water to the mark 30 c.c. It is inverted once, and is then compared with a tube made up in the same manner with a standard sample of methylic alcohol.

Distinctive Reactions of Santonine and Strychnine.—Colin Tocquaine.—Treatment with sugar and sulphuric acid gives the same result with both. But if the mixture is then treated with a drop of officinal tincture of iodine, and then with an excess of acid nitrate of mercury, there is produced with strychnine an intense brown colouration, but with santonine, a white precipitate, which becomes in time slightly yellow.

The Separation of Wool and Silk in Woven Goods.—A. Rémont.—The following method is sufficiently exact for commercial purposes:—The sample is kept for a quarter of an hour in boiling water containing 5 per cent of hydrochloric acid, and is then washed and dried. The threads of the warp are then separated, if possible, from those of the weft, and examined separately as follows:—A thread is burnt. There is given off a smell like burning horn, and a thread heated with a fragment of caustic soda evolves ammonia. In this case some threads are plunged in basic zinc chloride at a boil. If they dissolve completely the threads are *silk*. If on adding hydrochloric acid there is a plentiful flocculent precipitation, the threads are silk mixed with wool or with vegetal fibres. If nothing dissolves in zinc chloride, the threads are plunged in a boiling solution of soda, not too concentrated. If they dissolve completely, *wool*. If partially, *wool* and *cotton*. If no odour of burnt horn is given off, the threads consist entirely of vegetal fibres. These results may be confirmed by means of the microscope. For the quantitative examination, if the preliminary tests show silk, wool, and cotton, four swatches weighing each 4 grms. are cut; one is laid aside and the three others are boiled.

Determination of the Dressing and the Dye.—The swatches are plunged into 200 c.c. of hydrochloric acid diluted to 3 per cent, and heated to a gentle boil, which is kept up for a quarter of an hour. If the liquid is deeply coloured, it is poured off, and fresh acid is substituted, which is again boiled for a quarter of an hour. The swatches are then washed in water, and dried by wringing them in a piece of linen. The purpose of this boiling is to remove the dressing. As for the dye which colours the fibres, it is easily removed from cotton by this process; less readily from wool, and from silk very incompletely. When the latter material is dyed light shades by means of the coal-tar colours, the weight of the dye is trifling, and may be neglected. It is not the same if the silk is dyed deep colours, and especially black. The weighting or loading may be completely removed from iron if it does not exceed the fourth of the weight of the thread, and the colour of the latter borders on a maroon. Beyond this proportion the stripping of the dye is incomplete. An approximate idea of the weighting retained by the tissue may be got by afterwards incinerating the boiled swatch.

If the proportion of oxide of iron remaining is slight, it may be overlooked, but if it reaches 5, 8, or 10 per cent, calculated on the weight of the silk in the cloth, it must be taken in account.

Separation of the Silk.—One of the boiled swatches is set aside, and the two others steeped for a minute or two in a boiling solution of basic chloride of zinc at 60° B. (J. Persoz). M. Morin prepares this reagent by heating the following mixture till dissolved:—

Melted zinc chloride..	1000 parts.
Distilled water	850 „
Zinc oxide	40 „

The two swatches are, when drained, thrown into a glass of water, where the greater part of the salt of zinc is separated. They are then washed with acidulated water, and then with plain water till the washings no longer give a precipitate with ammonium hydrosulphate.

Separation of the Wool.—One of the two swatches freed from silk is put aside, and the other is steeped in 60 to 80 c.c. of soda-lye of specific gravity 1·020. It is heated to a gentle boil, which is kept up for a quarter of an hour. The bulk of the liquid must not be allowed to decrease, and in washing and drying the residue it must not be rubbed lest losses be occasioned by the breaking of the fibres.

Drying and Weighing the Swatches.—The four swatches are placed in a drying oven heated by boiling water. After the lapse of an hour they are taken out and exposed to the air in the place where the sample was originally kept. They are weighed the next morning. The swatch which has undergone no treatment should weigh 2 grms., a difference of 0·005 grm. more or less may be neglected, but beyond this figure the change of weight should be taken into account in the calculation. The difference between the weight of this swatch and that of the one merely treated with acid gives *dressing and dye*. From the weight of this second swatch deduct the weight of that treated with zinc chloride and it represents *silk*. As for the fourth swatch it represents approximately all the *vegetable fibre*; approximately, for soda, even in dilute solution, attacks vegetable fibres, so that a correction must be made in the weight found. From numerous trials made it appears that the average loss of cotton on treatment with soda is 5 per cent. On adding to the fourth swatch 5 per cent of its weight, we have the cotton. The figures found are multiplied by 50 to bring the result to percentages. The difference between the sum of these figures and 100 gives the weight of wool.

Les Mondes, Revue Hebdomadaire des Sciences.
No. 13, July 28, 1881.

M. Tommasi pursues with success the construction and the trials of his secondary horizontal battery.

M. Moigno agrees with Mr. C. Latimer, that in a few years the mètre will be rejected, even in Paris, in favour of the cubit of the great pyramid.

Dissociation of Sulphuric Acid.—MM. J. Kœchlin and Gerber.—The authors support the hypothesis of M. Maumené that sulphuric acid when heated is partially dissociated into sulphuric anhydride and water, and these two bodies do not immediately re-combine when the liquid is suffered to cool.

No. 15, August 11, 1881.

Reaction of Bi-imido-naphthol with Aqueous Ammonia.—MM. Ludwig and Mauthner.—The results of the reaction are the same as those yielded by the treatment of oximido-naphthol, though mixed with a small quantity of a substance resulting from the contact of oximido-naphthol with hot water.

Oxalates of Iron.—MM. Eder and Valenta.—The authors describe a yellowish green normal oxalate, a red-brown basic salt, and three double salts containing three molecules of alkali.

Action of Light upon Ferric Chloride and other Ferric Salts.—J. M. Eder.—The ferric oxalates, citrates, and tartrates, and their double salts, as also the mixtures of ferric chloride with organic matter, are all decomposed by the action of light.

Resin of Guiacum.—H. Wieser.—Not suitable for abstraction.

Resins.—K. Bötsch.— So-called dragon's blood, if heated with zinc powder, yields styrol, meta-styrol, and ethylated benzol. Guiacum resin if similarly treated yields creosote, toluol, meta- and para-xylol, and a smaller proportion of pseudo-cymol.

MISCELLANEOUS.

The Reduction of Copper Solutions by Glucose* appears first to have been utilised by Trömmer. Frommherz suggested the employment of a citrate to keep the cupric oxide in solution. Modifications of the ordinary alkaline tartrate solution have been devised by Barreswil, Poggiale, Rosenthal, Chevalier, Boussingault, Reveil, Fehling, Strohl, Viollette, Magneshahens, Lowenthal, Joulie, Possoz, &c. Loewe employed glycerin instead of a tartrate. Various treatments of the precipitated cuprous oxide have been proposed by the following chemists:—Mohr disolves the oxide in hydrochloric acid, and titrates with permanganate. Brunner dissolves in an acid solution of ferric chloride, and estimates the reduced iron by bichromate or permanganate. Champion and Pellet dissolve the precipitate in hydrochloric acid and chlorate of potassium, boil off free chlorine, and titrate the liquid with stannous chloride. Girard and Soxhlet reduce the cuprous oxide in hydrogen, and weigh the metallic copper. Muter dries the cuprous oxide at 100° C., and weighs it as Cu_2O. O'Sullivan and other operators ignite the precipitate strongly, and weigh as CuO. Ferdinand-Jean dissolves the cuprous oxide in hydrochloric acid, and weighs the metallic silver precipitated on adding ammoniacal silver nitrate. Maumené uses an excess of copper solution, filters, adds ammonia to the filtrate, and estimates the residual copper by titration with sodium sulphide, for which Perrot substitutes potassium cyanide. Lastly, Pavy adds ammonia to the alkaline cupric solution, and runs in the sugar solution till the hot liquid is decolourised.

Cantor Lectures.—On Monday evening last (21st inst.), the first lecture of the first course was delivered by Mr. Thomas Bolas, F.C.S., the subject being "Some of the Industrial Uses of the Calcium Compounds." Mr. Bolas alluded to the distribution and occurrence of calcium in nature, and the abundant existence of carbonate of lime as limestone, chalk, marble, calcspar, shells, &c. He referred to the new metallurgy of Davy, as initiated by the isolation of potassium; and pointed out the probability that some of those metals which are abundant, but not in general use, may soon come into notable importance. In conclusion, some of the most important points in the general chemistry of the calcium compounds were demonstrated. The isolation of the metal calcium by the electrolytic decomposition of its fused chloride was shown experimentally, the necessary electric current being furnished by a machine constructed on Pacinotti's principle, and driven by a small gas motor.

Photographic Exhibition.—The substitution of a film of dried gelatin for the thin layer of wet collodion, which the photographer formerly employed as a vehicle to retain the sensitive salts of silver in a suitable condition on his glass plate, has involved considerable alterations in the mechanical appliances used in photography. For out of doors work, or work away from home, the photographer no longer requires to carry what was practically a portable laboratory. Not having to "develop" his pictures on the spot, he need take with him neither dark tent nor

* From an Advance-Sheet of Allen's "Commercial Organic Analysis," vol. ii.

chemicals. On the other hand, he must have some provision by which his store of dry plates can be placed, one after the other, in the camera and properly "exposed" without the risk of the slightest particle of light reaching their sensitive surface, other than the light properly directed upon them by the lens. As he wishes to carry an ample supply of plates with him, and as the glass plates themselves make an appreciable burden in a long walk, it s essential that the apparatus for carrying them should be as light as possible; hence have arisen considerable improvement in the camera and its "slides." Again, the increased sensitiveness of the gelatin films makes it possible to give exposures shorter than can be effected by the hand uncapping and re-capping the lens; hence the invention of numerous "instantaneous shutters," by which exposures of a few hundredths of a second can be given, and pictures of moving objects readily secured. These are but instances of the many novel appliances which recent progress in photographic science has originated, and, besides these, there has been, during recent years, many and important improvements in the applications of photography to the production of permanent illustrations for books and newspapers. All these varied applications of the art are to be illustrated by an exhibition of photographic appliances which the Council of the Society of Arts announce will be held during January and February next, in connexion with a course of Cantor lectures to be given before the Society by Capt. Abney. Full particulars of this exhibition are given in the *Journal of the Society of Arts* for last week.

NOTES AND QUERIES.

*** Our Notes and Queries column was opened for the purpose of giving and obtaining information likely to be of use to our readers generally. We cannot undertake to let this column be the means of transmitting merely private information, or such trade notices as should legitimately come in the advertising columns.

Evaporation.—Can any of my fellow readers inform me if the patent for the "Porion Evaporator" (1865) has expired?—MURIATE.

Barcenium.—Can you or any of your readers favour me with some reference to the newly-discovered element Barcenium? I have recently seen casual allusion to it, and can find no account of its discovery, properties, &c.—H. C. B.

Vegetable Parchment.—Will any of your readers kindly afford information as to the best cements for dialysers, &c., made of vegetable parchment? The cement should withstand the action of hot liquids.—DIALYSIS.

MEETINGS FOR THE WEEK.

SATURDAY, 26th.—Physical, 3.
MONDAY, Nov. 28th.—Medical, 8.30.
— Society of Arts, 8. "Some of the Industrial Uses of the Calcium Compounds," by Thos. Bolas, F.C.S.
TUESDAY, 29th.—Institute of Civil Engineers, 8.
WEDNESDAY, 30th.—Society of Arts, 8. "The Distribution of Time by a System of Pneumatic Clocks," by J. A. Berly.
— Royal, 4. Anniversary.
THURSDAY, Dec. 1st.—Chemical, 8.
FRIDAY, 2nd.—Geologists' Association, 8.
— Society of Arts, 8. Discussion on the Society of Arts Patent Bill.

Lists sent on Application.

Photographs, Plans, and other information supplied on receipt of Order.

ST HELEN'S ENGINE, BOILER, AND BRIDGE WORKS AND FOUNDRY, LANCASHIRE.

Carr's Patent Laboratory Mill.

For Chemicals, Drugs, Powders, Minerals, Paints, and General Laboratory Purposes.

Approved by some of the most eminent Chemists, and awarded the Silver Prize Medals of the Manchester and Liverpool, and the Middleton Agricultural Shows.

From Messrs. E. H. Smyth & Co., 21 Duke Street, Edinburgh, and 69, Coleman Street, City, London.—The small Levigator Mill we recently got from you works most efficiently, and is a great economiser of time.

The chief feature in this machine is, that although it can be turned with ease by a boy, it has immense frictional power for levigating purposes. This is caused by the runner being driven at a much greater speed, but in the same direction, than the bowl. The surfaces being Minton ware, they are clean, smooth, and durable.

Testimonials on application.

£11 nett cash, delivered in Manchester.

The diameter of the bowl is 18 ins., and it and the runners are made Minton ware. It is useful for Painters, Chemists, Grocers, and Cooks, for triturating and mixing Medicines, Vegetable Powders, Ointments, Paints, Sugar, Salt, Spices, Herbs, Meat for Potting, and will grind the coarsest Emery into a nearly Impalpable Powder in a few seconds. The pan can be tilted for emptying, as shown in the dotted lines; it can be worked by hand or power.

SOLE MAKERS—

DETECTION OF STARCH SUGAR SYRUP MIXED WITH SUGAR-HOUSE MOLASSES.*

By P. CASAMAJOR

IN previous communications I have given processes for detecting the adulteration of cane-sugar by starch-sugar. The adulteration of sugar-house syrups by starch glucose is still more extensively practised than that of sugar, and a great portion of the syrups sold by retailers in this market is adulterated with starch glucose. This form of adulteration may be very easily detected by the use of strong methylic alcohol, in which the alcohometer of Tralles or of Gay-Lussac will indicate about 93½°.

A straight sugar-house syrup when mixed with three times its volume of this strong methylic alcohol will dissolve by stirring, giving a very slight turbidity, which remains suspended; while syrups containing the usual admixture of starch-sugar give a very turbid liquid, which separates, when left at rest, into two layers, the lower being a thick viscous deposit containing the glucose syrup.

Considerable quantities are sold of a thin syrup, of about 32° Baumé, in which the proportion of sugar to the impurities is greater than in common sugar-house molasses. When a syrup of this kind is stirred with three times its volume of methylic alcohol, a marked turbidity and deposition will take place, which consists of pure sugar. The crystals are hard and gritty. They adhere to the sides of the glass, and are deposited on the bottom. There is no resemblance between this precipitate and that due to starch-sugar syrup.

It may not be useless to mention that if a straight sugar-house syrup of about 40° B. density is stirred with three times its volume of *ethylic* alcohol of about 93½° the syrup will not dissolve. Hence ethylic alcohol of this strength is not suitable for distinguishing a syrup mixed with starch glucose from a *straight* sugar-house syrup.

The presence of starch glucose in sugar-house molasses may be easily detected by the optical saccharometer when the syrup has the usual density of about 40° B., and when starch-sugar has been added in the usual quantities.

For making the test the usual weight should be taken (16·35 grms. for Duboscq's saccharometer, and 26·048 grms. for Ventzke's instrument). The direct test should show a percentage of sugar not higher than the number of Baumé degrees indicating the density, and it may be from 2 to 3 per cent lower. To understand this, we must refer to the composition of cane-sugar molasses of 40° B.:—

Sugar	37·5
Insoluble impurities	37·5
Water	25·00

If the direct test should indicate 55 per cent of sugar, and if the molasses were straight, the composition would be—

Sugar	55
Soluble impurities	20
Water	25

Now a product of this composition would not be a clear syrup at 40° B., but a mixture of syrup and crystals. Therefore if the product is a clear syrup at 40° B., and it tests 55 per cent, it cannot be *straight*.

The presence of starch glucose in sugar-house molasses may also be detected by the copper test. The possibility of applying this test, as well as those already indicated, rests on the fact that starch glucose is always added in very large quantities for the purposes of adulteration. A very small addition could not be satisfactorily detected.

The detection by the copper test rests on the observation that very nearly one-half of the soluble impurities in sugar-house molasses consists of glucose in the shape of inverted sugar. We have seen above that for a molasses of 40° B. the soluble impurities amount to about 37½ per cent. We may, then, lay down the rule: that the percentage of glucose shown by the copper test cannot, in a straight sugar-house molasses, be much greater than one-half of the number expressing the density in Baumé degrees. The reason is obvious from what has been said of the test by the optical saccharometer.

* A Paper read before the American Chemical Society, September 2, 1881.

ATOMIC PHYLLOTAXY.

By PLINY EARLE CHASE.

GERBER (CHEMICAL NEWS, vol. xliii., p. 242-3) says that "no simple relation exists among" his divisors, therefore they "have no value in themselves." There is, however, a relation which he failed to discover, for they are phyllotactic, as will be seen by the following comparison:—

Gerber.		Phyllotactic.	
H ..	0·9997	1-16 O ..	0·998
D_1 ..	0·769	$D_1 = 5\text{-}13\ D_2$ ..	0·768
D_2 ..	1·995	$D_2 = \frac{1}{2}$ O	1·996
D_3 ..	1·559	$D_3 = (\frac{1}{2} \times \frac{2}{3})^2$ O ..	1·559
D_4 ..	1·245	$D_4 = \frac{2}{3} D_2$	1·247

These relations may have an important bearing upon the interpretation of frost crystals and protective mimicry.

Haverford College, Pa., Nov. 10, 1881.

RELATIVE PURITY OF THE CITY WATERS IN THE UNITED STATES.

By Dr. A. R. LEEDS.

A LEGAL suit has recently been instituted, which will probably have a very important bearing in the future upon the quality of the water supplied to many of the principal cities in the United States. To understand more readily the nature of the questions raised in this suit, a few words of previous explanation will be requisite. The three cities of Newark, Jersey City, and Hoboken, with an aggregate population of 300,000 inhabitants, all draw their water supply from the river Passaic. This is a large stream, having a daily flow at Newark of about one million gallons. Its water-shed is mainly granitic in character, and occupies about 950 square miles in the northern part of the state of New Jersey. About 3 miles above the City of Newark, the Belleville pumping-stations are located, and at this point the supplies of the three above-mentioned cities are taken. Some 18 miles farther up the stream is the town of Paterson, a community almost entirely engaged in the manufacture of paper, cotton, woollen, and silk goods, locomotives, &c., and which throws its entire refuse and the sewage of 50,000 inhabitants into the Passaic. Above Paterson there are few villages and factories, so that the water going over the Great Falls at this place is of superior quality for drinking purposes. Below Paterson manufactories are gradually springing up, and are a constant source of uneasiness and alarm to the large population using the water as pumped at Belleville. During the course of the year just passed, one of these factories, an extensive paper-mill, situated on the Third River, a small tributary emptying into the Passaic a short distance above Belleville, threw into the water the refuse derived from washing out some carbolised

paper. The taste and odour of carbolic acid were so strong that they caused a temporary suspension of the use of the Newark, Jersey City, and Hoboken water for drinking. The Newark Aqueduct Board summoned the parties to desist, which they did at the time, but afterwards repeated the offence, when suit was brought against them by the Board. In defence, the plea was entered, and an attempt made to substitute it by the testimony of many manufacturers, that the water was already so badly polluted at Paterson that it could not be made more unfit for drinking purposes by the introduction of some carbolic acid. In fact, it was urged that so far from being rendered any worse by the carbolic acid, it was actually made better, for the reason that the carbolic acid served to purify and disinfect the water. The case was decided in favour of the Aqueduct Board.

The importance of having successfully established such a precedent can scarcely be over estimated in connection with its future influence upon the sanitary welfare of rapidly-growing communities. In this category are to be placed the large cities in the eastern and middle United States, nearly all of which are contending with one phase or another of the evils arising from the crowding in of population, and a population in many instances devoted to manufacturing, upon their sources of water-supply. As a consequence, the problem whether to abandon the original sources, which in most cases are those apparently designed by nature, and seek more distant and expensive ones, or to restrain the pollution by legal processes, is most urgent.

In this connection the author has been asked by the Boards of Water Commissioners of Newark and Jersey City to examine into the amounts of impurities in the river Passaic, beginning with a point above Paterson, and making analyses of samples collected at an interval of a mile, until the stream has passed the City of Newark. The collection was made all upon the one day, at the close of a period of many weeks of almost unexampled drought. The analyses of the forty samples thus collected will show not only the composition of the river-water in its worst condition, but likewise the changes in that composition during a flow of 21 miles.

Connected with this inquiry was the important one of determining the quality of the water-supply as compared with that of other cities. The design was to collect the samples on the same day, and analyse them all by the same methods. It was but partially successful, owing to a failure to obtain simultaneous co-operation in so many places. In the case of Washington, this was due to the fact that Dr. Smith Townsend, the Health Officer of the District of Columbia, at the very time of receiving my telegraphic request was summoned to attend the wounded President in the railroad station at Washington. In the great excitement and general distress the telegram was naturally lost sight of for several days. Neither was it a mode of comparison unexceptionable in point of principle, inasmuch as the climatic conditions were not exactly the same in the various places. So that from the results gathered it would be manifestly unfair to state that the order of purity was fixedly maintained as that given. It could only be said that at the time when the comparison was made, about the 1st of July of this year, such an order existed.

Together with these determinations, a number are given of the water of the River Passaic as delivered at widely different points, and at nearly the same time on the same day, in Jersey City and Hoboken. They show not inconsiderable differences in composition, and illustrate to what extent water may differ when flowing at very different rates of velocity, or in the case of dead ends scarcely at all, in one and the same system of distributing pipes. Nearly all these pipes were of iron, cement pipes being little used. The results given are in parts per 100,000.

The labour of making a comparison was greatly facilitated by plotting these results on a large chart, so as to form a graphic representation of them. From this the following order of relative purity was inferred:—

I. Brooklyn.
II. Rochester.
III. Philadelphia.
IV. Baltimore.
V. Washington.
VI. New York.
VII. Newark, J. City, Hoboken.
VIII. Cincinnati.
IX. Oswego.
X. Wilmington, Delaware.
XI. Boston.

In many particulars the order thus arrived at was quite unforeseen, and was a matter of great surprise. This was more especially true of Boston, which I anticipated would stand nearly at the head of the list, but which actually came at the bottom; and yet the water-sheds of both Brooklyn and Boston are upon drift gravel. A month later I found that the best hotels in Boston, and private citizens who were willing to be at the extra expense, were supplied by spring-water carted into the city and sold at the rate of 10 cents per gallon. This state of affairs continued until the 28th of August, when I visited the city

again, and inspected the Cochituate Lake and the Sudbury and Mystic Rivers, the three sources of supply. The water in the reservoirs supplied by the two latter streams had a yellow colour and disagreeable musty taste and smell. During the earlier portion of the summer all the reservoirs had contained an abundant growth of algæ, which later on had decomposed, leaving behind the bad taste referred to. A striking peculiarity of these Boston waters is the large amount of decomposable organic matters held in solution. These points will best appear by examination of the results of analyses of samples collected on the 29th and 30th of August. (See Table at foot of preceding column).

The causes of the inferior character of the Boston water supply are, first, its pollution by a few manufacturing towns; and, secondly, the growth of algæ; which again, is favoured by the shallow character of portions of the reservoirs and impounded streams. The worst of these sources of pollution is Pegan Brook, which flows through the town of Natick, a town of ten thousand inhabitants almost entirely engaged in the manufacture of shoes, and empties into Cochituate Lake. The attempt has been made to mitigate the evil by throwing two filtering dams across the outlet of the stream, but both the fore-bays thus formed are densely over-grown with the lowest forms of aquatic vegetation, and may to a certain extent act as nurseries for the growth of these plants.

The Rochester water supply is derived from Hemlock Lake, remote from all sources of contamination, and after flowing through conduits for a number of miles is discharged through a noble fountain into a reservoir near the city.

A large portion of the Philadelphia supply is obtained from the river Schuylkill. At one time it was in imminent danger of fatal pollution from the growth of manufactures on the borders of the stream; but the City purchased the lands on both banks, nearly to the factory town of Manayunk, located about seven miles above, and included these lands in a great park so as to keep back all buildings from the water's edge.

New York and all the places mentioned lower on the list receive their water supply from contaminated sources. The feeders which empty into Croton Lake, the principal reservoir of the New York water, pass through a settled country, with numerous tanneries, factories, &c., along their banks. Analyses of the Croton water, made at different seasons during the past five years, have shown that it is to be classed among contaminated water supplies.

On the publication of the results above stated, it was indignantly claimed by the newspaper press of Wilmington, Delaware, that an injustice had been done to their city. But subsequently letters published in reply by citizens of the place have affirmed the correctness of the judgment formed on the analytical data, and have enumerated the various breweries, woollen, cotton, and other mills and dye-houses, as affording a sufficient explanation of the low position assigned to the water-supply.

In conclusion, it is worthy of mention that the different State Governments have passed, or are about passing, laws on the subject of the pollution of water supply, and these laws lean more and more strongly upon the side of public as against private manufacturing interests.

NOTE ON THE

RECOMBINATION OF THE SPECTRAL COLOURS BY A SECOND PRISM REVERSED.

By ALFRED W. SOWARD.

It is well known that if white light be passed through a prism a coloured spectrum is produced, and that if a second similar prism be placed in a reversed position in the path of the spectral rays white light is apparently reformed. But as to how this apparent recombination is effected, a very great misapprehension would appear to prevail. The subjoined figure (1), extracted from a well-known work on physics, well expresses the general belief as to the matter. A moment's consideration will, however, show the impossibility of the light passing through the

FIG. 1.

second prism as depicted. The adjacent sides of the two prisms being parallel to one another, it is evident that the rays 1—2 and 3—4 respectively, must also be parallel to one another; and if the angles be worked out for any particular case it will be found that they are so. Figure 2 then represents the actual state of affairs.

It follows from this that a second prism reversed has not the power of re-compounding the spectral rays to form white light, but merely of rendering them parallel. The

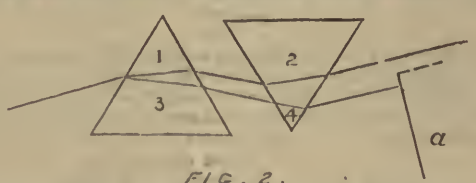

FIG. 2.

light incident upon the first prism is of the same composition throughout; if any portion be shaded off the residue is still white. Whereas the light emitted from the second prism has not a uniform composition; if one side be shaded off (as by the screen *a*) the residue is coloured.

That the light issuing from the second prism appears white is probably an effect due to the eye. Imagining the slit from which the light issues to be made up of a great number of physical points, each point would send forth its light, which would be decomposed by the first prism, rendered parallel by the second prism, re-compounded by

the lens of the eye, and focussed upon the retina as a white image of the physical point from which it emanated. In this way there would be built up upon the retina a white image of the slit.'

NOTICE OF A PHOSPHORUS OXYIODIDE.

By BEVERLEY S. BURTON.

HAVING frequently observed, on closely examining the residue in the retort after preparing ethyl iodide, minute golden scales, I was induced to examine these more closely. To this end the residue was treated with water and filtered from the excess of red phosphorus; the filtrate was then evaporated on the water-bath.

When quite concentrated, and allowed to cool, a quantity of granular red crystals was deposited, which were purified by drying on filter-paper and re-crystallisation untill all free iodine was perfectly removed. On one occasion the crystals were obtained much larger, with brilliant facets: the form was not determined. It is very soluble in water, alcohol, and ether, the solution being perfectly colourless. This property is made peculiarly striking when the dish is simply wet with the solution and placed on the water-bath, thus becoming almost instantly a deep orange colour to a beautiful scarlet, which again disappears when held a moment in the steam.

On heating, the crystals melt to a deep reddish brown crystalline mass, the melting-point being 140°.

By increasing the heat yellowish vapours are given off which blue starch-paper. These vapours condense on a cold surface as a yellowish red crystalline deposit, which behaves in all respects as the original body, *i.e.*, sublimes, in part, unaltered.

The portions used in the further examination were purified perfectly from all free iodine and dried over sulphuric acid. It being found that a solution of the body was conpletely decomposed by silver nitrate, the method of analysis was the following:—

An excess of silver nitrate was added to the solution, the separated silver iodide filtered off, and the excess of silver in the filtrate separated by hydrochloric acid. To the filtrate, free from silver, an excess of sodium carbonate was added, also a little sodium nitrate, then the whole evaporated to dryness and fused. The solution of the fused mass is then precipitated with magnesia mixture, any alumina or silica which might separate on addition of ammonia being previously removed.

The following results were obtained:—

	I.	II.
I	77·93	77·44
P	9·66	9·71
O	12·41	12·85
	100·00	100·00

Corresponding to the formula $I_6P_3O_8$. On one occasion this body was also observed in the residue from the preparation of fuming hydriodic acid; it was extracted, purified, and the analysis made as above described, yielding the following:—

I	81·91	81·88
P	8·36	8·22
O	9·73	9·90
	100·00	100·00

Corresponding to I_2PO_2, or, for better comparison with the above, $I_8P_4O_8$.

As it was considered not improbable that hydrogen might enter into its composition, a combustion was made, the substance being introduced in a boat before which was laid copper oxide, a long layer of lead chromate, and a silver spiral, but the amount found was too minute to be regarded.

I would mention here that in the preparation of methyl iodide the same body is apparently formed; but on attempting to purify in the same manner, a brown residue remained on treating with water. This was filtered off, and on evaporating the filtrate the crystals before noticed were not formed, but yellow flocks resembling freshly precipitated arsenic sulphide separated, which behaved very differently from that previously obtained.

An attempt to prepare this compound was made by leading phosphine gas, evolved by the action of water upon phosphonium iodide, into a solution of iodine in hydriodic acid, but so far without success. Owing to the very small quantities at disposal, and the want of a method of preparation, its more exact constitution cannot be given. As at present no definite formula seems to be indicated, any speculations as to the nature of this body, or whether possibly two or more exist, are premature.

Its further study will be continued at the earliest opportunity.—*American Chemical Journal.*

VI. REVISION OF THE ATOMIC WEIGHT OF CADMIUM.

By OLIVER W. HUNTINGTON, *of the Senior Class.*

The method adopted by Professor Cooke for verifying the value of the atomic weight of antimony, described previously, proved to be so definite and conclusive, that it seemed desirable to apply it in all other cases to which it was suited, in order not only to verify the received values of the atomic weights, but also to test more fully the hypothesis of Prout, an hypothesis to which recent investigation and speculations have given renewed interest.†

The method of Professor Cooke is applicable to all those elements of which a pure, stable, well-defined, and soluble bromide can be prepared. It consists in determining in one series of analyses the bromine of the compound as bromide of silver by the usual gravimetric method with the precautions already described; and in another series of experiments, or in the same analyses, when practicable, determining the amount of silver required to precipitate the bromine. We thus obtain not only the relation of the atomic weight sought both to that of bromine and to that of silver, but also the relation between the atomic weight of bromine and that of silver; and since all experimenters agree on this last ratio to within one ten-thousandth of its value it is evident that the comparison of the two series of results gives a sharp control of the accuracy of the work.

Professor Cooke assigned to me the atomic weight of cadmium as my portion of the work he had planned on the revision of the atomic weights, and this investigation was made with his aid and under his immediate direction. Bromide of cadmium fulfils all the conditions which the new method requires; and, since the accepted value of the atomic weight of cadmium is a whole number, it seemed probable that a revision of this value by a more exact process would bring additional evidence in support of the hypothesis of Prout.

Having found that bromide of cadmium could not readily be purified by repeated crystallisations on account of its very great solubility in water, we sought to obtain a pure

* Presented to the American Academy of Arts and Sciences, May 11, 1881.

† See Revision of the Atomic Weight of Aluminum, by J. W. Mallet, *Philosophical Transactions*, part iii., 1880: also various papers by J. Norman Lockyer on the disassociation of the chemical elements in *Nature* and in the *Proceedings of Royal Society*; also Cooke's "Chemical Phi osophy," revised edition, page 272.

compound by preparing pure carbonate of cadmium on the one hand and pure hydrobromic acid on the other.

To prepare pure carbonate of cadmium the commercial metal was first dissolved in pure hydrochloric acid. From this solution, still strongly acid, sulphide of cadmium was precipitated by sulphide of hydrogen and the precipitate thoroughly washed with hot distilled water. The sulphide having been re-dissolved in hydrochloric acid, and the resulting sulphide of hydrogen expelled by boiling, the cadmium was next precipitated as carbonate by carbonate of ammonia, and the precipitate digested with a large excess of this reagent. The white carbonate thus obtained was thoroughly washed and re-dissolved in hydrochloric acid, and the same series of precipitations repeated. Lastly, in order to remove any possible trace of adhering chloride, the carbonate of cadmium which had thus been twice precipitated by carbonate of ammonia, and twice digested with a large excess of this reagent, was dissolved in pure hydrobromic acid, and a third time precipitated and digested with pure carbonate of ammonia.

The hydrobromic acid used in this investigation was made by the process described by Dr. Edward R. Squibb, of Brooklyn, in the *Transactions of the Medical Society of the State of New York*.* In order to purify the acid, it was repeatedly re-distilled with a small amount of a concentrated solution of bromide of potassium, rejecting each time the distillate until the boiling-point rose to 128°; when, as is well known, an acid containing about 47 per cent of HBr distils unchanged. The acid thus obtained was as colourless as water.

Meanwhile, in order to test the purity of the hydrobromic acid and also as a basis for the rest of our investigation, we prepared a quantity of pure silver by the method already fully described, and with the pure silver thus prepared the following two setsof determinations were made.

For the first set, weighed amounts of silver were dissolved in very carefully purified nitric acid, using only a very slight excess of this solvent in any case. We prepared for the purpose a dilute acid by mixing one part of acid, having sp. gr. 1·355, with four parts of water and of this weak acid 5·3 c.m.³ were required for each gramme of silver. We were thus able to estimate the amount necessary for each analysis, and we used generally one half a cubic centimetre in excess.

The silver having been perfectly dissolved, and the solution diluted with water to from 200 to 500 cubic centimeters according to the amount of silver used, we gradually and cautiously precipitated bromide of silver by adding pure hydrobromic acid, prepared as just described, but greatly diluted until the acid was very slightly in excess. For the method of washing and collecting this precipitate, we may refer to vol. xii. page 124, of the *Proceedings of the American Academy of Arts and Sciences*.

The results were as follows:—

	Weight of Silver.	Weight of Bromide of Silver.	Per Cent of Silver.
1.	1·4852 grms.	2·5855 grms.	57·444
2.	1·4080 ,,	2·4510 ,,	57·446
3.	1·4449 ,,	2·5150 ,,	57·451
	Mean value		57·447

* "The formula and process for making an acid of this strength are as follows:—

Take of potassium bromide .. .. 6 parts
Sulphuric acid, sp. gr. at 15·6° C. 1·838, at 25° C. 1·828 .. 7 parts
Water .. .. 9 parts

"Add to the sulphuric acid one part of the water and cool the mixture. Then dissolve the potassium bromide in six parts of the water by means of heat, supplying the loss of water by evaporation during the heating. Pour the diluted sulphuric acid slowly into the hot solution with constant stirring, and set the mixture aside for twenty-four hours, that the sulphate of potassium may crystallise. Pour off the liquid into a retort, break up the crystalline mass, transfer it to a funnel, and, having drained the crystals, drop slowly upon them two parts of the water so as to displace and wash out the acid liquid. Add the liquid, thus drained off and washed out, to that in the retort, and distil the whole nearly to dryness, or until nothing further distils off by moderate heating. The distillate will weigh about ten parts and should contain about thirty-seven per cent of hydrobromic acid.

For the second set of experiments bromide of silver, precipitated, washed, and dried as described (*loc. cit.*), was melted in a platinum crucible, and then reduced by a voltaic battery under dilute sulphuric acid. This process was devised and perfected by Mr. L. P. Kinnicutt, Assistant in this Laboratory, who had the great kindness to conduct the reduction in the following determinations:—

	Weight of Bromide of Silver.	Weight of Silver.	Per cent of Silver.
1.	4·1450 grms.	2·3817 grms.	57·444
2.	1·8172 ,,	1·0437 ,,	57·434
3.	4·9601 ,,	2·8497 ,,	57·449
		Mean value	57·442

These results show conclusively the great accuracy of Mr. Kinnicutt's process, which he will describe in detail in another place. The mean of the two sets of results gives for the per cent of silver 57·445, the theoretical per cent (Ag=108 and Br=80) being 57·446. If we throw out No. 2 of second series, which is obviously less trustworthy than the other two determinations of the same series, on account of the comparatively small amount of material used, the mean of the remaining five determinations corresponds absolutely to theory, and the total result, therefore, leaves no doubt whatever, as to the absolute purity of the materials employed.

Bromide of cadmium was now prepared by dissolving pure carbonate of cadmium in pure hydrobromic acid, and subliming the product previously dried at 200° in a current of pure and perfectly dry carbonic dioxide gas. The carbonic dioxide was prepared by mixing bicarbonate of soda and sulphuric acid with a large volume of water in a strong generator, and drawing off the gas under pressure through appropriate washers and driers; and the apparatus used for subliming the bromide of calcium was similar to that described in the *Proceedings of the American Academy of Arts and Sciences* (vol. xiii., p. 57), using, however, a porcelain tube heated by a gas furnace in place of a tube of glass. The bromide of cadmium when thus sublimed crystallises in pearly scales around the open mouth of the tube.

Prepared as we have described, anhydrous bromide of cadmium is a splendid preparation. The precise form of the highly lustrous crystals could not be distinguished, but the scales are tabular crystals having a single optical axis normal to the extended face of the scales, and having a high negative double refracting power. Although so soluble, the crystals are not sensibly hygroscopic, and can be weighed on an open watch-glass without the slightest variation of weight during the process. They dissolve at once in water without leaving a trace of residue.

The following determinations were all made with the material we have described, and since only a few grains could be sublimed at a time the separate analyses were made with the products of nearly as many sublimations. Some of the material was sublimed twice, and the constancy of the composition under these circumstances is the best proof possible of the definiteness of the compound. The results of the analyses may be classed under two heads.

In one series of determinations the bromide of antimony, whose weight had been accurately determined, having been dissolved in pure water in a stoppered flask, a little less than the calculated amount of silver required to precipitate the bromide was carefully weighed out and dissolved in a measured amount of weak nitric acid, allowing, as before described, a slight excess. This solution properly diluted was then gradually added to the solution of bromide of cadmium under constant agitation, in order to avoid the aggregation of the bromide of silver in lumps. The agitation was frequently renewed until the precipitate settled, and then a standard solution of silver (1 grm. to the litre) was cautiously added until the precipitation was complete, and the last drops did not produce the faintest opalescence after standing. The precipitate was now

washed by decantation five times successively, using each time a volume of cold distilled water equal to the volume of the original solution, and pouring off the water into a porcelain crucible, from which it was drawn by the reverse filter. Finally, the precipitate was washed into the crucible, and, after drying at from 120° to 130°, weighed with the small filter.

In a second series the determinations were conducted in the same way as in the first, excepting that the chief attention was directed to determining the exact point of complete precipitation. In several cases, indicated by an asterisk, both the amount of silver required and the amount of argentic bromide formed were determined in the same experiment; but this was not always practicable.

7.	3·6510 ,,	2·8951 ,,	112·39
8.	3·9782 ,,	3·1551 ,,	112·35
	Mean value		112·32

As can easily be calculated according to the mean of the first series of determinations, 1·0000 grm. of bromide of cadmium gives 1·3808 grms. of argentic bromide, and according to the mean of the second series 1·0000 grm. of bromide of cadmium requires for complete precipitation 0·7932 grm. of silver. Hence, as a mean of these experiments, 0·7932 grm. of silver yields 1·3808 grms. of argentic bromide, and therefore corresponds to 0·5876 grm. of bromine. Moreover, since—

0·7932 : 0·5876 = 108·000 : 80·006,

it follows, with a very high degree of probability, that—

Ag : Br : Cd = 108·00 : 80·00 : 112·31,

within one ten-thousandth of the value of either quantity. It must of course be regarded as absolutely proved that, in the material analysed, the proportion of bromine to the remainder of the mass, assumed to be pure cadmium, is as 2 × 80·00 to 112·31, but it is always conceivable that the material used contained some unknown impurity. In the present case, however, such an assumption is highly improbable; first, because such extreme care was taken in the preparation; secondly, because the products of the different sublimations were so constant in composition; and, thirdly, because the presence of any of the metals usually associated with cadmium would tend to lower and not to raise the apparent atomic weight. If any impurity is present it would seem as if it must be some unknown element; and only on such a bare chance as this can the evidence be invalidated which the results of this investigation furnish against the hypothesis of Prout.—*Proceedings of the American Academy of Arts and Sciences.*

PROCEEDINGS OF SOCIETIES

PHYSICAL SOCIETY.

Saturday, November 26th, 1881.

Prof. W. G. Adams in the Chair.

Mr. C. Vernon Boys read a paper on "*Integrating Apparatus.*" After referring to his original "cart" machine for integrating, described at a former meeting of the Society, he showed how he had been led to construct the new machine exhibited, in which a cylinder is caused to reciprocate longitudinally in contact with a disk, and give the integral by its rotation. Integrators were of three kinds—(1) radius machines; (2) cosine machines; (3) tangent machines. Sliding friction and inertia render the first two kinds unsuitable where there are delicate forces or rapid variation in the barometer to be integrated. Tangent machines depend on pure rolling, and the inertia and friction is inappreciable. They are therefore more practical than the other sort. It is to this class that Mr. Boys's machines belong. The author then described a theoretical tangent integrator depending on the mutual rolling of two smoke rings, and showed how the steering of a bicycle or wheelbarrow could be applied to integrate directly with a cylinder either the quotient or product of two functions. If the tangent wheel is turned through a right angle at starting, the machine will integrate a reciprocals or it can be made to integrate functions by an inverse process. If instead of a cylinder some other surface of evolution is employed as an integrating surface, then special integrations can be effected. He showed a polar planimeter in which the integrating surface is a sphere. A special use of these integrators is for finding the total work done by a fluid pressure reciprocating engine. The difference of pressure on the two sides of the piston determines the tangent of the inclination of the tangent wheel which runs on the integrating cylinder, while the motion of the latter is made to keep time with that of the piston. In this case the number of revolutions of the cylinder measures the total amount of work done by the engine. The disk cylinder integrator may also be applied to find the total amount of work transmitted by shafting or belting from one part of a factory to another. An electric current meter may be made by giving inclination to the disk, which is for this purpose made exceedingly small and delicate, by means of a heavy magnetic needle deflected by the current. This, like Edison's, is a direction meter; but a meter in which no regard is paid to the direction of the current can be made by help of an iron armature of such a shape that the force with which it is attracted to fill the space between the poles of an electro-magnet is inversely as its displacement. Then by resisting this motion by a spring or pendulum the movement is proportional to the current, and a tangent wheel actuated by this movement causes the reciprocating cylinder on which it runs to integrate the current strength. Mr. Boys exhibited two such electric energy meters, that is, machines which integrate the product of the current strength by the difference of potential between two points with respect to time. In these the main current is made to pass through a pair of concentric solenoids, and in the annular space between these is hung a solenoid, the upper half of which is wound in the opposite direction to the lower half. By the use of what Mr. Boys calls "induction traps" of iron, the magnetic force is confined to a small portion of the suspended solenoid, and by this means the force is independent of the position. The solenoid is hung to one end of a beam, and its motion is resisted by a pendulum weight, by which the energy meters may be regulated like clocks to give standard measure. The beam carries the tangent wheels, and the rotation of the cylinder gives the energy expanded in foot-pounds or other measures. The use of an equal number of turns in opposite directions on the movable

solenoid causes the instrument to be uninfluenced by external magnetic forces. Mr. Boys showed on the screen an image of an electric arc, and by its side was a spot of light, whose position indicated the energy, and showed every flicker of the light and fluctuation of current in the arc. He showed on the screen that if the poles are brought too near the energy expended is less, though the current is stronger, and that if the poles are too far apart, though the electromotive force is greater the energy is less; so that the apparatus may be made to find the distance at which the greatest energy, and so the greatest heat and light, may be produced.

At the conclusion of the paper, Prof. W. G. Adams and Prof. G. C. Foster could not refrain from expressing their high admiration of the ingenious and able manner in which Mr. Boys had developed the subject.

AMERICAN CHEMICAL SOCIETY.*

November 4, 1881.

Dr. Albert R. Leeds in the Chair.

The minutes of previous meeting were read and approved, after which the following gentlemen were elected as active Members:—Dr. C. W. Volney, Prof. R. A. Witthaus, C. E. Munsell, Nelson H. Darton, W. W. Share, and T. D. O'Connor.

As there were no new members to nominate, the next in order was the report from the Nominating Committee. This had to be deferred, however (as Dr. Endemann, the Chairman of said Committee, was absent), till Dr. Geyer and Mr. Casamajor had made out a list of candidates.

The Recording Secretary then announced the resignation of Prof. W. W. Wiley, which was duly accepted. After which the Recording Secretary read the death of Mr. Chas. Schmick, who died of pneumonia in March, 1881. It was then moved that Mr. Schmick's death be entered on the minutes. Carried unanimously.

The first paper of the evening, "*On some New Salts of Alpha-thymol-sulpho-acid, and some New Facts concerning the same*," by James H. Stebbins, jun., S.B., was then read. Mr. Stebbins in the course of his lecture described the calcium, ammonium, and soda salts of alpha-thymol-sulpho-acid, and likewise the free sulpho-acid, which was obtained by decomposing the lead salt with sulphuretted hydrogen. The calcium salt shows a beautiful effect of circular polarised light.

After some questions by Mr. Elliott, the second paper of the evening, "*On the Combination of Diazo compounds with Alpha-thymol-sulpho-acid*," by James H. Stebbins, jun., S.B., then followed. The following compounds were described:— Azo-benzol-alpha-thymol-sulpho-acid,

$$C_6H_5-N=N-C_6H(CH_3)(C_3H_7)(HSO_3)OH,$$

produced by the action of diazo-benzol chloride on an alkaline solution of alpha-thymol-sulpho-acid. Para-azo-toluol-alpha-thymol-sulpho-acid,—

$$C_6H_4(\overset{4}{CH_3})-N=N-\overset{1}{a}C_6H(CH_3)(C_3H_7)(HSO_3)OH,$$

produced by the action of para-diazo-toluol-chloride upon an alkaline solution thymol-sulpho-acid. Azoxylol-alpha-thymol-sulpho-acid,—

$$C_6H_3(CH_3)_2-N=N-aC_6H(CH_3)(C_3H_7)(HSO_3)OH,$$

produced by the action of diazo-xylol chloride upon an alkaline solution of alpha-thymol-sulpho-acid.

After some questions by Messrs. Elliot and Friedburg, the third paper, "*On the Constitution of the Explosive Derivatives of Glycerin*," by Dr. Volney, was then read. Some questions by Dr. Friedburg and others then followed.

The report of the Nominating Committee was now ready, and the following gentlemen were duly nominated for the coming elections:—For Corresponding Secretary—Mr. P. Casamajor. For Treasurer—M. Alsberg. Recording Secretary—James H. Stebbins, jun. Librarian—Dr. E. Waller. For Curators—Messrs. Rossi, Fesquet, and Rupp. For Committee on Nominations—Arthur H. Elliott, J. F. Battershall, O. H. Krause, Mr. Herreshoff, and T. O'C. Sloane. Committee on Papers and Publications—Arno Behr, A. R. Ledoux, H. Endemann. As Directors—P. Casamajor, James H. Stebbins, jun., H. Morton, C. F. Chandler, M. Alsberg, E. R. Squibb, W. H. Nichols, W. M. Habirshaw, Elwyn Waller, H. Endemann, August Eimer, Geo. Prochazka.

The meeting then adjourned.

* Communicated by James H. Stebbins, jun., Recording Secretary.

NOTICES OF BOOKS.

Elementary Treatise on Physics, Experimental and Applied, for the Use of Colleges and Schools. Translated and edited from Ganot's "Eléments de Physique," by E. Atkinson, Ph.D., F.C.S., Professor of Experimental Science, Staff College, Sandhurst. Tenth edition, revised and enlarged. London: Longmans and Co.

When a book like this has already reached its tenth edition it may well claim to be beyond the scope of criticism, as having won the approval of such competent judges as the professors of experimental science in our leading colleges. Nor can our readers expect much to be said by way of description of a work so well known. The various branches of physics are here arranged in the following order:—The phenomena depending upon gravitation,—included by some methodologists under the name "barology," and by others as dynamics, but here not included under any general head,—acoustics, heat, light, magnetism, and electricity. This classification agrees with that of Comte, save that the latter intercalates acoustics between thermics and optics—an arrangement not in harmony with his law of decreasing generality.

The present edition contains a considerable amount of additional matter descriptive of recent discoveries, and may be pronounced fairly on a level with the present state of science. A few points may be noticed in which the editor has adhered too closely to the French original. Thus we regret to see the term "Daltonism" retained as a name for colour blindness. It is offensive, inexpressive, and utterly needless. In speaking of hydrometers, that of Beaumé is described in place of the direct specific gravity instrument, or of Twaddle, both of which are not merely much more generally used in England, but are admitted to be more rational by foreign technologists, such as the late Prof. Bolley.

It might also have been well, in speaking of the lactometer, to have shown that the reason of its worthlessness lies not so much in the varying density of milk in its natural state, as that the abstraction of the cream raises the specific gravity, which can then be restored to its original standard by admixture with water.

The experimental results of MM. Cailletet and Pictet are duly noticed, and though "permanent gases" are mentioned in the index, a reference to the text shows that no such class of bodies exists.

The account of recent improvements in the electric light is perhaps as complete as the quantity of space at the editor's disposal would allow. The Jablochkoff "candle" and the Werdermann and the Regnier lamps are described, though we have no mention of the Swan, the Siemens, or the Brush systems.

The work is admirably illustrated with 844 woodcuts and 4 coloured plates; the table of contents and the index are accurate and copious, and we have not observed any typographical errors. The present edition well deserves an increase of the approval which has been awarded to its predecessors.

An Elementary Treatise on Electricity. By James Clerk Maxwell, F.R.S. Edited by W. Garnett, M.A. Oxford: Clarendon Press. London: H. Frowde.

We have here a posthumous work by one who was not merely an eminent and successful physicist, but a profound and philosophic thinker, careful to draw no unwarranted conclusions from phenomena, and soundly critical in methods either for ascertaining new truths or for displaying those already established in their organic connection. It appears from the editor's preface that eight of the thirteen chapters of the present work were found in a complete condition. Chapters IX. and X. were nearly perfect, though some references, tables, and a small part of the text were still wanting. The remaining three chapters have been completed by the introduction of matter from Professor Maxwell's earlier and larger work, "Electricity and Magnetism," the continuity of the whole being preserved as well as possible. The fragmentary portion of the author's preface which has been discovered is important as showing the point of view of the present volume. He tells us that its aim is different from that of his larger treatise on electricity and magnetism. In that treatise the reader is assumed to be familiar with the resources of the higher mathematics, and the course of study laid down is calculated to give him the power of dealing mathematically with the various phenomena of the science. In the work before us such methods are not employed; the author has sought to present concisely and compactly such phenomena as appear to throw light on the theory of electricity, using them successively for the development of clear ideas in the reader's mind. There is a further difference between the two works. In the earlier the author has employed certain methods, not as being in themselves the best, but as necessary for the student if he is to follow the investigations of those physicists who have founded the mathematical theory of electricity. Professor Maxwell subsequently became more convinced of the superiority of the class of methods used by Faraday, and has therefore used them from the outset.

The first chapter opens with experiments showing electrification by friction, the electrification of a conductor, positive and negative electrification, the nature and use of Volta's electrophorus and of the gold-leaf electroscope. By means of these experiments the author is able to explain electromotive force, which is defined as whatever produces or tends to produce a transfer of electrification; the meaning of the term potential, which he defines thus:—Electromotive force from any point along a path drawn in air to a certain point chosen as a point of reference is called the potential at that point. We find here a useful caution against a common and misleading expression:—"We may introduce once for all the common phrase *The Electric Fluid* for the purpose of warning our readers against it. It is one of those phrases which, having been at one time used to denote an observed fact, was immediately taken up by the public to connote a whole system of imaginary knowledge. As long as we do not know whether positive or negative electricity, or both, should be called a substance or the absence of a substance, and as long as we do not know whether the velocity of an electric current is to be measured by hundreds of thousands of miles in a second or by an hundredth of an inch in an hour, or even whether the current flows from positive to negative, or in the reverse direction, we must avoid speaking of the electric fluid." We find here also an explanation of equipotential surfaces, and a further illustration of the idea of electric potential by comparison with pressure in the theory of fluids and with temperature in the theory of heat.

In the second chapter we find further experiment on an electrified body within a closed vessel; on the comparison of the charges or total electrification of two electrified balls, proving the electrification of the inside of a closed vessel equal and opposite to that of the enclosed body, and showing how to discharge a body completely and to charge with any given multiple of a particular charge. In this manner the author displays electric charge as a quantity capable of being measured, and demonstrates five of the principal laws of electric phenomena.

The third chapter is composed of deductions from these facts, treating on electric work and energy. Those readers who have not some acquaintance with elementary mathematics may, according to the author's recommendation, omit this chapter in their first perusal of the work.

The fourth chapter is devoted to the electric field and the methods for its electrification. In the following chapters the author treats successively of Faraday's law of lines of induction, of particular cases of electrification, of electrical images, capacity, the electric current in metals, electrolysis, and dielectrics, the phenomena of an electric current which flows through heterogeneous media, the maintenance of an electric current, the measurement of electric resistance, and on the electric resistance of substance.

For the student who wishes to obtain a really sound knowledge of electricity we say emphatically, this is the book. We may add that even the accomplished physicist, who is already acquainted with every fact here described, and with every law laid down, cannot fail to find here an intellectual treat of no mean order. It is a pleasure to see how clearly the phenomena are described and arranged, and how happily they are made to establish the generalisations of the science.

Manchester Mechanics' Institution. Syllabus of Classes, 1881-82. Manchester: A. Ireland and Co.

The Manchester Mechanics' Institution is, we believe, one of the most efficient and successful establishments of its class. It has more distinctly than many kept in view the original object expressed in the first paragraph of this pamphlet, viz., "To instruct the people in the principles of the Arts they practise, and in other branches of sound and useful science and learning," and now offers very great facilities to students. Turning naturally to the Science Department, we find that there are special classes for sound, light, and heat, for electricity and magnetism, in both which the text-book for the more advanced grade is Deschanel's "Natural Philosophy"; for inorganic and organic chemistry; for geology, mineralogy, and metallurgy. There are also technical classes for the subjects of telegraphy and telephony, photography, and a school of dyeing conducted by Mr. C. O'Neill, whose introductory lecture we notice elsewhere.

Introductory Lecture to a Course of Technical Instruction in Dyeing, Calico-printing, and Bleaching. By C. O'Neill, F.C.S. Manchester: John Heywood.

It appears that in connection with the Manchester Mechanics' Institution a laboratory for instruction in the tinctorial arts has been opened. In the introductory lecture before us, which appears to have been delivered a year ago, Mr. O'Neill does not take a very sanguine view of the benefits to be derived from technological instruction, or even the need of it, in this country. The dyers, &c., of Manchester it seems are less thoroughly convinced than their neighbours in Leeds and Bradford that we have any room for improvement. We read here—"When a manufacturer is shown something in dyed work or in prints superior to his own productions, he will most usually say that he could do that if it suited him to do it, but he prefers to stick to what he is doing and leave to others the fancier styles. This reminds us of the assertion of a certain poet of low degree that he could write as well as Shakespeare if he had a mind. Does it not seem as if our sticking to inferior work—to the "cheap and nasty" styles—was not quite a matter of choice on our part? Was it not declared by independent judges, *e.g.*, that at the last Paris Exhibition certain alizarin-red grounds produced in Russia were superior in brightness to anything of English origin?

Again—"I never heard from manufacturers the complaint that they suffered from an inferiority of technical knowledge either in themselves or in their employees." Now it is well known that a man in any business or art is generally the very last to perceive his own shortcomings. These are generally detected by others. But admitting for argument's sake that the Polytechnic Schools of Germany, Switzerland, &c., have not succeeded in raising the manufacturers and foremen of those countries to a position superior to our own, is that any reason that we should rest on our oars and leave improvement to accident or to the desultory action of individuals? But we certainly should have thought that by this time the progress made on the Continent would have startled the most self-complacent disciple of rule-of-thumb from his dreams, and silenced his sneers against "theorists." It seems we were mistaken, and we own it with sorrow.

CHEMICAL NOTICES FROM FOREIGN SOURCES.

NOTE.—All degrees of temperature are Centigrade, unless otherwise expressed.

Comptes Rendus Hebdomadaires des Séances, de l'Académie des Sciences. No. 18, October 31, 1881.

This issue contains no chemical or physical matter.

No. 19, November 7, 1881.

Limits of Electrolysis.—M. Berthelot.—It is known that the researches of Joule and Favre have established relations between the electro-motor forces and the combining-heats of the metals, but the application of these laws to the electrolysis of salts is often very obscure, especially when secondary actions are produced and it is required to know the exact sum of all the energies which concur in the electrolytic phenomenon. Physicists admit at present that the electrolysis of potassium sulphate takes place in the same manner as that of copper sulphate. The metal goes to the negative pole, and the sulphuric acid to the positive. If the metal does not decompose water, it is precipitated on the electrode; otherwise it is replaced by hydrogen, as happens with potassium sulphate. The electro-motor force necessary to produce the electrolysis may be calculated in three different manners, which the author gives in detail, and the last of which agrees with his experimental results.

Combustions effected by Nitrogen Binoxide.—M. Berthelot.—An important thermo-chemical paper, not suitable for abridment.

Synthetic Experiments on the Artificial Reproduction of Meteorites.—F. Fouqué and Michel Lévy.—By means of igneous fusion the authors have succeeded in reproducing two types of crystalline associations, which, in their mineralogical composition and the principal features of their structure, are analogous if not identical with certain oligosideric meteorites. The only notable difference results from the habitual brecchoid state of the meteorites, which contrasts with state of quiet solidification of the artificial compounds.

Silica and Lithium Silicates.—P. Hautefeuille and J. Margottet.—The authors have obtained three crystalline lithium silicates—$SiO_2 2LiO$, $SiO_2 LiO$, and $5SiO_2 LiO$. The two former are acted on by acids, whilst the third resists the action of concentrated acids; they are almost as infusible as the magnesium silicates. At high temperatures they become very fluid and absorb much heat, which they evolve again at the moment of their solidification. Melted lithium chloride has enabled the authors to establish that silica may take the form of quartz in presence of a melted chloride.

The Yield and the Limit of the Operation of the Transfer of Power by means of Electricity.—M. Maurice Lévy.—Two purely mathematical papers, not capable of abstraction.

Possibility of Electric Equilibrium.—Lucien Lévy

Experimental Method for the Determination of the Ohm.—G. Lippmann.—This memoir requires the accompanying illustration.

The Action of Cold on the Voltaic Arc.—D. Tommasi.—When the voltaic arc plays between two metallic rheophores, of copper for instance, each formed of a U-tube traversed by a rapid current of cold water, and placed horizontally opposite each other, the following facts are observed:—The luminous power of the arc is considerably weakened; it is reduced to a mere luminous point even when a current of 50 to 75 Bunsen elements of the large pattern is employed. The arc is very unstable and the least breath is sufficient to distinguish it. If a leaf of paper is placed above the arc at the distance of 0·004 to 0·005 metre a black point is produced in a few moments, which spreads and becomes a perforation, but the paper does not ignite. The arc consists of a luminous globule, moving between the two rheophores up and down and back again. The form of this globule, as well as its extreme mobility, cause it to resemble a drop of water in the spheroidal state. If we approach to the voltaic arc the south pole of a magnet the arc is attracted to such a degree that it leaves the rheophores and is extinguished. The same facts are observed in an inverse form on presenting the north pole of a magnet to the arc. The quantity of ozone seems greater than when the arc is not refrigerated. It is to be noted that notwithstanding the refrigeration of the rheophores the flame of the arc is slightly green, proving that a portion of the copper is burning. It becomes a question whether the arc would be produced on taking as rheophores two tubes of platinum in which is caused to circulate, *e.g.*, alcohol cooled to $-30°$.

An Electric Method of Determining by means of a Needle the Position and the Depth of a Projectile or other Metallic Substance in the Human Body.—A. Graham Bell.—The substance of this communication is already well known.

Cuproso-cupric Sulphite.—A. Etard.—This double sulphite is obtained by passing a rapid current of sulphurous acid into a solution of cupric acetate saturated in the cold and kept at 65°. The passage of the gas is stopped when the liquid which was at first turbid becomes clear, and the salt in question is deposited as a crystallo-granular precipitate.

Hydrated Chromium Bromide.—M. Varenne.—The author obtains this compound, $Cr_2Br_3 + 16HO$, by submitting a hot and concentrated solution of potassium or ammonium trichromate to the action of dilute hydrobromic acid. The liquid, if left to stand at a temperature near 0°, deposits the new compound in fine violet crystals.

The Action of Hydracids upon the Alkaline Chromates.—L. Varenne.—An examination of the especial action of hydrofluoric acid upon the alkaline trichromates.

Reply to M. Debray's Observations on the Dissociation of Ammonium Hydrosulphate.—MM. Engel and Moitessier.—A question of priority.

Artificial Peridote produced in Presence of Watery Vapour at the Ordinary Pressure.—St. Meunier.—The author's method consists in exposing the metal to be silicated to the simultaneous action of a red heat, of steam, and of silicium chloride.

Modifications in the Composition of Green Forage Preserved in "Silos."—G. Lechartier.—There is a slight decrease in the percentage of nitrogenous matter, whilst an increase in ammonia shows an incipient decomposition of the albumenoids. There is a more considerable loss of glucosides and an increase of fatty matter.

Vapour Tensions of Ammonium Carbamate.—M. Isambert.—The law announced by MM. Engel and Moitessier (*Comptes Rendus*, xciii., p. 395) does not agree with the experimental results of the author.

Action of Hydriodic Acid upon Propylene Chloro-iodide and Isopropyl-chloride.—R. D. Silva.—The results of the reaction is isopropyl-iodide.

Justus Liebig's Annalen der Chemie,
Band 209, Heft 1.

Addition-Products of Atropic Acid.—G. Merling.—The author has obtained a β and an α hydrochloratropic acid. The former of these is obtained by the combination of atropic acid with hydrochloric acid, either at 100° or in the cold. It melts at 87° to 88°, and is decomposed at 170°. On boiling with an alkaline carbonate or with water it yields chiefly tropic acid along with small quantities of styrol and atropic acid. The α acid is formed by the action of hydrochloric acid upon atrolactic acid. It melts at 73° to 74°, decomposes at 110°, and yields no styrol when boiled with an alkaline carbonate. He has also obtained and described a β and an α hydrobrom-atropic acid and a β amido-hydratropic acid.

Diabetic Aceton-urea.—Dr. A. Beichmüller.—In a fatal case of diabetes, 40 litres of urine, giving a red reaction with ferric chloride, yielded 22·5 grms. of aceton, but no alcohol. Hence the red reaction is due not to acetester, but to free acetic acid.

Urine which is Coloured Red by Ferric Chloride.—B. Tollens.—The author has examined specimens of diabetic urine from the above described case, and comes to a similar conclusion.

Conchinamine.—A. C. Oudemans, jr.—The author describes the preparation of conchinamine and quinamine from the quinetum of Darjeeling; the properties and composition of conchinamine, its reactions, and specific rotatory power in solution in presence of different acids.

Conchinamine.—O. Hesse.—The author describes the properties of conchinamine, $C_{19}H_{24}N_2O_2$; its salts and optical behaviour.

Action of Zinc-methyl upon Chlorine Substitutes of Acetyl-chloride.—J. Bogomolez.—Not susceptible of useful abstraction.

Communications from the Laboratory of the University of Zurich.—This article consists of researches on benzol-quinon and certain of its derivatives by E. Sarow. The author examines the action of quinon on concentrated hydriodic, hydrobromic, and hydrochloric acids. He concludes that quinon and concentrated hydrochloric acid form, in the first place, quinhydron, which finally passes into mono-chlor-hydroquinon. With hydrobromic acid there is produced, first, quinhydron, then mono brom-hydroquinon along with dibrom-hydroquinon. Hydriodic acid converts quinon into hydroquinon. The bromised hydroquinons are easily formed by the reaction of different quantities of bromine upon hydroquinon. If the solutions of the bromised hydroquinons are treated with dehydrogenising agents, there are formed the corresponding bromised quinons. Upon concentrated hydrobromic acid the bromised quinons act as oxidising agents.

Ethers of Naphthalin.—C. Graebe.—This treatise consists of three papers, on α and β dinaphthylen-oxide, by W. Knecht and J. Unzeitig; on α and β naphthylen-phenylen-oxide, by J. von Arx; and on naphthyl-ether, by C. Graebe.

Naphthyl-phenyl-amin.—Jacob Streiff.—An examination of α and β naphthyl-phenyl-amin, and their compounds.

Band 209, Heft 2 and 3.

Communications from the University Laboratory at Graz.—These include a memoir by F. Pfeifer on the electrolysis of solutions of antimony chloride and on explosive antimony; a paper by K. Garzarolli-Thurnlackh, on the supposed chlorine trioxide; and an account of certain salts of chlorous acid, by K. Garzarolli-Thurnlackh and K. Freiherr von Hayn.

Communications from the Chemical Institute of the Royal School of Forestry of Aschaffenburg.—These communications refer to syntheses effected by means of malonic ester, and include papers by M. Conrad and C. A. Bischoff on nitroso-malonic ester and its derivatives; a memoir by the same authors on mono-chloro-malonic ester and tartronic acid; a paper by M. Guthzeit on ethyl- and isobutyl-chloro-malonic ester, ethyl- and isobutyl-tartronic acid, ethyl- and isobutyl-hydroxy-acetic acid; and an account of benzyl-chloro-malonic ester, benzyl-tartronic acid, and phenyl-lactic acid.

Galleine and Cœruleine.—Dr. K. Buchka.—In this very elaborate memoir the author treats, first, of galleine; secondly, of cœruleine; thirdly, of the derivatives of galleine springing from triphenyl-methan, such as tetra-acetyl-galleine, tetra-benzoyl-galleine, dibrom-galleine, tetra-acetyl-dibrom-galleine, hydro-galleine, galline, tetra-acetyl-galline, gallol, penta-acetyl-gallol, anhydro-pyro-gallol-keton, tetra-acetyl-anhydro-pyro-gallol-keton. In the fourth chapter he considers the derivatives of galleine which are traced to phenyl-anthracen, such as cœruleine, triacetyl-cœruleine, cœruline, tetra-acetyl-cœruline, and finally the conversion of cœruleine into phenyl-anthracen.

The Halogens.—Dr. H. Züblin.—A re-examination of the theory that the halogens are oxides of unknown radicles. Notwithstanding all attempts made in the most varied manners and under the most favourable conditions no facts were observed which could in any way support the assumption of the presence of oxygen in the halogens.

Isoheptylic Acid from β-Hexyl-iodide.—Otto Hecht.—This paper does not admit of useful abstraction.

Anhydro-Compounds.—H. Hübner.—In the several sections of this voluminous memoir we find an account of diphenyl, its derivatives, and its anhydro-base; of the paramido-diphenyl-compounds; the amidation of mono-nitro-benz-paramido-diphenyl; the iso-amido-diphenyl-compounds; the acetanhydro-compounds; trichloracetic acid and an ortho-diamide; and the anhydro-bases formed with bibasic acids.

Journal für Praktische Chemie.
Nos. 14 and 15, 1881.

Action of Chloride of Lime upon the Alcohols.—Dr. A. Goldberg.—In this memoir the author examines the action of chloride of lime upon ethylic alcohol in equivalent proportions. In a former volume (19, p. 393), the author describes the production of a greenish yellow oil, which on exposure to light or heat explodes, giving off chlorine, hypochlorous acid, and hydrochloric gas. He next describes the action of lime upon mono-chlor-acetal, upon alcohol in other proportions, upon dilute alcohol, upon chemically pure methylic alcohol, and iso-amylic alcohol.

Urethan.—W. Schmid.—By the action of chlorine upon urethan or ethyliden-urethan, the author obtains dichlor- and mono-chlor-ethyliden-urethan, almost in theoretical proportions.

Action of Sulphuric Acid upon Citric Acid and Resorcin.—Max Wittenberg.—By this reaction the author obtains a crystalline product, which he names resocyanin, $C_{21}H_{18}O_6$. It is almost insoluble in cold water, sparingly soluble in hot water and in ether, but readily soluble in alcohol. It is characterised by a beautiful blue fluorescence. In capillary tubes it melts at 185°. Its solutions are not coloured by ferric chloride.

Preparation of Sulphuryl Chloride: a Contribution to the Doctrine of Catalysis.—Hans Schulze.—An experimental inquiry into the fact that sulphurous acid united in a solution with camphor is capable of combining

with chlorine gas to form sulphuryl chloride. The author does not succeed in solving the problem. He feels inclined to seek the source of the almost unlimited activity of camphor and its consorts (the number of which will be doubtless considerably increased) not in purely chemical forces. It will more probably be found in mechanical causes, the nature of which can be merely conjectured.

Methods of and Researches in Physical Chemistry.—Otto Petterson.—The first portion of an extensive memoir, dealing chiefly with the liberation of heat and the change of volume in solid bodies when melting or when near their melting-points.

Anthology of Modern Chemical Utterances.—H. Kolbe.—The "flowers" are plucked from the writings of Wislicenus, Kekulé, &c.

Bulletin de la Société d'Encouragement pour l'Industrie Nationale. 3e Série. Tome viii., No. 92.

Action of Solar Light upon Glass.—Thomas Gaffield.—The translation of a paper read before the Chemical Section of the American Association for the Advancement of Science, Aug. 27, 1880.

Tome viii., No. 93.

Report on the Electric Counter (Gasmeter) of M. Demoulin-Froment, Presented by M. Serbert on behalf of the Committee of Economical Arts.—This paper requires the accompanying illustrations.

International Congress of Electricians.—Under this head are placed the speeches delivered by M. Dumas and by M. Mascart at the final session of the Congress.

Electric Measures.—M. Dumas.—This paper has been already noticed.

Modification of the Electric Lamp.—M. Jamin.—Taken from the *Comptes Rendus*.

The Magnesia Industry.—T. Schlœsing.—Taken from the *Comptes Rendus*.

Neutral Refined Oils.—A. Thiollier.—Oils for lubricating purposes should be neither oxidisable nor capable of oxidising other bodies. They should contain neither free fatty acids nor mucilage. An account is given of certain oils prepared by a M. Melizan, which are said to be free from both these constituents, but his process is not explained.

Annales de la Société des Sciences Industrielles de Lyon. No. 1, 1881.

These Annales still persist in avoiding the especial industries of Lyon.

Les Mondes, Revue Hebdomadaire des Sciences. No. 15, August 11, 1881.

Derivatives of Saligenine.—K. Bötsch.—A notice of the salicylic, ethylic, and methylic alcohols.

Compounds of the Pyrrol Series.—Dr. Ciamician.—The homo-pyrrol of animal oil is probably a mixture of two acids, the α- and β-carbo-pyrrolic.

Sulph-ortho-phenolic Acid.—Dr. Herzog.—The ortho-acid, on fusion with potash, yields pyro-catechine and a diphenol.

Ellagic Acid.—M. Cobenzyl.—The author obtains γ-hexa-diphenol on treating an alkaline solution of ellagic acid with sodium amalgam.

No. 16, August 18, 1881.

Passivity of Iron.—E. Roman.—The passivity of iron plunged into nitric acid is due to the formation of a layer of magnetic oxide on its surface.

Relation between the Magnetism of Bodies and their Atomic Weights.—L. Evrera.—The author has reached conclusions similar to those of Mr. Carnelley; he has experimented independently, and it is alleged at an earlier date.

No. 17, August 25, 1881.

This number contains no chemical matter not taken from other journals.

No. 18, September 1, 1881.

The Faure accumulator has been tried on a tramway-car of peculiar construction, but the exact result has not been made known.

Improvements in Magnets.—M. Trouvé.—The substance of this paper has been already extracted from the *Comptes Rendus*.

Bleaching of Silk and Wool by Liquid Sulphurous Acid.—Raoul Pictet.—In a paper read before the Faculty of Sciences at Geneva the author recommends sulphurous anhydride in place of the fumes of burning brimstone. Among the disadvantages of the latter he mentions the injury to the health of the workmen, and occasional damage to the cloth or yarns from volatilised particles of sulphur, which become attached to the fibre and occasion a burn, or at least a spot.

The Cyclides and the Encyclides in the Three Kingdoms of Nature.—Dr. Charles Brame.—The author traces numerical relations which approximate to the multiple proportions of chemistry.

No. 1, September 8, 1881.

Analysis of the Light of the Comet *b* of 1881.—M. Fievez.—A great portion of the light of the comet is inherent in it, whilst another part is reflected. The strong polarisation of the nucleus indicates a decided state of condensation. The spectrum of the comet differs little from that of others which have been examined.

Effects of Lightning upon Trees Planted near a Telegraph Wire.—C. Montigny.—The vicinity of a telegraph wire exposes objects not merely to the dangers of induction sparks, but to the direct stroke of the lightning.

The Electric Brake.—The writer describes an arrangement patented by A. Basin.

MEETINGS FOR THE WEEK.

MONDAY, Dec. 5th.—Medical, 8.30.
—— Society of Arts, 8. "Some of the Industrial Uses of the Calcium Compounds," by Thos. Bolas, F.C.S.
—— London Institution, 5.
—— Royal Institution, 5. General Monthly Meeting.
TUESDAY, 6th.—Institute of Civil Engineers, 8.
—— Pathological, 8.30.
WEDNESDAY, 7th.—Society of Arts, 8. "The American System of Heating Towns by Steam," by Capt. Douglas Galton, C.B., F.R.S.
—— Geological, 8.
—— Pharmaceutical, 8.
—— Obstetrical, 8.
THURSDAY, 8th.—Royal, 4.30.
—— Royal Society Club, 6.30.
FRIDAY, 9th.—Quekett Microscopical Club, 8.
—— Astronomical, 8.
SATURDAY, 10th.—Physical, 3.

BERNERS COLLEGE of CHEMISTRY.

Instruction and preparation in CHEMISTRY and the EXPERIMENTAL SCIENCES under the direction of Professor E. V. GARDNER, F.A.S., M.S.A.

The Class Rooms are open from 11 to 5 a.m. and from 7 to 10 p.m daily.

Especial facilities for persons preparing for Government and other examinations.

Private Pupils will find every convenience.

Analyses, Assays, and Practical Investigations connected with Patents, &c., conducted.

Prospectuses and full particulars on application to Prof. Gardner at Berners College, 44, Berners-street W.

IRISH HILL BAUXITE (Alum Clay).

THE IRISH HILL MINING CO. are now, and always have been, the LARGEST PRODUCERS OF THIS CLAY, of Superior Quality, and supply the Manufacturers of Alum, Sulphate of Alumina, and Alum-Cake, of the United Kingdom, America, and the Continent, almost exclusively.

ANALYSIS BY JOHN PATTINSON, ESQ.

Supplies over 90 % of the Bauxite (Alum Clay) used.

	Dried at 212° F.		
	Gertrude (extra qual.)	1st Quality.	2nd Quality.
Alumina	59·00	53·83	52·00
Peroxide of Iron	0·47	1·57	4·57
Silica	18·00	8·67	12·00
Titanic Acid		5·80	6·20
Lime, Magnesia, Potash, Soda, and Sulphuric Acid	0·23	0·83	1·14
Combined Water	22·30	29·27	24·00
	100·00	99·97	99·91

Supplies over 90 % of the Bauxite (Alum Clay) used.

Our MINES, DRYING KILNS, and GRINDING MILLS are situated very close to the Shipping Ports of BELFAST and LARNE, and adjacent to Railways running alongside both Steamers and Sailing Vessels at both Ports, from either of which shipping is abundant and cheap, therefore we can guarantee Regular Delivery as Buyers require it, and are prepared to quote prices f.o.b. c.i.f., or delivered at any Port, in Bulk or Bags, Lump or Ground.

THE CHEMICAL NEWS.

VOL. XLIV. No. 1150.

ON THE

CONSTANCY OF THIOSULPHATE SOLUTIONS.

By SPENCER UMFREVILLE PICKERING, B.A., Oxon.,
Assistant Master at Highgate School, and Lecturer in Chemistry at Bedford College.

In the course of some work in which standard solutions of sodium thiosulphate were in constant use, it became desirable to ascertain the circumstances under which solutions of this salt remained most constant. In order to accomplish this a number of solutions, both of sodium and of potassium thiosulphate, were prepared and subjected to different conditions, their titres being determined from time to time by comparison with a standard solution of potassium bichromate, or with weighed quantities of that salt.

The following method was usually adopted in the titration of the solutions:—A given volume of the standard bichromate solution was treated with definite quantities of potassium iodide and hydrochloric acid. A certain volume of the thiosulphate solution sufficient to be very nearly equivalent to the liberated iodine was then added, and the small quantity of iodine which still remained free was determined by a standard solution of thiosulphate, the strength of which had been previously ascertained. The various corrections for the acid added and for differences of temperature were made in accordance with the results of a previous research (*Journ. Chem. Soc.*, 1880, 128); the results given in the following tables being also reduced so as to be more easily comparable with each other: a difference of 0·012 c.c. in the tables corresponds to a difference of about 0·01 c.c. in the actual observations.

In some preliminary experiments an apparent increase in the strength of the thiosulphate solutions was noticed during the first few days, and, as this could only be explained by a corresponding decrease in the strength of the bichromate solution, a few experiments were made in order to ascertain whether a neutral solution of this latter salt would oxidise any organic matter which might happen to be present in it.

A standard solution of potassium bichromate was taken, and, after ascertaining that its strength was not altering at the time, a small quantity of dust was introduced and its strength again determined from time to time. The following results were obtained:—

Strength of the solution at first	100·00
" " after 1 day ..	100·02
" " " 2 days ..	99·89
" " " 3 " ..	100·15
" " " 4 " ..	99·99

Some dust was then introduced.

Strength of the solution after 1 day ..	99·68
" " " 3 days ..	99·79
" " " 6 " ..	99·76
" " " 52 " ..	99·56
" " " 362 " ..	99·28

Again, a solution of bichromate, to which some grape-sugar had been added, was found to have lost 11·52 per cent of its oxidising power in the course of eight months, a brown deposit of chromium hydrate being formed at the same time. Light, although not essential to the action, was found to accelerate it.

These experiments clearly show that any organic matter which might happen to be present in the water used for dissolving the bichromate would cause a diminution in the available strength of the solution.

The bichromate solution used in the following experiments was one which had been made for some time, and in which no change whatever took place throughout the whole duration of the experiments, a fact which was ascertained by direct determinations made from time to time.

In the experiments given in Table I. all the solutions were approximately decinormal in strength, containing 0·019163 grm. of $Na_2S_2O_3$ per c.c. The experiments, extending over a year, were begun in the latter end of December. At the beginning the bottles were about three-quarters full of the solution, while at the end they were about half full. The amount of potassium hydrate added in the case of solution D was very minute, while the ammonium carbonate added to the solution E amounted to about 5 grms. per litre, a quantity recommended by

Rose in his text-book as having a preservative effect on the strength of the solution.

These experiments, it will be observed, indicate that a sodium thiosulphate solution is more constant in the dark than it is when exposed to light, and that, when that light is weak diffused daylight, the permanence of the solution is slightly increased by using a bottle of blue glass instead of one of white glass. The solution to which a little potash had been added (D), when compared with B, shows that the potash has a small preservative effect on the thiosulphate; the amount of alkali here added was, however, very minute. The experiments with the solution E shows that the addition of ammonium carbonate has, in spite of Rose's statement to the contrary, a very prejudicial effect; it not only makes the solution more unstable, but also renders the results obtained with it at any given time more untrustworthy and less concordant with each other.

In Table II. other experiments similar to the foregoing ones are given. Here the solutions were somewhat more dilute, containing 0·01817 grm. $Na_2S_2O_3$ per c.c. A comparison of J with K indicates more clearly than one of A with B does the advantage of using a blue bottle instead of a white one, while the experiments with solution L show, as in the case of D, the good results produced by the addition of some potassium hydrate; the experiments on L, however, were unfortunately not continued as long as the others. The experiments on J, K, and L are in two particulars not exactly comparable with those given in Table I., since they were commenced three months later than the latter, and the bottles in which they were kept were nearly empty at the conclusion of the experiments. The former of these differences does not appear to have produced any measurable effect, but the latter renders the loss in strength greater towards the end of the time, when the proportion of air in the bottle became very considerable. Solution I, in Table III. illustrates this point more strikingly; here the solution was kept in a Winchester quart bottle, which was frequently opened, and which, towards the end of the experiments, was nearly empty; the loss in strength during the first year while the bottle was well filled amounted to 1·25 per cent, but another three months produced an additional change of 2·75 per cent. By the experiments on H in Table II. the prejudicial effect of a strong light is well shown, although it is probably somewhat masked during the first 40 days owing to there being a far smaller proportion of air in the bottle than was the case with the solutions J, K, and L.

In Table III. are given the results obtained from some similar experiments on solutions of potassium thiosulphate. F and G are comparable in every respect with B and A. While showing that light affects the stability of the potassium salt in the same manner as it does that of the sodium salt, they show that the former is more liable to change than is the latter.

The general conclusions arrived at may be summed up in a few words.

A solution of sodium thiosulphate is preferable to one of potassium thiosulphate. The solution should be kept in a bottle of blue glass, or preferably in the dark, and should be protected as much as possible from the access of air.

A very small quantity of potassium hydrate may be added with advantage*; the addition of ammonium carbonate is, however, decidedly injurious.

In making a standard solution of potassium bichromate care should be taken that no traces of organic matter be present in the water used.

Manurial Researches in the Lutter Experimental Field.—With potatoes, the heaviest gross crop, but the lowest nett return, was produced by farmyard manure.—*Biedermann's Centralblatt.*

THE

ELECTROLYTIC DETERMINATION OF COPPER,

AND THE

FORMATION AND COMPOSITION OF SO-CALLED ALLOTROPIC COPPER.*

By J. B. MACKINTOSH, Hoboken, N.J.

The quantitative determination of copper, by means of electro-deposition, offers so many advantages that it is to be preferred, when properly executed, to all other methods for ease and accuracy. The object of the present paper is to give the results of a number of experiments made during the past few months, and to indicate some sources of error which must be avoided in order to attain the necessary accuracy.

In 1867 C. Luckow, in competition for a prize offered by the directors of the Mansfield Copper Works, submitted the following process for the estimation of copper, and received, not indeed the prize, but an honourable mention for the simplicity, cheapness, and elegance of his process. He directs that the copper and the accompanying metals be obtained in the form of nitrates in solution in dilute nitric acid containing not more than 0·100 grm. of the pure acid in each cubic centimetre: to this solution is added a few drops of a solution of an organic acid, such as tartaric or oxalic, and the copper is then precipitated on platinum in the usual manner. It is claimed that the copper is obtained in beautiful reguline form, while zinc, iron, and nickel are not precipitated at all.

In adapting this method to the analysis of copper alloys I dissolved the alloy in nitric acid, evaporated the solution to dryness to get rid of the excess of acid, dissolved the residue in water with the addition of a few drops of nitric acid to dissolve the basic nitrate of copper formed, and to this solution added four or five drops of a concentrated solution of citric acid. This solution was then precipitated in a platinum dish with a current from two Bunsen cells of about one quart capacity. In precipitating several samples at once I have it arranged so that the whole current traverses the row of dishes, the negative pole of each set being connected with the positive pole of the next succeeding one. In this case if n be the number of dishes, then $n+1$ is the number of battery-cells of that size used.

Some of the results obtained by this method, and on duplicate portions by precipitation from sulphuric acid solution, are as follows:—

	Sulphuric Acid.	Nitric+Citric Acid.	Error.
1 grm. pig copper ..	98·00	99·42	+1·42
,, ,, ..	99·80	101·22	+1·42
,, ,, ..	98·92	100·41	+1·49
,, ,, ..	98·72	100·27	+1·55
,, ,, ..	99·60	100·45	+0·85
1 grm. brass	65·83	66·93	+1·10
,, ,, ...	65·83	66·58	+0·75

In only one case was a smaller percentage obtained by the use of this method, and in that case the precipitation of the copper was not complete. In many cases, also, in which the amount of error was less than 1 per cent. small quantities of copper escaped precipitation, and were afterwards found in the solution.

The metallic precipitate thus produced is of a much lighter colour than ordinary copper from the electrolysis of the sulphate solution, but it is, as Luckow says, deposited in beautiful reguline form, which, however, hardly compensates for the error of perhaps 1 per cent or more, which we see is, as a general rule, the case.

Moreover, if the current is strong, after all the copper has been thrown down, zinc will be deposited on the surface of the copper, as a dark coating, which may be recog-

nised as such by dissolving in dilute sulphuric acid and applying appropriate tests.

In the presence of the organic acid the formation of peroxide of lead on the positive pole is hindered, and in its absence it is very difficult to precipitate the whole of the copper from the solution.

In order to obtain sufficient material for analysis, to ascertain the cause of the excess in weight, the precipitation of the copper was made on a piece of platinum foil. On attempting to strip the deposit from the foil I found that it was extremely brittle, and scaled off easily,—so brittle, indeed, that it could be reduced to an impalpable powder in an agate mortar with very little trouble. This agrees exactly with the description of the allotropic copper of M. P. Schutzenberger, which was published in *Comptes Rendus* (vol. lxxxvi., part 2). M. Schutzenberger obtained the material he describes by the electrolysis of a 10 per cent solution of the neutral acetate of copper. He found that the product contained from 5 to 10 per cent of suboxide of copper. In the material which I prepared from the nitric and citric acid solution I did not find *any* suboxide of copper; on the other hand, both carbon and hydrogen have been detected and estimated. These latter were determined by combustion of the finely divided sample in oxygen; the method used to estimate the suboxide of copper was that of Hampe.* However oxygen is present, though, as this test shows, not as cuprous oxide.

The results of the analyses of several samples, prepared at different times, are given above. The determinations were all made on the amount of 1 grm.

The results which are bracketed are from duplicate analyses. These samples were all prepared from the nitric and citric acid solution. *a*, *b*, and *c*, *d* were prepared simultaneously, the solution of *b* containing a little more citric acid than that of *a*, and *c* *d* more than either. The samples *e*, *f*, *g*, and *h* were heated to about 100° C. for fifteen minutes before being introdued into the combustion-tube, and the samples *c*, *d*, *e*, and *f* were the same. The results given under *h* are low, probably due to imperfect oxidation.

It will be seen that there is a deficiency of 0·02116 and 0·02088 respectively in the total of the duplicate analyses *c* and *d*. The precaution was taken in one case of passing the products of the combustion over a red-hot layer of oxide of copper, to make sure that no hydrocarbon was distilled out by the gradually increasing heat, and so escaped oxidation. The results in this case, however, differed in no material manner from those already obtained. We must therefore conclude that this deficiency must consist either of *oxygen* or *nitrogen*, or of a mixture of both. I have already mentioned that there is no oxygen in the form of cuprous oxide present, so that it must, if present, be combined in some other form. The following synthetical experiments seemed to indicate that *nitrogen* was also an essential constituent.

These experiments were conducted as follows:—Solutions were prepared of nitrate and of sulphate of copper; to these solutions were added respectively citric acid, tartaric acid, and alcohol. All three of the solutions of the nitrate furnished the brittle deposit, while all three of the sulphate solutions gave a tough deposit of apparently ordinary electrotype copper. The amount of copper was determined in 1·0008 grms. of the precipitate from the sulphate solution containing alcohol, and found to be 0·9991.

* *Zeitschrift für Analytische Chemie*, 1878, p. 127

This difference is probably due to impurities in the copper, which was prepared in the first place from the commercial sulphate, which contained lead and other impurities.

During the electrolysis of the nitrate solutions containing citric acid, a very strong odour of hydrocyanic acid was perceptible.

If an insufficient amount of organic matter be added the precipitated copper obtained is not brittle, but it nevertheless contains carbon and hydrogen, and gives a total result less than 100 per cent. This is due to admixture of ordinary copper. It is not possible to divide such a precipitate sufficiently finely to ensure perfect oxidation.

The amount of nitrogen present in the nitric-citric precipitated copper, was determined by heating the finely pulverised sample in a vacuum and collecting the gases evolved. The products thus obtained were hydrogen, carbonic acid, and nitrogen. Although in this case it was probable that an excess of oxygen would be present, yet the analytical results showed the absence of that gas in any appreciable quantity.

The volumes given are those of the dry gas at 0° C. and 760 m.m.

1 grm. heated in vacuo.		½ grm. in Oxygen.	1·15 grm. in Oxygen.
Gas obtained	9·95 c.c.	8·23 c.c.	17·52 c.c.
CO_2 absorbed by KOH ..	4·72 ,,	7·35 ,,	15·70 ,,
Gas not CO_2	5·23 ,,	0·88 ,,	1·82 ,,
Oxygen added	7·77 ,,		
	13·00 ,,		
Volume after explosion ..	7·44 ,,		
Loss—Water	5·56 ,,		
No CO_2 formed: *Hydrogen*	3·71 ,,		
Residue: *Nitrogen*.. ..	1·52 ,,		

These residues, treated with moist phosphorus to absorb oxygen, and then with KOH, did not change, proving the absence of oxygen.

The circumstances of formation were such as to preclude the existence of hydrogen, therefore these residues must be nitrogen.

The percentage results in the foregoing three cases are respectively for nitrogen—0·191, 0·221, 0·199; and in the two last for carbon—0·792, 0·736. The ratio of $\frac{C}{N}$ being 3·6 and 3·7.

One sample of the product, made with tartaric acid, weighing 2 grms., was also analysed for nitrogen, and 1 c.c. of dry nitrogen at 0° C. and 760 m.m. obtained. It is difficult, when working on such small quantities of gas, to obtain very accurate results.

Some of the allotropic copper prepared from the chemically pure acetate, according to M. Schutzenberger's directions, and which therefore could not contain nitrogen, and also some prepared from an acetate of copper containing nitrate of soda, were compared and analysed. The material thus obtained was apparently the same in both cases, and differed considerably in some of its properties from the nitric-citric acid solution precipitate. In appearance, brittleness, and composition there was no essential difference, but it was very unstable and liable to oxidise; in fact, it was not possible to preserve it of con-

stant composition in the air, while the nitric-citric precipitate can be preserved indefinitely without change.

Two samples, of 1·0014 and 1·0004 grms. respectively, were weighed out. The first was heated for about fifteen minutes to 100° C. in an air-bath; on cooling and weighing it had gained 0·0215 grm. The second sample was exposed to the air at the ordinary temperature for two hours and three-quarters: at the end of that time it had gained 0·0225 grm.; it was then heated to 100° C. for fifteen minutes, when it lost 0·0020 grm., giving a net gain of 0·0205 grm.

The amounts of carbon and hydrogen were determined in the second sample of the material from the acetate solution containing nitrate of soda, and in two samples from the chemically pure acetate preparation.

	$Cu(C_2H_3O_2)_2 + NaNO_3$.	$Cu(C_2H_3O_2)_2$	
Amount taken..	1·004 grm.*	1·0000 grm.	1·0000 grm.
CO_2 found ..	0·0145 ,,	0·0175 ,,	0·0154 ,,
Equivalent to C	0·00395 ,,	0·00477 ,,	0·0042 ,,
H_2O found ..	0·0081 ,,	0·0092 ,,	0·0081 ,,
Equivalent to H	0·0009 ,,	0·00102 ,,	0·0009 ,,
Ratio, C : H ..	4·4 ,,	4·676 ,,	4·666 ,,

The cause of the rapid oxidation of these samples seems to be that the deposit is very porous, while that from nitric solutions is very dense.

M. Schutzenberger mentions that he had at one time a considerable quantity of this allotropic copper (*sic*) reduced to powder and dried in a vacuum, which, at the moment when air was admitted to it, was transformed to ordinary copper, attended by a considerable evolution of heat. The amount of oxygen he found was not altered by this occurrence.

To account for this phenomenon he frames the theory that the allotropic copper corresponds to cuprous copper, and that the molecular change to cupric copper is accompanied by the development of heat. But we can easily see how liable to spontaneous oxidation a large quantity of such finely divided material would be, when it contains both carbon and hydrogen in a weak state of combination, and it is unnecessary to suppose the existence of another form of metallic copper to account for the phenomena noticed.

The practical conclusions to be drawn from these results are, that some organic matters, and in all probability all, in the presence of nitric acid in the copper solution undergoing electrolysis, cause erroneous results; that from a nitric acid solution, with no organic matter, it is extremely difficult to separate all the copper; and that the old method of electrolysis from the sulphate is the best.

Discussion.

Dr. Egleston, New York—The paper which I have just read is one of great interest. It represents the work of my assistant, who is a man of great skill in this particular line of his profession, for nearly a year in my laboratory. There will certainly be in this connection two subjects which must come up for discussion in the Institute before a great while, and these are "What is copper?" and "What copper is," and which will have, in a commercial point of view, as great or even greater interest than the similar discussion which took place a few years ago about steel. What is sold in the market as copper may contain anywhere from one-tenth to one per cent of foreign material. Out of a very large number of analyses of the ordinary commercial coppers, the best sample that we were able to get contained only 99·91 per cent of copper. This is much more important than it would at first sight appear to be, because there is a direct relation between the purity of the copper and its electrical conductivity. The presence of so small a quantity as nine-hundredths of a per cent of foreign matter may be sufficient to take away more than 10 per cent of the conducting power of the material. The manufacture of pure copper for the application of electricity to the industrial arts, which will in a few years be one of the greatest commercial questions to be solved, is therefore much more important than is generally supposed. This is not only true of copper, but of its alloys. Certain alloys made from metals of high quality have become of great commercial importance within a few years; but great difficulty has been experienced in manufacturing them, for while some of the alloys do not stand the test, and are therefore rejected at once, others will stand it for a few weeks or months, and will then become brittle and worthless. I hope, therefore, that this matter will receive from the chemists of the country the careful attention which it deserves.

The paper of Mr. Mackintosh is the result of analyses of over seventy samples of copper and brass, from different parts of this country, in all stages of their manufacture. There are many samples of copper in which less than one-half of 1 per cent of foreign material has made the copper perfectly worthless for certain large industrial applications, and it requires but an extremely small amount to render it worthless for processes of conductivity. A change takes place in the alloys of copper which is partly physical and partly chemical, which may render the alloy useless after a certain time, although it may satisfactorily undergo all the tests immediately after its manufacture. In view of the very small quantities of foreign matter which make the changes in copper, the question which Mr. Mackintosh has brought before the Institute is one of very great importance.

Whatever may be the method which is used for analysing copper there is one thing which must be very carefully taken into account, and that is the influence of organic matter in solution. It makes no difference what the method is; if organic matter of any kind gets into the solution the analysis of the copper will be likely to be incorrect.

I have seen very large works make the determination of copper in porcelain vessels with platinum strips. We have found that under such circumstances it is impossible to get accurate results, for if even very small quantities of copper become detached from the strips and fall upon the porcelain the copper is in danger of oxidation. Mr. Mackintosh has devised a very ingenious arrangement of copper wires switching into mercury, by which the whole current of the battery passes under a number of dishes, equally divided amonst them all; and if there is any necessity for so doing, he can switch out one or two vessels and pass the current through the remainder. This system has been in use in my laboratory for over two years, and has worked most satisfactorily; it is so arranged that each platinum dish rests upon a metallic support, which passes underneath the vessels, and is connected with the battery by means of thumb-screws and wires.

Extremely minute amounts of cobalt, nickel, oxide of copper, and zinc will reduce the conductivity of the copper wire very largely. In fact almost everything, except silver, which may be contained in the copper will reduce it. In the case of iron wires I had occasion recently to ascertain that oxide of iron, which is generally neglected in the analysis of copper wires used for electrical purposes, is one of the most deleterious materials ever found in it.

The experiments which I have been making during the last year have been made with wires having different mechanical and chemical compositions; and in order to be certain of the results we have gone so far as to solder wires together, some of which were afterwards drawn down, and others tested without being drawn, but no appreciable difference was found. Oxide of iron is certainly not evenly distributed throughout the mass, and causes the fibres to separate in such a way, both in the interior and the exterior of the rod, that this want of homogeneity may possibly have as direct an influence as

* Oxidised by exposure to air and heating in air-bath before combustion.

that of the presence of an alloyed impurity. There is no doubt whatever about the effect of cobalt, nickel, and zinc. A series of experiments were made by the first Cable Company as to their effect. which have been fully confirmed by my analyses and experiments during the last year. The presence of silver would have the effect of raising the conductivity even in the presence of nickel and cobalt, since its conducting power is much higher than that of copper.

Mr. S. P. Sharples, Boston—If there is any one metal which has interested me more than another during the last fifteen years, that metal has been copper. While I was a student in the Lawrence Scientific School under Dr. Wolcott Gibbs, during the winter of 1866-7, he called my attention to some analyses that were made by Mr. E. V. McCandless, in the laboratory of the school. These analyses were published in the *American Journal of Science and Arts*, January, 1865, the paper bearing date October 1st, 1864. He found that he could completely precipitate copper from a sulphuric acid solution, using a platinum plate for the positive and a platinum dish for the negative electrode. The copper after precipitation was carefully washed with distilled water, and dried *in vacuo* over sulphuric acid.

Dr. Gibbs suggested that I should take some pure copper and dissolve it in sulphuric acid with the addition of some nitric acid, and then evaporate to dryness over a lamp so as to expel the nitric acid and the excess of sulphuric acid, and then precipitate and weigh. After weighing, the copper was again dissolved in the same dish, and again evaporated to drive off excess of acid, dissolved in water, precipitated again, and weighed. This operation was repeated several times with closely agreeing results, thus confirming Mr. McCandless's work. The paper by Dr. Gibbs was published in German in *Fresenius's Zeitschrift für Analytische Chemie*, vol. iii., 1864. In vol. viii. of the same journal is a long paper by C. Luckow, in which he says he had first described this method in *Dingler's Journal* in 1866, or a year after it was described by Dr. Gibbs. I have been particular in regard to dates, because this method, or some trifling modification of it, is re-published every few years as something new.

I have made many hundreds of determinations of copper by this method, and with uniformly good results. In the course of this work I have found that many of the precautions that we originally considered necessary may be omitted. In the first place a little nitric acid in the solution does no harm. The evaporating to dryness is time wasted. Care should be taken, however, not to have too great an excess of acid of any kind present. If from any cause we find that too much free acid is present in the solution, it can be readily neutralised by the addition of a little ammonia water, not quite sufficient to neutralise the acid. The drying *in vacuo* is also unnecessary. Dr. Gibbs suggested that the water be removed by a little alcohol, as this would evaporate in less time than water: this was tried with satisfactory results. The next suggestion (whose I know not) was that the alcohol might be burnt off: this also works well.

The process of analysis which has been followed in my laboratory since 1871 is as follows, and it is just the same whether the substance be a matte, an alloy which does not contain metals thrown down by the battery in an acid solution, or an ore:—Two grms. of the substance, if it contains more than 10 per cent of copper, or 4 or 5 grms. if it is poor in copper, are weighed into a porcelain dish. This is treated with 5 c.c. of strong sulphuric acid, and then a little nitric acid is added from time to time until the action ceases. It is then heated to boiling over a lamp, allowed to cool and diluted to about 50 c.c., boiled, and filtered. If the substance is well ground a single treatment is generally sufficient; if, however, any black residue remains, this treatment is repeated. If there is any lead in the ore it is converted into a sulphate, and remains behind on the filter; the trace that goes through may be neglected, since it is not precipitated with the copper. The copper solution is filtered directly into the platinum dish, which should hold about 200 c.c., though with care one holding 100 c.c. can be used.

This operation generally is completed in half an hour from the time the ore is weighed. The precipitation takes care of itself; the dish being placed in the circuit when the laboratory is left in the evening, in the morning we find the work finished. The solution is tested by taking out a drop and putting it on a white plate with a drop of hydric sulphide: if the copper is completely precipitated the dish is removed from the battery, the solution poured out, and saved if necessary for the determination of other substances. The dish is then washed with pure water, followed by alcohol; the alcohol is then drained out as completely as possible, and the little that adheres to the dish set fire to. This operation not only serves to dry the copper, but it also prevents the oxidation during the drying. A very slight blueing of the copper does no harm, as it will not perceptibly change the weight. The whole operation, from the time the precipitation is complete until the copper is weighed, need not take more than ten minutes.

Within a few months I have had occasion to test the method very carefully. Certain parties were dissatisfied with my results, which they claimed were too high, and demanded my samples. The samples had already been sent to an eminent chemist, who returned them to me with his method of analysis. His results were about one-tenth of a per cent higher than mine, while the method employed by him involved about five times the work. I have had no further advices from the dissatisfied parties, though they have had the samples for two or three months.

This method bids fair to become the standard method of copper determination in this country. I know of some heavy contracts in which it has been inserted as part of the agreement.

In connecting the precipitating dish with the battery, I find it is better, when more than one dish is used, to connect the positive pole of the battery with a sheet of metal or wire on which both of the dishes are set, and to connect the platinum strips with the wire proceeding from the other pole of the battery. In this way the current is divided between the cells, and the resistance is less than if the cells are in series. I find that two small Grove cells are sufficient for the purpose.

The commercial allowance for variations in analyses of copper ores is one-half of one per cent; the actual variation on analyses made by this method in duplicate does not often exceed one-tenth of one per cent.

PROCEEDINGS OF SOCIETIES.

CHEMICAL SOCIETY.

Thursday, December 1, 1881.

Prof. H. E. Roscoe, President, in the Chair.

The ballot for the election of Fellows did not take place, as the requisite number of Fellows was not present. The President, in postponing the ballot to the next meeting (December 15), said that he hoped that the Fellows would endeavour to be present on that occasion, so that the ballot might take place.

The following certificates were read for the first time:—F. Barkas, E. D. Chester, J. Gray, H. E. J. Irons, F. H. Lescher, J. P. Laws, H. F. Moore, D. O. Masson, T. Perry, J. R. Parker.

The President then called on Dr. Armstrong to read a paper entitled "*Researches on the Laws of Substitution*

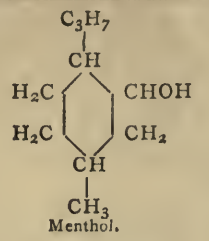
in the Naphthalen Series (Part II.)." In this communication Dr. Armstrong describes the results which Mr. Graham and himself have obtained in continuing their examination of certain naphthalen derivatives. The product of the action of cold sulphuric acid on β-naphthol, described by Mr. Stallard and Dr. Armstrong at the last meeting of the Society in June, proves not to be identical with the isomeric naphthol-sulphonic acid patented by Mr. Dixon on behalf of Dr. Rumpf (CHEMICAL NEWS, vol. xliv., p. 46), but to be merely β-naphthyl-sulphonate, $\beta C_{10}H_7OSO_3H$. The same substance may be obtained far more easily and in theoretical amount by the action of SO_3HCl on a cold solution of β-naphthol in carbon disulphide. It is converted into mono-brom-naphthol, identical with that from bromine and β-naphthol, on treatment with bromine, but yields *di*-nitro-naphthol on treating with dilute nitric acid. The formation of a dinitro compound is explained by the fact that mono-nitro-naphthol is readily converted into the dinitro compound, even by dilute nitric acid. β-naphthyl-sulphate is converted into Schæffer's β-naphthol-sulphonic acid by heating on the water-bath. When acted upon by SO_3HCl it yields the sulphate of Schæfer's acid. This sulphate is converted by the action of bromine into bromo-naphthol-sulphonic acid, identical with that produced by brominating Schæffer's acid, or by acting on ordinary bromo-β-naphthol with SO_3HCl. Bromine and the sulpho-group, therefore, do not assume the same position when the sulphate is treated with bromine and SO_3HCl respectively. β-naphthyl acetate in like manner yields the acetate of Schæffer's acid when acted upon by SO_3HCl. The author proposes to examine the behaviour of other β-naphthylates, as modifications of the OH group appear to lead to important modification of the laws of substitution. Dr. Armstrong also stated that the third isomeric naphthalen-disulphonic acid which Mr. Graham and himself obtained gave a chloride fusing at 126°. On treatment with PCl_5 this chloride is converted into a dichloro-naphthalen, which appears to be identical with θ-dichloro-naphthalen. By acting on naphthalen with SO_3HCl they have obtained a fourth disulphonic acid. Its chloride melts at 180°, and yields γ-dichloro-naphthalen on distillation with phosphorous pentachloride.

Mr. E. H. RENNIE then read a paper "*On Benzyl-phenol and its Derivatives.*" This investigation was undertaken to obtain, if possible, more definite information regarding the derivatives of benzyl-phenol than is given by Paterno and Fileti, who first prepared and examined these bodies (*Gaz. Chim. Ital.*, iii., 121, 251). The benzyl-phenol was obtained by the action of benzyl-chloride on phenol in the presence of zinc, the mixture being kept cool. By the action of a slight excess of sulphuric acid over that required by theory, a mono-sulphonic acid was obtained; also its ammonium and barium salts. These bodies are crystalline, and the salts are but sparingly soluble in water; the dibarium salt is almost insoluble. By the action of dilute nitric acid (1 : 1) on potassium-benzyl-phenol-sulphonate in fine powder, a crystalline yellow salt was obtained, which proved to be a mono-nitro-benzyl-phenol-sulphonate, $C_7H_7,C_6H_2(OH)(NO_2)SO_3K$; it yields an orange dipotassium salt. By the action of bromine on potassium benzyl-phenol-sulphonate, a white salt, $C_7H_7,C_6H_2(OH)BrSO_3K$, was obtained. By the action of strong nitric acid on the above potassium salt, a trinitro-derivative was prepared, giving an orange-red potassium salt. The author considers benzyl-phenol to be a para-derivative. He endeavoured to prove this point by oxidising the methyl-ether of the phenol with chromic liquor, but only benzoic acid was formed. By oxidation with alkaline permanganate neither benzoic nor anisic acid was formed, but a white crystalline substance, soluble in alcohol, and melting at 60°, which is still under examination. The author promises to lay before the Society the results of a further investigation on this subject.

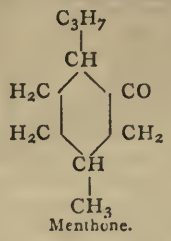
"*Note on the Action of Ethylic Chloro-carbonate on Benzene in the Presence of Aluminic Chloride,*" by E. H. RENNIE. Ethyl-chloro-carbonate in contact with aluminic chloride in the cold, decomposes violently into carbonic anhydride and mono-chlor-ethane; if benzene be present the mono-chlor-ethane acts upon it, and ethyl-benzene is formed. If ethyl-chlor-acetate be substituted for ethyl-chloro-carbonate, no reaction takes place in the cold, and on heating, though some hydrochloric acid is evolved, no ethyl-phenyl-acetate is formed.

Dr. ARMSTRONG said the investigation was of great interest, as it was the first case in which the substitution-products had been investigated with the introduction of a positive radical. He did not think the substance was a para-derivative, because the trinitro- body gave an orange salt, which should have been crimson had the benzyl been in the para-position; it was, therefore, more likely to be in the ortho- or perhaps meta- position.

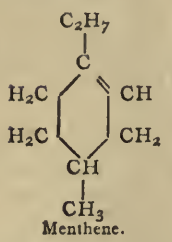
The SECRETARY then read a paper "*On Peppermint Camphor (Menthol) and some of its Derivatives,*" by R. W. ATKINSON, B.Sc., and H. YOSHIDA. Peppermint camphor is usually contaminated with oily matters which accompany it in the plants. After repeated purification by distillation, careful pressing between filter-paper, &c, the authors obtained menthol melting at 42·2°, solidifying at 40·3°, and boiling at 212° (cor.). Mr. Moriya has shown (*Jour. Chem. Soc.*, March, 1881), that menthol when heated with acid bichromate solution at 120° yields an oil boiling at 204°, having the composition of menthone, $C_{10}H_{18}O$. The authors have repeated these experiments, using large quantities. By repeated treatment with fresh oxidising mixtures the product gave a positive rotation, $[\alpha]=+21°$. Menthone is a colourless mobile liquid, neutral to test-papers, soluble in alcohol, chloroform, benzene, and bisulphide of carbon; insoluble in water. When cohobated repeatedly with zinc chloride a hydrocarbon was obtained, in too small a quantity, however, to admit of its identification. If a solution of menthone in petroleum be heated with sodium, the solution formed decomposed by carbonic acid, the product shaken with water, rapidly separated from the oily layer and set aside, minute crystals of menthol are obtained. Menthol, therefore, stands to menthone in a similar relation to that which borneol stands to camphor. The menthol thus produced from menthone melts at 42·2°, but has a rotatory power of only −39°. The specific rotatory power, the specific gravity and rate of expansion, and the molecular refraction of menthone were determined by the authors. The molecular refraction was 75·3, using Brühl's numbers for C, H, and O; the calculated value is 75·1, the carbon atoms not being doubly combined. The authors then prepared menthene, $C_{10}H_{18}$, by heating menthol with zinc chloride; the crude product was purified by careful fractionation and long digestion with sodium. The pure product distilled over constantly at 167·4°. Its specific rotatory power, its specific gravity, and rate of expansion were determined. Its molecular refraction was found to be 74·045; calculated for carbon atoms in single union, 71·82; or supposing one pair of carbon atoms doubly united, 73·82. Menthene is a colourless mobile liquid, moderately soluble in ether and alcohol, more soluble in benzene, turpentine, and petroleum. Its colour resembles that of cymene: fuming hydrochloric acid yields $C_{10}H_{19}Cl$. By treating menthol with hydriodic acid, distillation, treatment with caustic soda, sodium, &c., a colourless hydrocarbon was obtained, which consisted chiefly of $C_{10}H_{16}$ with a small quantity of $C_{10}H_{18}$, or $C_{10}H_{20}$. The authors then determined the specific volumes of these menthol derivatives, but do not place much reliance on the results. The authors conclude with some remarks on the constitution of menthol. From the above experiments they think that there is great similarity in constitution between camphor and menthone. Zinc chloride, when it acts upon camphor, produces cymene; with menthone, a hydrocarbon containing two atoms of hydrogen more than cymene. They give the following as the probable constitution of these bodies:—



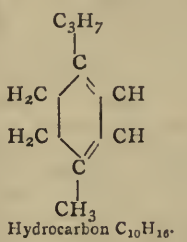
Menthol.



Menthone.



Menthene.



Hydrocarbon $C_{10}H_{16}$.

These formulæ receive considerable support from their close alliance to Kekulé's formula for camphor. The authors propose to study the action of nitric acid on menthol.

Dr. WRIGHT said that the constitution of menthene given by the authors could not be accepted, as it did not explain the direct combination of bromine and menthene to form a tetra-bromide, $C_{10}H_{18}Br_4$, mere traces of hydrobromic acid being evolved (*Chem. Soc. Journ.*, 1876, p. 2).

The SECRETARY then read a paper "*On the Production of Oxalic Acid from Paraffin Oil*," by J. GALLETLY and J. S. THOMSON. The authors treated a paraffin oil, sp. gr. about 0·800 obtained by the destructive distillation of shale with twice its volume of nitric acid, sp. gr. 1·3 The action is at first violent, but has to be completed with the aid of a gentle heat. After the reaction is finished the liquid separates into three layers. The lower one, consisting of the excess of acid, on evaporation at a gentle heat, yielded a crop of yellow crystals, which, after recrystallisation, were obtained in a colourless condition. They proved to be pure oxalic acid. The authors identified the body by its reactions and analyses of the acid, and its calcium salt.

The Society then adjourned to December 15, when a paper "On some Higher Oxides of Manganese and their Hydrates," Part II., by V. H. Veley, will be read.

NOTICES OF BOOKS.

A Manual of Practical Assaying. By JOHN MITCHELL, F.C.S. Edited by WILLIAM CROOKES, F.R.S. Fifth Edition. London: Longmans, Green, and Co.

CONCERNING the value of Mitchell's Manual practical men are decidedly unanimous: there is no work in the English language by which it can be superseded. Nevertheless, here, as in every application of science to technical pursuits, changes are incessantly taking place. On the one hand, new and improved methods are being from time to time devised, and such of them as when carefully tested show some distinctive advantage in accuracy, convenience, or economy of time and materials, require to be generally known. On the other hand, the demands made upon the assayer are becoming more stringent. He is expected to work with greater accuracy, and at the same time with greater speed, than his predecessors. Further, whilst formerly the ores which came under his hands were derived from few sources, and were consequently of generally known composition, he has now to deal with minerals brought from all parts of the world, and is frequently compelled to modify his routine processes on account of the presence of some unusual constituent. Hence the rule-of-thumb is at an end: the assayer must be a man of science, and have at his command the resources of analytical chemistry. It is from this point of view that the editor has set out in modifying and extending the work before us. Methods which have been superseded have been omitted, whilst new and improved processes have been introduced in their room, and thus, without sacrificing those features which have won for Mitchell's "Manual" in its earlier editions such general favour, it has been brought into harmony with the wants of the day.

When the fourth edition appeared there was, we remember, some little division of opinion as to whether the Editor had been well advised in retaining the nomenclature and notation of what is now called the "old chemistry," *i.e.*, that generally prevalent about the middle of the century. Now, however, as all the chemical schools have adopted these changes, and as they are incorporated in all manuals and text-books, it became imperative to recognise them in the present volume as in all other technological treatises. This accordingly has been done. We are not ignorant of the conservative turn of mind prevalent among many practical assayers, but we trust that they will see the necessity of conforming to what is now a universal practice.

The valuable electrolytical methods for the quick and accurate determination of various metals, *e.g.*, copper, are here fully described, and will doubtless be more and more widely introduced into practice. Indeed it is probable that, so far at least as inorganic analysis is concerned, electricity has a great part to play.

Hopes were entertained at one time that a still more modern analytical instrument, the spectroscope, would by this time have effected an even more striking simplification, especially in the assay of the precious metals. Hitherto the attempt has failed in the most competent hands, and the obstacles discovered are of such a nature as to leave little hope for the future. It appears that in alloys the spark elects as its vehicle the one of the metals present which is most rapidly volatilised. Hence, in alloys of copper containing from 20 to 25 per cent of gold, the spectrum of the latter metal is scarcely visible. Further, it is impossible to obtain alloys of gold so perfectly homogeneous that the minimum trace which yields the spectrum may safely be taken as a representative of the entire ingot.

First Results of Studies on the Formation of Colouring Matters by the Electro-Chemical Way. (Premiers Resultats des Etudes sur la Formation des Matières Colorante par voie électro-chimique.) Exhibited by F. Goppelsroeder. Mulhouse: Veuve Bader et Cie.

WE have here an account of some exceedingly interesting experiments performed by Prof. Goppelsroeder, the results of which have been on view at the Paris Exhibition. It appears that as far back as April 14th, 1875, the author read before the Chemical Committee of the Industrial Society of Mulhouse a preliminary notice on the action of free ozone and of the voltaic current upon certain substances belonging to the aromatic series. Since that time he has carried out these investigations with great care, and has arrived at results which may not improbably become of considerable practical importance, and which must at any rate be recognised as of scientific value. He himself gives the following general sketch of what he has already in part accomplished and hopes to contemplate in the future:—

"To make use of the galvanic current for decomposing water and its typical derivatives, and arrive at colouring matters of the different series by adding to the water any solution of the primary aromatic bodies which may be converted into dyes. To imitate by this electro-chemical method the purely chemical methods usually employed in obtaining colouring matters. To incorporate with water or with one of its typical derivatives a mixture of any

solution of aromatic matters with organic substances or organic electrolytes, whose atoms or groups of atoms, set free by the action of the electric current, may take part in the metamorphoses in the molecules of the aromatic bodies, so that the hydrogen or other atoms of the latter may be replaced by other atoms or groups of atoms of the substances added." "To effect inversely at the negative pole a retrogressive metamorphosis so as to arrive at the aromatic bodies which had been the point of departure, or which are theoretically supposed to be. To arrive even at such primary matters as benzol, toluol, naphthalin, anthracen, &c.", "To seek to discover the process of the formation of colouring matters in the animal and vegetable kingdom, and to ascertain if such are not also formed galvanically."

At Paris the author exhibited 71 specimens of coal-tar colours, black, red, blue, violet, brown, and yellow. We do not find mention of any green colour. There were displayed also 36 samples of silk dyed electrolytically. The processes employed in the production of the colours are exceedingly simple, and will be rendered much less expensive by the substitution of *e.g.*, a Gramme machine for the Bunsen batteries used to give a current. The author hopes to develop an electro-chemical dyeing process, the colours being fixed upon the fibre at the moment of their formation.

Principles and Objects of the Chemistry of Coal. (Grundzüge und Ziel der Steinkohlen-Chemie.) By Dr. F. Muck, Principal of the Mining Laboratory and Teacher of Chemistry at the Westphalian Mining School at Bochum. Bonn: Emil Strauss.

The author of this work makes in his preface the startling, but perfectly true, remark that "in the manuals and textbooks of chemistry, whether pure or technological, there is to be found little concerning the chemistry of coal, and in that little there is a portion either erroneous in point of fact or based upon false and arbitrary assumptions." Whilst an enormous amount of the highest chemical talent has been applied to coal-tar, the raw material, the coal itself, has received but a small fraction of the attention which its technical importance might justly claim. In accordance with the requirements of his position, Dr. Muck fell to work to collect the matter bearing on this subject which exists scattered in geological and metallurgical works and in the scientific journals, and to submit it to a searching criticism. The result has been the following monograph, which we think will be exceedingly welcome to a great number of scientific men. The author gives here in succession certain generalities on the percentage composition of coals and on their proximate constituents. He then proceeds to consider the classification of coals according to their behaviour when heated either in the presence or absence of air. Next is discussed the connection existing between the properties of coal, especially its fusibility; yield in coke; degree of tumefaction when heated and nature of flame, with the percentage composition, exclusive of the ash. We then come to a consideration of the influence of the mineral constituents upon the yield of coke. The fifth chapter is devoted to the "mechanically admixed" ingredients of coal, exclusive of ash and of the sulphur compounds. Under this head the author treats of the different kinds of coal, the resinous soluble constituents, the proportion of water, and the hygroscopic character, and the gases occluded and given off. The author is still engaged with researches on the soluble constituents. He quotes the experiments of Guignet, who obtained 4 per cent of soluble matter from finely-powered coal, and by treatment with nitric acid succeeded in preparing oxalic acid and trinitro-resorcin. In his attempts at obtaining resorcin from coal there came over merely ammonia and aniline. This subject is the more interesting, since the manufacture of the coal-tar colours cannot occupy a sound position till its raw materials can be bought at any time in open market as required without the perilous necessity of "contracting." We next come to the mineral, and especially the sulphuretted constituents; the changes which coal undergoes on exposure to the air, weathering, and spontaneous ignition. In the eighth and last chapter the author expounds existing views on the chemical processes involved in the formation of coal, and treats of the experiments on the artificial production of coal, and the relations of coal to other fossil fuels. Dr. Muck inclines to the view of Goeppert that not merely lignite, but true coal, may have been formed in the wet way and in a relatively short time. Hence he ascribes little direct importance to the experiments of Cagniard, Latour, and Violette. He infers from Frémy's researches that the impressions of plants in coal and coal-shales prove, not that the coal is derived from such plants, but that it must once have existed in a plastic condition.

An appendix describes the method of calculating the heating-power of coal from its elementary composition, and gives a general view of the educts of coal and their utilisation.

Dr. Muck's monograph ably supplies a very distinct want in the chemical literature of the modern world.

CHEMICAL NOTICES FROM FOREIGN SOURCES.

Note.—All degrees of temperature are Centigrade, unless otherwise expressed.

Comptes Rendus Hebdomadaires des Séances, de l'Académie des Sciences. No. 20, November 14, 1881.

Researches on Electrolysis.—M. Berthelot.—The limit of effective electromotive forces is uncertain when there is polarisation. To take account of this, and to show if it enters into the common law, it is necessary to know the real nature of the compounds brought into action and their formation-heat. But here, as in thermochemistry and in a multitude of natural phenomena, we encounter the mechanical notion of the least action.

Synthesis of the Nitrogenous Colloids.—E. Grimaux.—The author defines the proteic matters as nitrogenous albumenoids which may be resolved by hydration into amidic acids, carbonic acid, and ammonia. Coloured reactions do not belong to the albumenoid molecule; thus the red tinge produced by Millon's reagent indicates a residue of tyrosine. He supposes that the amidic acids formed by the decomposition of the proteic molecule are fixed there with loss of water, forming condensed anhydrides, analogous to the polylactic acids of Wurtz and Friedel. As there are no mixed anhydrides of the amidic acids known, the author took up the condensation-product of a single amidic acid, the aspartic anhydride of Schaal. If this body is heated for two hours to 125° to 130° with half its weight of urea, it is transformed into a thick mass, perfectly soluble in boiling water. The solution is gummy, filters with difficulty, and possesses all the characters of the colloids; it is precipitated by the acids, the alkaline salts, by magnesium and aluminium sulphates, the salts of iron, mercury, and copper, by tannin; all these precipitates are gelatinous, and so thick that with concentrated solutions they do not fall out if the vessel is inverted. The precipitates formed by hydrochloric and nitric acids dissolve in an excess of the acid; the addition of water causes a separation of gelatinous flocks. The jelly yielded by acetic acid is converted on drying into translucent plates, presenting the aspect of dried albumenoid matters; it is then insoluble in boiling water, which merely softens it. It dissolves in potash; its alkaline solution, if treated with copper sulphate, takes a violet colour, having absolutely the same shade as the proteic substances. The solution of poly-aspartic amide may be isolated by dialysis. We thus obtain a liquid which dries up in a vacuum to a translucent mass, presenting the same appearance as the

precipitate formed by acetic acid, from which it is distinguished by its solubility in water. If the solution is evaporated, not in a vacuum, but on the water-bath, the residue becomes in great part insoluble. If it is possible to produce mixed anhydrides containing residues of aspartic acid, leucine, tyrosine, they may be thus transformed into amides, which approximate more and more to the colloids formed by living organisms.

Crystallographic Observations on a Variety of Natural Blende.—P. Hautefeuille.—Not suitable for abstraction.

Researches on the Absorption-Spectrum of the Earth's Atmosphere, at the Observatory of Paris.—N. Egoroff.—During eleven nights, from 8 to 10 p.m., and in different kinds of weather, the author has studied the absorption-spectrum of the atmospheric stratum between Mont-Valérien and the Observatory, the spectrum being produced by a very intense electric light, concentrated and directed by a Mangin projector. On November 3rd and 5th, during rain, with temperatures of 10·9° and 13·8°, all the rays marked in Angström's Atlas were distinctly visible. Twelve lines of the group B were easily distinguished, and those of the neighbouring part of the group *a*. The lines D and D_2 were more feeble than in drier weather. May not these be telluric lines, depending on absorption by the vapour of sodium? It would be desirable in further researches to compare the absorption-spectrum of the earth's atmosphere with the emission-spectrum of the air, as well as to examine if changes in the spectrum would be produced during storms. It is probable that besides watery vapour, air is the only strongly absorbent body. The author proposes to continue his observations between Oranienburg and Cronstadt so as to have an absorption-spectrum freed from the vapour of water.

Electrolysis of Water.—D. Tommasi.—The author shows here that if one of the two electrodes of the voltameter is of aluminium, zinc, or carbon, the decomposition of the water takes place equally.

Reversibility of the Electro-chemical Method for the Determination of Equipotential or Efflux Network.—A. Guébhard.—Not susceptible of useful abstraction.

Magnetic Properties of the Nickel-iron of Santa Caterina, Brazil.—H. Becquerel.—This iron is much less magnetic than pure iron. If heated for an hour to bright redness in lime, to avoid too great oxidation, and then slowly cooled, the ingot became twenty times more magnetic than in its natural state, and almost equal to iron.

Proportions of Carbonic Acid in the Higher Regions of the Atmosphere.—A. Muntz and E. Aubin.—Specimens of air taken at the summit of the Pic de Midi gave results extremely similar to those previously obtained in the plain of Vincennes.

Moniteur Scientifique, Quesneville.
September, 1881.

Studies on the Alkaloids.—Dr. W. Kœnigs.—The first part of an extensive memoir, in which the author, after a historical introduction, treats of the mutual relations of these bodies, their behaviour with acids and alkalies, their oxidation, and the relation between the alkaloids and the pyridic bases. He then gives an account of quinoline and lepidine, the behaviour of the former with reducing agents, its nitro- and amido-derivatives, the oxidation of quinoline and lepidine, the pyridinocarboxylic acids and bases, and piperidine.

A New Class of Colouring-Matters Discovered by H. Kœchlin and O. N. Witt.—The colours in question are blues and violets, remarkable for their cheapness and fastness; they have received the name of indophenols, and have been patented by the inventors. They are applied in dyeing in a manner approaching that in use for indigo. Thus, in order to dye wool the colouring-matter is stirred up in alkaline water and heated to 80° with grape sugar. The liquid becomes greenish with bronze striæ and reflections on the surface. It is then diluted with much hot water, and the wool is entered. When the shade has been reached it is taken out, drained by pressure between rollers, washed in abundance of water, and the colour is developed by exposure to the air or better by a passage through an oxidising bath. For printing the colour is thickened with white starch, [illegible] soda is added, and a reducing [illegible] which have won for Mitchell's "Manual" hydrosulphite. It is then printed upon cloth which has been prepared in sulpholeate of ammonia and steamed for one and a half to two hours. In this manner indophenol blue can be associated with alizarin reds, aniline blacks, &c., and all steam colours. Prof. Noelting considers that these colours will prove more dangerous rivals to indigo than the artificial indigo of Baeyer.

Review of Chemical Researches Published in Germany.—A collection of extracts from the *Berlin Berichte*, from the *Journal für Prakt. Chemie*, and the *Annalen*.

Radiophony.—W. H. Preece.—A translation from *Engineering*.

The Magnesia Industry.—T. Schlœsing.—Already noticed.

Les Mondes, Revue Hebdomadaire des Sciences.
No. 2, September 15, 1881.

A certain M. Paul Carrière, resident in New York, is said to have invented a heat-accumulator, or "thermophere," of such power that a box of 5 centimetres cube will serve to warm a house during a long winter. The editor of *Les Mondes* quotes the old proverb "A beau mentir qui vient de loin."

Position of the Carbons in Electric Arc Lamps.—M. Duboscq.—The author recommends that the two carbons should not be placed exactly in the same straight line, but that the negative should be a little in front of the positive. Otherwise the positive carbon is formed into a depression, at the bottom of which, and masked by its edges, is found the most intense light.

On Ammonium Bicarbonate.—M. Melsens.—This salt is almost fixed in ordinary air, but is easily dissociated if moistened with a little water.

On Cathodes and Phosphorescent Light.—M. Goldstein.—In this memoir, which is continued from the last number, the author seeks to prove the improbability of a convective discharge in spaces filled with rarefied gases. He ascribes the relative darkness of the space near the cathode to the small number of the luminous particles of the electrodes, and not, as does Mr. Crookes, to the want of collision of the radiating matter with the particles of the gas.

MEETINGS FOR THE WEEK

Saturday, 10th.—Physical, 3.
Monday, Dec. 12th.—Medical, 8.30.
— Society of Arts, 8. "Some of the Industrial Uses of the Calcium Compounds," by Thos. Bolas, F.C.S.
— London Institution, 5.
Tuesday, 13th.—Institute of Civil Engineers, 8.
— Royal Medical and Chirurgical, 8.30.
— Photographic, 8.
Wednesday, 14th.—Society of Arts, 8. "Electric Lighting at the Paris Electrical Exhibition," by W. H. Preece, F.R.S.
— Microscopical, 8.
— Society of Public Analysts, 8. "Some Observations on the Permanganate Test," by Dr. Dupré, F.R.S. "A New Method of Testing for Alum," by A. Wynter Blyth, M.R.C.S.
Thursday, 15th.—Chemical, 8.
— Royal, 4.30.
— Philosophical Club, 6.30.
— London Institution, 7.
— Society of Arts, 8. Adjourned Discussion on the Patent Bill prepared by the Society of Arts.

THE CHEMICAL NEWS.

Vol. XLIV. No. 1151.

...which are theoretically supposed to be.

ITS FIRE RISKS AND THEIR REMEDIES.

By HENRY MORTON, Ph.D.
President of the Stevens Institute of Technology.

Some very lamentable accidents have strongly directed public attention to the question of danger possibly accruing to life and property through the rapidly increasing employment of electricity as a source of light, and as the actual conditions of this danger, like the true properties of the agency from which it may arise, are but little known, a brief explanation of some simple facts related to this subject will be at this time seasonable and perhaps useful.

I would propose, then, to treat this subject under two general heads, namely:—1st. The sources of danger; 2nd. The conditions of their prevention, or of security.

The sources of danger in the use of the electric light are essentially two: from the conducting wires and from the electric lamps.

As long as the electric fluid, or electric energy, is conveyed by a sufficiently good conductor it is perfectly harmless, resembling a river flowing in its natural channel, and powerless to rise above its banks: it is only when some easier channel into surrounding objects is offered or some partial obstruction of a certain character impedes its regular flow that trouble may arise.

The conditions of these difficulties are, moreover, very peculiar.

Thus, for example, if two electric conducting wires, forming the outgoing and returning paths of a powerful current, are placed near each other, but are separated by a bad conductor,—as, for example, when both are tacked on to a board partition wall—the current will follow the wire from end to end, with no development of heat in the same, or tendency to leave the conductor or pass into any adjacent object. If, however, between the two conducting wires we introduce some imperfect conductor, such as a small wire, some metallic dust, or a film of water containing mineral matter in solution, then a portion of the current will be diverted into this "short-cut" from wire to wire and may heat the fine wire, or the metallic dust, or the wood wetted with the aqueous solution, so as to cause the ignition of inflammable matter.

Accidents of this nature have already occurred. Thus, a telegraph or telephone wire having fallen across one or more of the conductors used for street-lighting purposes has been fused, or, itself escaping, has caused the fusion of finer wires connected with it.

Again, two wires, being the outgoing and return circuits of a powerful current, have been nailed side by side, without other insulation, on the same board of a floor, partition, or ceiling; and though used safely for a long time, while the woodwork was in its normal state, have developed a very dangerous activity when the wood between them was wet with dirty or impure water. In that case the water offers a circuit through which a cross current is established, which first heats the damp wood, then chars it, and finally establishes a series of minute arcs or electric sparks along this charred surface, which would soon develop a conflagration if left uncorrected.

Again, two such wires as above, insecurely attached near each other, may be brought into momentary contact and then separated, in which case an electric arc, with its intense light and heat, will be established between them. In like manner a conducting wire itself may be insecurely connected at some point, and if the abutting ends are separated slightly during use, a similar "arc" with its intense heat may be there developed.

These examples will give a fair idea of the dangers arising from the conducting wires, and they are manifestly to be guarded against by a proper separation and insulation of the wires themselves. Of this, however, more anon. At present I would only further point out that there is no risk whatever of any heating or other injurious action arising in or from the conductor itself when an adequate one is used, as must be the case from motives of economy; since an inadequate conductor would involve ruinous expense in the use of the electric current.

Electricity is not to be regarded as a sort of fluid fire passing along the conductor; and some popular notions on this head are as absurd as were similar ones which prevailed in reference to illuminating gas at the time of its first introduction, and which caused rules to be made in some places that no gas-pipe should be allowed to come in contact with any wood-work.

Turning next to the dangers which might be expected from the electric lamp, it is to be remarked in the first place that these in the case of the arc lights depend much upon the number of lamps operated on the same circuit. Thus, if thirty or forty lamps are operated in series, the electromotive force of the current must be sufficient to maintain a correspoding number of arcs; and, therefore, if by any means many of these arcs are closed out the electromotive force of the current available for the remaining ones would be so excessive that their arcs might become excessively long, and even the metallic carbon holders and other parts of the lamps constitute poles between which the arc would spring, melting the metal work and establishing a very dangerous centre of combustion.

To avoid this class of dangers two provisions should be made.

In the first place some arrangement in the lamp itself by which, whenever the arc exceeds certain safe limits, the current will be automatically diverted from it and carried through a good and sufficient conductor; and, in the second place, some apparatus in connection with the electric generating machine by which the electromotive force of its current should be varied automatically in correspondence with the resistance of the circuit, so that any diminution of such resistance, as by the closing out of several arcs, should cause a corresponding diminution in the force of the current generated.

Numerous contrivances for both of these purposes have been already carried to greater or less perfection and efficiency, and it is manifestly possible by such means to secure immunity from risks of this sort.

The securing of adequate insulation for the conducting wires in view of the endless ramifications of telegraphic and telephonic systems, to say nothing of the other conductors found in all buildings, is a problem of no small difficulty. One important general principle would seem to be the equal insulation of the return as well as of the outgoing wires, as well as of the machines, and the avoidance of all ground connection for any part of the circuit. Another general rule would be the separation of outgoing and return wires as far as possible from each other; and yet another, the continuous insulation of conductors, leaving no vulnerable places even where danger would not directly result from accidental contact.

Fully to discuss all the details of this subject would be impossible within the proper limits of such a note as the present, and I will therefore only say in conclusion that, with well matured plans and skilful and intelligent provision, all these dangers may be provided against, and electric lighting may be made as safe as that obtained by gas or by candles; but without such care and judgment the use of electricity on the grand scale, either for lighting or for transmission of power, would involve serious additions to the risks which accompany so many of the conveniences which constitute a large factor of our modern civilisation.

What I have here written is but a fragment of the entire subject involved, and at some future time I hope to fill out and complete this preliminary sketch.

METHYL-ORANGE AS AN INDICATOR IN ALKALIMETRY.

By Professor G. LUNGE.

Many enquiries having been addressed to me from time to time concerning the use of "Tropæoline," &c., in alkalimetry, I think it will be convenient to explain this matter in your columns.

Some time ago Dr. W. von Miller recommended the use of Dr. O. N. Witt's Tropæoline O O as an indicator, and pointed out that it is indifferent to CO_2, so that alkaline carbonates can be titrated with it in the cold. Shortly after I drew attention to the fact that several other azo compounds are far more sensitive than the above, and I especially recommended one which was at that time best known as Poirrier's Orange, No. III. The same has also been sold as "Helianthine" and as "Tropæoline D." It is in reality a salt of sulpho-benzene-azo-dimethylamin, for which long name I propose the short and sufficiently clear name "Methyl-orange." This compound imparts a yellow colour to alkaline solutions, and turns pink with the slightest excess of a strong acid: the transition is more delicate and sudden than with any other compound I have tried. It has, moreover, the advantage that it is indifferent, not merely to CO_2, but also to H_2S and acetic acid, so that it can be employed, among other purposes, for titrating black-ash solutions in the cold. Only mineral acids can be employed as standard liquors in this case: oxalic acid (the same as the other vegetable acids and sulphurous acid) gives an irregular and less accentuated transition of colour. Sodium thiosulphate behaves like a salt of the strong mineral acids. Nobody who has once or twice tried methyl-orange *in the proper way* ever reverts to the use of litmus, which involves boiling the liquid and spending three or four times as much time over the test, and for several years past the former has been employed almost exclusively, both in my own and in my colleague's (Victor Meyer's) laboratory.

But a difficulty has arisen in this way. Several persons have tried other tropæolines,—have not found them to answer, or they have even tried methyl-orange, but not in the proper way, to be described below. It has also been very difficult to procure the latter; for just owing to its extreme sensitiveness in the presence of traces of mineral acid it is not a good dye, and its manufacture as such had ceased. But as I found it to be such an excellent indicator, and that many people enquired after it, I induced a Swiss colour works to manufacture it on purpose. Dr. T. Schuchardt, of Goerlitz, has undertaken the retail sale, and Messrs. Mawson and Swan, of Newcastle-upon-Tyne, will supply it to British customers. Since only a minute quantity of it must be taken for each test, it is actually much cheaper than litmus, a few grammes lasting a lifetime.

Methyl-orange is employed in a very dilute aqueous solution, of which only so much should be added to the liquid to be tested, say with the point of a glass rod, that an extremely faint yellow colour is produced. There should be sufficient to show a decided pink with an excess of acid; but if the alkaline liquid be strongly yellow, the transition from this to pink is only gradual, and no sharp results can be obtained. The transition from pink to a faint yellow, in titrating acids by means of standard alkali, is equally sharp; and a solution of sodium carbonate is just as good for this purpose as one of caustic soda, the CO_2 making absolutely no difference. The test must be made at the ordinary temperature, or near the same; with warm liquids the results are unequal and erroneous.

LONDON WATER SUPPLY.

Report on the Composition and Quality of Daily Samples of the Water Supplied to London, for the Month ending November 30th, 1881.

By WILLIAM CROOKES, F.R.S.

WILLIAM ODLING, M.B., F.R.S., F.R.C.P., Professor of Chemistry at the University of Oxford;

and C. MEYMOTT TIDY, M.B., F.C.S., Professor of Chemistry and of Forensic Medicine at the London Hospital; Medical Officer of Health for Islington.

To the Right Honourable the President of the Local Government Board.

December 7th, 1881.

Sir,—In the following tables you will find recorded the results of our analyses of the 182 samples of water, collected by us during the month of November on the days and at the times indicated, from the mains of the seven London water companies taking their supply from the Thames and the Lea.

Of these 182 samples, one was recorded as "slightly turbid," and 5 as "very slightly turbid." The remaining 176 samples were bright, clear, and efficiently filtered.

In Table I. we have recorded the analyses in detail of samples, one taken daily from November 1st to November 30th inclusive. The purity of the water in respect of organic matter has been determined by the Oxygen and the Combustion processes, and the results of our analyses by these methods are stated in columns XIV. to XVIII.

We have recorded in Table II. the tint of the several samples of water as determined by the colour-meter described in a previous report.

Of the 26 samples supplied by the New River Company, the whole were found to be well filtered, clear, and bright.

Of the 26 samples from the mains of the East London Company, the whole were found to be well filtered, clear, and bright,

Of the 26 samples from the mains of the Chelsea Water Company, the whole, excepting one which was "very slightly turbid," were found to be well filtered, clear, and bright.

Of the 26 samples from the mains of the West Middlesex Company, the whole, excepting one which was recorded as "very slightly turbid," were found to be well filtered, clear, and bright.

Of the 26 samples from the mains of the Lambeth Water Company, one was recorded as "slightly turbid," and one as "very slightly turbid." The remainder were found to be well filtered, clear, and bright.

Of the 26 samples from the mains of the Grand Junction Company, the whole, excepting one which was "very slightly turbid," were found to be well filtered, clear, and bright.

Of the 26 samples from the mains of the Southwark and Vauxhall Company, the whole, excepting one which was recorded as "very slightly turbid," were found to be well filtered, clear, and bright.

In Table III. we have recorded the oxygen required to oxidise the organic matter, and the quantities of free oxygen present in the whole of the samples collected.

These results show that the quality of the water supplied by the London companies continues to be excellent, notwithstanding the unfavourable condition of the rivers consequent on the heavy rainfall of the month. The aëration of the water is abundant, and its freedom from organic matter but little less complete than during the summer months.

We have the honour to remain, Sir,
Your obedient Servants,

William Crookes,
William Odling,
C. Meymott Tidy.

AN APPARATUS FOR THE RAPID ANALYSIS OF MIXTURES OF GASES.

By ARTHUR H. ELLIOTT, Ph.B., F.C.S.,
School of Mines, Columbia Coll., N.Y.

In gas-works, and also in many iron- and steel-works, it often becomes necessary to make a number of analyses of mixtures of gases daily, which, of course, is only possible with simple apparatus. The earliest and simplest form of apparatus was a tube for the determination of carbonic acid, very much like an inverted burette, used by C. Stammer.* This tube was further modified by F. M. Raoult,† who used two stopcocks, one above and another below; and to the upper stopcock was attached a funnel, which serves to introduce the chemicals in solution for treating the gas. After treating the gas, Raoult washed out the chemical used with water, introduced through the funnel, and the gas was measured by bringing the tube to a nearly horizontal position and allowing water to run in through the funnel.

Wilkinson modified this tube of Raoult by placing it in a wider tube having a stopcock below, and omitting the stopcock upon the lower end of the measuring tube. By this means he could adjust the pressure upon the gas by adding water to or drawing it from the exterior tube.

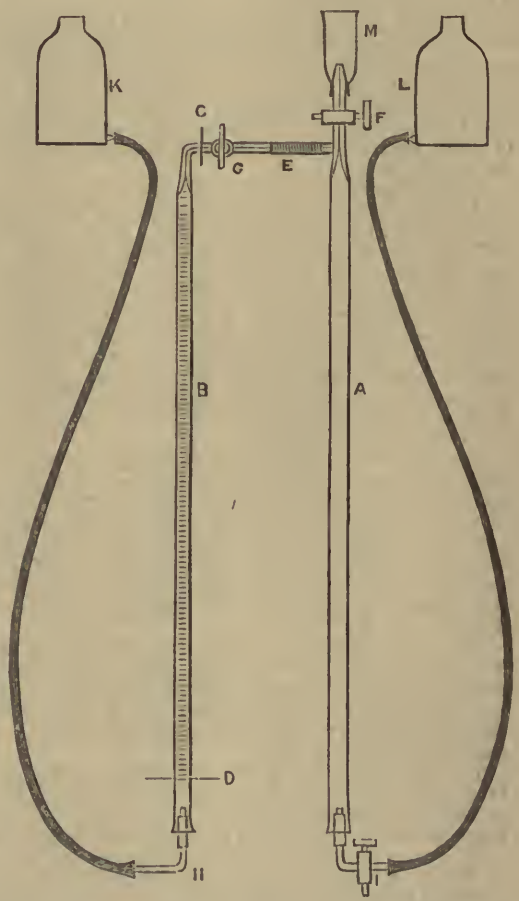
But the difficulty with these methods is the necessity of washing out the chemicals used to absorb the various gases. For example, after treating a gas mixture with pyrogallate of potassium, it is necessary to wash out all the pyrogallate before adding bromine to absorb the illuminants, otherwise the bromine is absorbed by the alkali before it can act upon the gas. To obviate this difficulty, and one or two others, I have used the apparatus described further on.

The apparatus of Orsat at once suggests itself as a remedy for these difficulties; but, unfortunately, to attain the same accuracy as with the apparatus I describe, you have to use four times the amount of time, and moreover the apparatus of Orsat is both costly and fragile.

The apparatus is shown in the accompanying drawing. The tube A is of about 125 c.c. capacity, whilst B, although of the same length, holds only 100 c.c. from the mark D, or zero, to the mark on the capillary tube at C, and is carefully graduated into one-tenth c.c. The attachments to these tubes below are seen from the drawing, except that the stopcock I is three-way, with a delivery through its stem. The bottles K and L hold about one pint each. The tubes A and B are connected above with one another, and with the funnel M by capillary tubing, about one m.m. in internal diameter. There is a stopcock at G and another at F, while the funnel M, holding about 60 c.c., is ground to fit over the end of F above. At E is a piece of rubber tubing uniting the ends of the capillary tubes, which are ground off square to make them fit as close as possible.

In beginning the analysis of a mixture of gases, the stem exit of the three-way cock I is closed by turning it so that L and A are connected through the rubber tubing; the stopcocks F and G are opened, and water is allowed to fill the apparatus from the bottles K and L, which have been previously supplied. When the water rises in the funnel M, and all air-bubbles have been forced out of the tubes, the stopcocks F and G are closed, the funnel M removed, and the tube delivering the gas to be tested attached in its place. By now lowering the bottle L slowly, and simultaneously opening the stopcock F, the tube A is nearly filled with gas, and the stopcock F is closed. The tube delivering the gas is now removed, the funnel M replaced, the bottle L raised, the bottle K lowered, and by opening the stopcock G the gas is transferred to the graduated tube B. By placing the bottle L on a stand at about the level of the water in A, the level in B and in the bottle K can be adjusted to the zero point, and the stopcock G is closed. The excess of gas in A is expelled by opening the stopcock F and raising the bottle L. The gas remaining in the capillary tube between C and the vertical part is disregarded, or in very careful work it may be measured and an allowance made in not filling the tube B quite to the zero mark, but usually it is too small to be worth notice.

Having measured the gas to be tested, it is now transferred by means of the bottles K and L into the tube A, and the fluid chemicals added by placing them in the funnel M and allowing them to flow down the sides of the tube slowly, care being taken *never* to let the fluids run below the level of the top of the vertical tube in the funnel. It is best to have a mark on the outside of the funnel at least three-fourths of an inch above the top of the level



of the vertical tube, and never to draw the fluid down below this point.

Having treated the gas with the chemical, it is transferred by means of the bottles to the tube B, to be measured. If the chemical gets into the horizontal capillary tube, the passage of a little water from the bottle K will remove it, before transferring the gas. When the gas residue is in B, and the fluid in A has been adjusted at the mark C on the horizontal tube, the stopcock G is closed, the bottle K is lowered till the level of water in it and that in the tube B are the same, and the reading is then made. The tube A is now filled with the chemical just used and water. By turning the stem of the three-way cock I, so that it communicates with A, and also opening the stopcock F, the contents of the tube can be run out, and water run through the funnel M to clean the tube for a new ab-

* *Dingler's Polytech. Journ.*, cii. 368.
† *Comptes Rendus*, 1876, 844.

sorption. When the tube is clean, by turning the stopcock I, so that A and L communicate, the water is forced into A, and the whole is ready to receive the gas for new treatment. By this means the gas is removed from the action of the water used to wash out the chemicals, and the chemicals are completely removed from any interference with each other when treating a mixture of gases. In using this apparatus the solutions are added in the following order:—

1. *Potassic hydrate*, to absorb carbonic dioxide (also hydrogen sulphide and sulphurous oxide* if present).
2. *Potassium pyrogallate*, to absorb oxygen.
3. *Bromine*, to absorb illuminants, like olefiant gas and acetylene, and after the absorption is complete, and the bromine vapours cause an expansion, a little potassium hydrate is added, to absorb these vapours before the gas is transferred and measured.
4. *Cuprous chloride* in concentrated hydrochloric acid solution, to absorb carbonic oxide. After this absorption is complete the gas is transferred to the measuring-tube, the contents of the tube A run out, the tube washed, and filled with water from the bottle L. The gas is now transferred to A, and treated with potassium hydrate solution, to absorb hydrochloric acid vapours, before the final reading is made in B.

The treatment up to this point takes from twenty to thirty minutes, according to the amount of practice the operator has had with the apparatus. The gas residue still contains marsh gas, hydrogen, and nitrogen. By removing the funnel M, and attaching in its place a rubber tube communicating with an explosion eudiometer in a deep cylinder of water (both eudiometer and rubber tube being drawn full of water), a portion of the gas residue can be mixed with oxygen, exploded, and the contraction and the carbonic acid determined, the marsh gas and hydrogen being calculated by the usual formula. The nitrogen is found by the difference of the addition of the other constituents and one hundred.

The explosion tube is simply a tube like A, without the lower attachment and the lateral capillary tube above, the funnel M being retained, and two platinum wires are fused into the glass near the top, to give the spark for ignition. It is only necessary to clamp this tube down upon a piece of cork in a vessel of water during explosion, and adjust the water-level in a tall cylinder of water when making the readings of contraction and absorption of carbonic dioxide.

The whole analysis can be readily completed in forty-five minutes, and with due care gives results that are practically correct. Analyses done with an Orsat apparatus, with great care, gave results almost identical with those obtained by the above-described apparatus in one-fourth the amount of time.

The great advantage of this apparatus over the single tube method is, that the gas is not submitted to the action of the water used to wash out the chemicals, which I have found to reduce the volume of the illuminants by 2 per cent.

Of course this method will not compare with the methods of Bunsen and others, where very delicate readings and nice precautions are taken, but it gives very good results for rapid work, and answers every purpose in every-day practice in a gas or metallurgical works.

The water used in the apparatus should be of the same temperature as the room in which the analysis is made, and by careful handling little or no chemicals get into the bottle L.

When working in a warm place the tube B should be surrounded with a water-jacket, to prevent change of volume in the gas while under treatment.

Movements of Viscous Liquids.—Dr. Margutes.—By keeping glycerin, castor oil, &c., in regular motion for some time, the author has obtained characteristic figures. —*Les Mondes.*

* If these gases are present in large quantities, special methods are necessary for their estimation.

ON A

NEW METHOD OF DETERMINING THE CHLORATE IN BLEACHING CHLORIDES.

By M. E. DREYFUSS.

THE various methods hitherto proposed for this purpose are very complicated and unfit for industrial purposes. The author's method is based on the property of cupric acid in a strongly hydrochloric solution of being reduced to cuprous oxide by the action of stannous chloride at a boil. The end of the process is indicated by the decolouration of the liquid, which from yellow becomes colourless. For the process are required:—

I. A solution of copper, made by dissolving blue-stone in distilled water so as to make up a litre, of which 10 c.c. represent about 0·1 grm. of metallic copper.

II. An acid solution of stannous chloride, made by dissolving 15 grms. of this body in 200 c.c. of hydrochloric acid and making up to a litre with distilled water.

III. A solution of potassium chlorate; 5·917 grms. of this salt are dissolved in a litre of distilled water; 10 c.c. of this liquid are exactly equal to 0·05 grm. calcium chlorate.

To find the value of the chlorate solution in comparison with that of potassium chlorate 10 c.c. of the solution of copper (0·1 grm. of copper) are poured into a flask or a conical glass of colourless glass, holding 150 c.c., and 50 c.c. of hydrochloric acid are then added. The mixture is heated to an incipient boil and titrated with the stannous liquid till decolourised. To the colourless liquid are added 5 c.c. of the potassium chlorate, which oxidise a corresponding quantity of cuprous chloride. This quantity is determined by titrating again with stannous chloride. By this titration is found the corresponding relation between the cupric and the chlorate solutions. When this relation is once determined it does not vary as long as the solution lasts.

Preparation of the Sample of Chloride of Lime.—10 grms. are stirred up in 100 c.c. of water, and saturated with ammonia, which is added by small quantities till there is a slight excess. It is then boiled till the odour disappears, and the liquid with the precipitate is passed into a flask marked at 500 c.c. The liquid is let settle, depositing a precipitate, which contains a little ferric oxide.

The introduction of a little potassa in the chloride, after it has been saturated with ammonia, much facilitates the settlement of the deposit. The presence of this deposit in the liquid has no very definite effect upon the results. When the solution of the chloride is thus prepared the chlorate is titrated; 10 c.c. of the cupric solution are raised to a boil with 50 c.c. of hydrochloric acid; it is titrated to decolouration with stannous chloride; then 50 c.c. of the solution of the settled solution of chloride are added; it is boiled, and the copper which has been oxidised is titrated again. This determination is applicable also to liquid chlorides.—*Bulletin de la Société Chimique de Paris.*

DETERMINATION OF POTASH IN POTASSIUM SALTS AND IN POTASSIC MANURES.

By M. A. ROUSSELOT.

ACCORDING to the nature of the salt there may have to be determined potash, soda, magnesia, chlorine, sulphuric acid, nitric acid, moisture, insoluble matter, &c. The author treats here merely of potash.

A. Dissolve 10 grms. in water and make up to a litre. Take, according to the nature of the salt, 125 or 250 c.c., and introduce into a half-litre flask. Boil for a few

moments, and add 20 c.c. baryta-water at 1-20th in case of a chloride, or 50 c.c. if a sulphate. Pass in a current of carbonic acid, boil for half an hour, let settle for some hours, filter into a flask marked at 500 c.c., and make up this volume with the washing-waters.

B. Take in duplicate 200 c.c. if a sulphate, or 100 c.c. for any other salt; put the portions into two porcelain capsules of 10 centimetres in diameter, add hydrochloric acid, and then 40 c.c. = 2 grms. platinic chloride at 1-20th. Evaporate to dryness in the water-bath, and take up in alcohol at 60° mixed with 1-10th ether; wash by decantation with the same liquid, so as to have about 200 c.c. of filtrate.

C. Put the filter and its contents into a ¼ litre flask, pour upon it boiling water in small quantities by means of a washing-bottle until the platinum salt is completely dissolved. Heat in a large porcelain capsule (16 to 18 centimetres in diameter) about ½ litre of distilled water, and add 20 c.c. = 2 grms. sodium formiate (solution at 1-10th), and heat to a boil. Pour then into the capsule the solution, likewise boiling, of the potassium chloro-platinate. Keep up the ebullition for a quarter of an hour, and until all escape of gas has ceased. When the liquid is clear and quite cold, filter, wash the precipitate with hot water acidulated with hydrochloric acid, and pour it finally upon the filter. Clean the sides of the capsule with a glass rod tipped with a small caoutchouc stopper, still using the acidulated water, and finally finish washing the filter with hot distilled water. The filter and its contents are dried, calcined in a small tared platinum capsule, and weighed. The net weight found after deduction of the ash of the filter is multiplied by 200 × 0·4747. We have thus at once the percentage proportion of KO in the salt analysed. This method, though somewhat long, totally eliminates the excess of barytic salt, and furnishes very accurate results.

For the determination of potash in manures the author takes 10 grms. After having ground it up in a mortar, and exhausted it completely with boiling water, he filters, and makes the solution up to 1 litre. He then operates upon quantities of the liquid corresponding to 1·25 to 5 grms. of the manure, and treats with baryta-water. Then, after a long boiling, at least half an hour, to expel ammonia and eliminate phosphoric and sulphuric acids, a current of carbonic acid is passed into it for half an hour. After boiling, to decompose the bicarbonates, it is let settle, and the analysis is completed by filtering as in the former case.—*Bulletin de la Société Chimique de Paris.*

METHOD FOR ACCURATE AND RAPID ANALYSES OF AIR.

By E. W. MORLEY, M.D., Ph.D.,
Hurlbut Professor of Chemistry in Western Reserve College.

I HAVE made a series of daily analyses in duplicate of air collected at this place for six months beginning with January 1, 1880, and one for six months and twenty days beginning October 1, 1880. The samples of air were collected in bottles with well fitting glass stoppers. A few drops of solution of potassium hydrate being put into the bottle, this was set in the open air, and the air in the bottle displaced by sufficient aspiration, the observer keeping at a little distance to the leeward side. The stopper was then put in place and wet with the potassium hydrate by inverting the bottle and turning the stopper. Experiment showed that it was possible to keep samples for many days in this way with the certainty that they remained unchanged.

A mercury pump was used to withdraw the sample from the bottle. A rubber stopper was used to make the needed connection with the pump. Experiment showed that this rubber in contact with the alkaline solution does not absorb more than a hundredth per cent of oxygen from the air in the bottle in twenty times the period during which it was in contact with the air used in the analysis. The pump discharged the air into a jar standing over mercury in the laboratory trough of the apparatus for analysis.

This jar being lowered, together with the cistern, over the recurved capillary end of the eudiometer tube, a certain quantity of air was taken into this tube. This quantity was measured approximately by using a journeyman pressure tube having a small bore. The quantity used was almost always the same, and occupied from 470 to 475 millimetres in length of the eudiometer tube, when the pressure on it was that of a column of mercury of this same length.

This quantity was then measured accurately with the standard pressure tube. This had a Jolly point in the vacuum at the level of the zero of the graduation on the eudiometer tube, which zero was at the top of the tube. The level of the mercury in the standard pressure tube being never permitted to vary more than a fraction of a millimetre, its vacuum was found to remain constant and unimpaired. When the mercury in it had been put in connection with the mercury in the eudiometer, and its upper level had been brought to the Jolly point by the use of a fine adjustment, the level of the mercury in the eudiometer was read with a microscope magnifying fifty diameters, and provided with an eye-piece micrometer. By this arrangement, when everything was prepared, it was possible to verify the contact at the Jolly point, to read the thermometer to the hundredth of a degree, and to read the level of the mercury in the eudiometer, in less than ten seconds. Uncertainty as to the actual temperature at the instant of final reading was in this way mostly avoided. This reading microscope is carried on a vertical cylinder which is solidly attached to the firm iron tripod which supports the whole apparatus. On this cylinder the mounting of the microscope can be clamped at the required height. The microscope is then made to give distinct vision of the graduation on the surface of the eudiometer. This graduation consists of lines not more than the eight-thousandth of an inch wide, cut with a diamond. No errors exist amounting to the hundredth of a millimetre in the parts of the graduation which have been used in these analyses. When distinct vision is obtained of the graduation, a fine adjustment moves the microscope vertically till the terminal lines of the eye-piece micrometer coincide with two lines of the graduation on the eudiometer. If now the horizontal focussing movement carries the microscope forward about half an inch towards the eudiometer, the microscope will give distinct vision of the meniscus in the tube, and its level can be read by the divisions of the eye-piece micrometer, which represent the divisions on the surface of the tube carried forward optically into its interior. It would be easy to show how far the use of such an arrangement is superior to that of a cathetometer for the purpose in hand, in accuracy, in rapidity, and in simplicity of reduction for expansion of the scale.

The measured quantity of air was next transferred to a jar standing over mercury in the laboratory trough.

A quantity of hydrogen amounting to about sixty-three per cent of the air taken was next measured approximately, and added to the air in the jar. This amount was always the same, so that any errors which were a function of the quantity of hydrogen should be constant in amount, and should not therefore affect the *differences* of the analyses. Sixty-three per cent was used in order that the last and first readings of volume might be made with the same position of the reading microscope.

After the air and hydrogen had had time thoroughly to mix, they were transferred back to the eudiometer, measured, expanded, exploded, and again measured. The expansion was always the same. In the transfers mentioned there is absolutely no possibility of loss or of admixture by leakage except by gross carelessness. The only place where leakage could take place is the stop-cock at

the top of the eudiometer. This stop-cock was specially made for this place, and has not yet been found to leak, though it has been tested for ten minutes against an internal vacuum before or after each analysis.

Two coincident readings were obtained for each measurement, though the result was always calculated from the last reading. To secure accurate determinations of temperature, the eudiometer and pressure tubes are enclosed in a box with plate-glass front and back, containing about ten litres of distilled water. This is vigorously stirred, except at the instant of reading the microscope, by means of a current of air from a condensing pump driven by power. I have had no difficulty in getting the required two coincident readings in half a minute when the thermometer was rising; but when the thermometer is falling, the difficulty in getting a reading of the thermometer which shall really represent the temperature is enough to make work very vexatious, for an error of a hundredth of a degree in the difference of temperature at two measurements in the same analysis is close upon the limit of allowance.

Great care has been taken to obtain hydrogen of sufficient purity. In the early analyses, a Bunsen's decomposing cell of the common form was used. It then often happened that the analysis made with the first hydrogen obtained after an interval of rest would give results showing a deficiency of oxygen of about a hundredth of one per cent. Often analyses had to be rejected, until the cell was freed from compounds of hydrogen with zinc or carbon, which had been produced by local action at the surface of the zinc. Finally, a cell was constructed which could be every morning connected with the air-pump and exhausted of hydrogen, so as to remove these compounds of hydrogen with zinc or carbon, whether they had risen through the liquid, or were still adherent to the zinc plate or dissolved in the dilute acid. The cell had a mercury stop-cock which interposed a barometric column against the leakage of air into the cell; but for additional security, the hydrogen coming from it passed through several inches of active platinum black. In this way I have now secured a supply of hydrogen which probably never occasions a difference of a five-hundredth of one per cent in two analyses of the same sample. Experiment shows that hydrogen may safely be left standing over mercury in a *clean* bell glass for a long time. I have left two samples for eleven weeks, which samples then were used in a duplicate analysis of a sample of air against a duplicate analysis of the same sample made with two samples of hydrogen just from the decomposing cell. Hydrogen was therefore sometimes used which had stood for a few days. Duplicate analyses were always made with different samples of hydrogen.

It may be observed that the corresponding measurements of different analyses were made under identical conditions. The calibration error, and the error caused by the imperfect parallelism of the reading microscope in its different positions, therefore, disappear from the *differences* of the analyses of different samples. The same is true of the error caused by the production of water in the eudiometer between the second and third measurements in each analysis. No correction has been applied for this error, because the distribution of the water above and below the meniscus cannot be easily determined. The amount of water adhering to the interior of the eudiometer before the commencement of an analysis has also been made always approximately the same. This has been accomplished by producing a vacuum in the eudiometer after the analysis, and the letting the mercury rise in it with a determinate velocity; when the eudiometer is clean, considerable uniformity is thus obtained.

In making observation as accurate as is required for my purpose, it is very important to keep the interior of the eudiometer very clean. A little irregularity in the film of water through which the meniscus is seen will spoil the reading. My eudiometer tube is cemented into a brass fitting which rests in a seat ground for it in the bottom of the enveloping box mentioned before. The eudiometer can be disconnected, removed, washed with castic potash and shot, rinsed out with dust free distilled water, and replaced ready for analysis, in an hour. The accurate fitting of the ground seat makes it possible to restore the zero of the graduation on the tube to the same level within the two hundredth of a millimetre, without even the bestowal of any thought on the matter. With this facility, the eudiometer has been kept sufficiently clean for accurate reading.

It is of course possible that the mean of all my analyses with the new apparatus is affected with a measurable constant error, though no measurable error has yet been traced to any assignable source. But it is certain that the differences in the means for different periods are affected with but very small errors. During the most favourable conditions under which I have used the apparatus, taking seventy minutes for each pair of analyses of the same sample, the mean error of a single analysis was, for half a month, less than the thousandth part of one per cent. Having commonly to work at odd times, and more rapidly than this, the accuracy attained has been less; but, for the whole seven hundred and eighty eight analyses made with it, the mean error of a single analysis has been less than the two hundred and eightieth of one per cent. If, then, two samples of air differ by one-fiftieth of one per cent in their contents of oxygen, the fact of a difference can be detected with a degree of probability nearly approaching certainty, at an expenditure of time not exceeding one hour for each sample. — *American Chemical Journal.*

CHEMICAL METHODS FOR ANALYSING RAIL-STEEL.*

By MAGNUS TROILIUS, Chemist to C. P. Sandberg, London.

Introduction.—By C. P. Sandberg.

Since the discussion on steel rails in America has forcibly drawn attention to the value of chemical analysis, if not as a necessary stipulation, at least as a guide to control the usual mechanical tests, some doubt has been thrown upon the accuracy of the analytical results obtained by different chemists.

To any one having the least acquaintance with chemistry it is quite clear that if exactly similar results are to be obtained from the same borings of steel, exactly the same methods must be used hy the different analysts. Hence the necessity (if complications are to be avoided) of establishing what I may call standard or normal methods, to be used both by the inspectors and chemists at the works. Remembering that the application of chemistry to steel rail inspection is yet in its infancy, it is of great importance to possess a perfect acquaintance with the best methods in use.

Being myself a grateful pupil of Professor Eggertz, of the School of Mines in Sweden, it occurred to me, two years ago, that I could not do better than start a laboratory of my own, and engaged one of his pupils, Mr. Troilius, for the purpose of analysing the steel borings from mechanically-tested rails, so that I might thus obtain, without delay, thoroughly accurate determinations.

Moreover, in order to carry on the operations in perfect accordance with the methods used at the steel works in England and Germany, where I had to control the manufacture, I deemed it desirable to allow Mr. Troilius to go through a course of training at these works; and I gladly seize this opportunity of expressing my grateful acknowledgments to several works in England and in Germany for affording every facility for such an exchange of

* Read before the American Institute of Mining Engineers October, 1881. From the *Journal of the Franklin Institute.*

information as was found necessary to arrive at the best analytical methods to be used.

The value of this preliminary training has already become evident, for, after working a year in my own laboratory, we find that the results hardly ever differ from those obtained at the works; or, at any rate, they rarely differ from the results of those professional chemists who check the same borings in case of any discrepancy.

Inasmuch as this work is principally executed for America, it naturally follows that if it is checked by American chemists it will be of interest, both for them and for the chemists on this side of the Atlantic, to know the methods of analysis followed in the two countries. With this view, I beg to introduce the following paper, which has been very carefully worked out by Mr. Troilius, and therefore deserves the attention of the members of the Institute.

I can only say of this paper, as I have said in my own, "On the Specification and Inspection of Steel Rails in Europe," that it fully explains the methods, which I have hitherto adopted, with excellent results. But if any better methods can be suggested by American chemists, I shall only be too glad to modify my present mode of working.

It only remains for me to add that Mr. Troilius will have great pleasure in answering any remarks or questions that may be addressed to him with reference to the following methods for the application of chemistry to steel rail inspection.

19, Great George Street, Westminster, August, 1881.

Chemical Methods for Analysing Rail Steel.

Useful Appliances.—One of the most useful and necessary appliances in a steel rail laboratory is the hot-plate. An iron plate, 12" × 18" × ⅜" thick, heated from below by a good Bunsen burner, will answer very well; or, if more convenient, the plate may be combined with a coke fire and a muffle-furnace, the coke fire thus heating both the plate and the muffle furnace. In any case, the plate should be heated in such a manner as to have a boiling temperature at only one part, from which part the heat should gradually decrease towards the edges. Thus arranged, the plate forms a very satisfactory substitute for water-baths, drying-boxes, &c., as will be seen in the following description of the methods. There is no risk of destroying beakers, &c., after sufficient experience in working the plate has been acquired.

A plate of this kind has been in use in the London School of Mines for about fifteen years, but, as far as I am informed, it was Mr. Snelus who first employed a plate in this way at Dowlais, and it has since become universally used in English and Welsh laboratories. I should also mention that it has been successfully introduced in the Stockholm School of Mines, in accordance with my suggestion last year in the *Jernkontorets Annaler*. In German steel laboratories the water-bath and other more "scientific" appliances are more generally in use than in England and Wales; in fact, I have not so far seen the plate used in any of the German steel works which I have visited. It is necessary to have the plate placed under a good draught, so as to remove all the noxious fumes which are evolved during the operations conducted on the plate.

As regards other useful appliances belonging to a well-fitted steel laboratory, they are all more or less common or are only occasionally used, and do not deserve as much attention as the above-named plate. Fluted funnels, however, are worthy of being mentioned as being somewhat quicker to work with than ordinary plain ones. I have not found them in use on the Continent as frequently as in the United Kingdom, but they are now beginning to be somewhat more appreciated, even in the Continental countries.

Carbon Determination.—Eggertz's colour-test is a very accurate method for determining carbon in rail-steel, provided the operator has sufficient experience and takes all the necessary precautions. At the same time, this method has the great advantage of being very rapid. It is now nearly twenty years since this method was described in Sweden and Germany by Professor Eggertz, and very shortly afterwards Mr. C. P. Sandberg published an English translation of the method in the Chemical News. In Great Britain the colour-test is now very largely used, every blow in the Bessemer converter being thus tested for carbon, and in the hands of skilled manipulators it gives every satisfaction. In German steel laboratories the colour-test is not so much used as in Great Britain, and costly arrangements are often employed for carrying out determinations of carbon by the combustion process on a large scale. For the daily control of rail-steel, however, this is rather an impracticable arrangement, when results, accurate within 0·01 per cent, can so rapidly be obtained by the colour-test.

Experience soon taught the manipulators at steel-works to modify the method in many respects so as to attain greater rapidity, thus deviating from the directions given by Professor Eggertz in 1862. There has, however, been some uncertainty as to many of the details, and as some rather serious discrepancies have occasionally occurred, especially in analysing the harder classes of steel, there have not been wanting people denouncing the whole method. It is, therefore, with great pleasure that I am able to accompany this paper with a translation of Professor Eggertz's recent article on the subject. As the contents of this article, or at least the more important points, were kindly communicated to me some weeks before it was published in Sweden, I have had ample opportunity of applying the experience thus gained, and have found it thoroughly corroborated by my own results.

The most important facts in Professor Eggertz's paper are contained in the rules given for (1) quantity of acid required for each 0·1 grm. of steels of different percentages of carbon, and (2) minimum addition of water required for each 0·1 grm. of steel dissolved in nitric acid to remove the iron colour.

Referring to the complete* translation, for further information I will now explain how I carry out my determinations of carbon in rail-steel by means of the colour-test. My mode of manipulation is the same as that used at most English and Welsh steel works, with the modifications of the two above-mentioned new rules of Professor Eggertz.

I use 0·2 grm. of the steel for testing, and along with every set of samples 0·2 grm. of standard steel is dissolved. This is indispensable with the mode of procedure I adopt, no precautions being taken to exclude the sunlight, &c. The solution is effected in test-tubes 6 inches long, and about 5-8th inch internal diameter. The dimensions of the test-tubes are not a matter of great importance, but they should not be too narrow.

The nitric acid I always allow to flow into the tubes from a graduated burette, this being by far the best way of adding the acid. The tubes are then put into a beaker 4 to 5 inches high, half filled with water. The beaker may be advantageously covered with a perforated tin plate, and the tubes put through the holes, and thus steadied. Heat is then applied, and boiling is continued until the steels are dissolved; this seldom requires more than half an hour, and is greatly promoted by the jumping of the tubes in the boiling water. When the solution is completed the tubes are put into cold water, and the determination of carbon is thereupon carried out by means of the carbon-tubes. The carbon-tubes are generally bought in sets of three tubes, one of which is graduated and the other two not. The tubes in each set are selected carefully so as to be of the greatest possible uniformity as to dimensions and quality of glass; their capacity is 20 c.c.

In my ordinary work I put the standard steel solution into one of the ungraduated tubes, measuring off by aid of

* The accompanying translation contains an addition made after publishing the article in Sweden, and is thus believed to be more complete than any translation which has already appeared in print.—See Appendix.

the graduated tube, and in very particular analyses I use standard steel solutions of different colours in both the ungraduated tubes. This helps the eye to catch faint differences in tint. The solutions for testing are put into the graduated tube.

The differences in the results, which are sometimes obtained when analysing the harder classes of steel by the colour test, are not observed as far as rails are concerned, and I find no difficulty in obtaining accurate results in this case. In fact, as far as my experience goes, the carbon in rails is that element which can be most easily accurately determined, and this by the simple colour test. But even for harder steels a very much greater certainty is now secured by the method described in Prof. Eggertz's latest publication.

It is always desirable, if not necessary, that the standard steel should have a percentage of carbon not differing too widely from the average percentage of carbon in the steels for testing; especially when dealing with *very* soft steels one finds the necessity of having a soft standard.

In working this method for carbon estimation, when the carbon ranges from 0·10 to 0·80 per cent, I have obtained accurate determinations with great rapidity; and this, indeed, is the great value of the method, which is best seen by its application for ascertaining the carbon in every blow, even at the largest steel works in England, where hundreds of charges are made per day. Ordinarily, a boy is trained to do this work, under superintendence of the chief chemist, and consequently the cost of execution is but very small.

The plan of dissolving rapidly, and then cooling the tubes, as just described, was originally employed by Mr. Snelus at Dowlais.

(To be continued.)

PROCEEDINGS OF SOCIETIES

PHYSICAL SOCIETY.

Saturday, December 10th, 1881.

Prof. W. G. Adams in the Chair.

New Members:—Lieut. C. E. Gladstone, R,N.; Lieut. C. Gauntlett Dicken, R.N.; Mr. Walter George Woolcombe, B.A., F.L.S.; Rev. Professor Sircomb; Mr. Arthur Clayden, M.A.

Professor Adams said that it had been thought advisable to invite the members to view the Smoke Abatement Exhibition now open, and the meeting was adjourned for that purpose, Professor Chandler Roberts acting as guide.

The next meeting of the Society will be held on Jan. 28, 1882.

NOTICES OF BOOKS.

Technisch-Chemischer Jahrbuch. (Technical-Chemical Annual.) Von Dr. Rudolf Biedermann. Berlin: Julius Springer.

This work, which is now making its third yearly appearance, contains a large amount of matter useful to technological chemists. We find, first, a statistical account of the chemical establishments, and the number of persons employed therein, throughout Germany on December 1, 1875. It must be noted that the table includes many departments of industry which, according to English notions, would be placed in different categories. Thus we find here enumerated coal-mines, brick-kilns, limestone quarries, and other establishments where the operations carried on are purely mechanical. It is not edifying to find that upwards of 6000 persons were at that date engaged in manufacturing articles for the adulteration of coffee, or—translating the German literally—in making "coffee surrogates." Next follow a table of the German production of metals, minerals, &c., for the years 1879 and 1880. There is a conspectus of the Patent Laws of different countries, accurate as far as the space will allow. No one can look over this section without feeling that the English law contrasts disadvantageously with those of most other States. Next follow a variety of legal regulations bearing upon manufactures and commerce. The bulk of the work is taken up with notices of recent improvements in the chemical arts, and is illustrated with 162 woodcuts of plant and apparatus.

Chemiker Kalender. (Chemist's Almanac.) Von R. Biedermann. Berlin: Julius Springer.

We have here a very useful pocket companion for the chemical profession. The author commences with a scientific chronology, giving the dates of remarkable discoveries and inventions, the promulgation of important theories, &c. Then follows the almanac properly so-called, in which the days are dedicated, not to the saints of mediæval tradition, but to the discoverers born on them. Thus February 19th is Volta's day, March 28th that of Laplace, April 18th Liebig's, &c. Not a few days, however, are still open, and not a few of the most illustrious men of science have found no place in the list.

The remainder of the work is composed of "auxiliary tables for the laboratory" of a highly varied and comprehensive nature. There are tables of the coinage of the principal nations; of the degree of fineness of the gold and silver alloys used; circumferences and contents of circles, squares, and cubes, square and cube roots, measurement of certain superficies and bodies; the metric system; measures and weights of different States; atomic weight, arrangement of the elements according to the periodic system of Mendelejeff; comparison and conversion of the thermometric scales of Celsius, Reaumur, and Fahrenheit; comparison of the degrees of the mercurial thermometer with those of the air thermometer: correction of thermometric degrees; boiling-points of aqueous solutions; refrigerating mixtures; heat and work, thermic capacity, specific heats of compound bodies, &c. In like manner the author passes through the subjects of expansion, vapour-tension, atmospheric pressure, light, electricity, specific gravity, specific gravity of liquids (including alkalies, acids, and salts), solubilities, the outlines of qualitative analysis (including the reactions of acids and bases), and the qualitative examination of solids in the dry way. Under quantitative analysis we find a table for the calculation of results, multiples of the atomic weights and their logarithms, and some of the more important molecular weights and their logarithms. We come next to volumetric analysis and to spectral analysis, the latter section being from the pen of Prof. H. W. Vogel. Finally, we have special directions for the technical analysis of water, alkali, bleaching-powder, &c., and a condensed list of recent improvements in chemical analysis. It is impossible, however, to form from this brief sketch any adequate idea of the value of the book. The labour of getting together, tabulating, and condensing such a quantity of facts and figures must have been immense. The chemist will, by simply consulting this pocket-book, find information, which it would take him hours to seek up from standard works and from files of journals and transactions. We consider that Dr. Biedermann has amply earned the gratitude of all chemists, and we hope that his work will find corresponding appreciation.

The book is printed in the Latin character, and with very little of that "reformed," semi-phonetic, orthography which has come into fashion in Berlin.

CHEMICAL NOTICES FROM FOREIGN SOURCES.

Note.—All degrees of temperature are Centigrade, unless otherwise expressed.

Comptes Rendus Hebdomadaires des Séances, de l'Académie des Sciences. No. 21, November 21, 1881.

Condition of Archromatism in the Phenomena of Interference.—A. Cornu.—A mathematical paper, not capable of useful abridgment.

Reactions of the Salts of Gallium.—M. Lecoq de Boisbaudran.—Copper sulphide precipitated from an acid hydrochloric solution is free from gallium, but is sensibly charged with it if formed in an acetic or ammoniacal liquid. Manganese and iron sulphides carry down gallium in a notable proportion. Silver sulphide carries down gallium if formed in an ammoniacal liquid. Arsenic sulphide takes down a notable quantity of gallium if produced in an acetic solution, but not in an hydrochloric solution. The precipitation of gallium by ammonia in excess, or ammonium sulphide, is prevented by the previous addition of tartaric acid. But the presence of this acid does not prevent gallium from being carried down by the metallic sulphides. If a neutral solution of gallium alum is left exposed to the cold for some months, there is formed a white deposit, which dissolves but slowly in dilute sulphuric acid, even with the aid of heat. The neutral solutions of the simple sulphate behave like those of alum. Lime and ferric oxide precipitated by potash in presence of salts of gallium, render an appreciable quantity of this metal insoluble. Salts of gallium give, with potassium ferrocyanide, a precipitate insoluble in hydrochloric acid. This reaction is very sensitive, but it is necessary to use very acid solutions containing from a quarter to a third of the concentrated acid. The washing must be effected with dilute hydrochloric acid, as pure water dissolves the precipitate. The reaction is not interfered with by salts of aluminium or by tartaric acid. One part of gallium shows thus after standing for an hour a perceptible turbidity in 175,000 parts of water. If there is present in a liquid little gallium and much ammonium or sodium acetate, gallium sesquioxide is not precipitated on boiling, or only in slight quantity. Barium carbonate completely precipitates gallium sesquioxide in the cold, but the precipitate, if zinc is present, contains an appreciable quantity of this metal. Calcium carbonate is therefore preferable, as it precipitates zinc less rapidly. Gallium sesquioxide is easily and completely precipitated if its hot acid solution is treated first with sodium sulphite (to reduce ferric salts), then with sodium carbonate almost to saturation, and finally with a slight excess of calcium carbonate. The very complex solutions obtained on attacking blende with *aqua regia* may be very advantageously reduced by means of scrap-iron, which is cheaper than zinc, and gives a much purer crude product.

Crystallisation of Cadmium and Zinc Sulphides.—P. Hautefeuille.—In order to obtain prismatic crystals terminating at both extremities with brilliant surfaces, the author places the amorphous sulphide at the bottom of a porcelain crucible of 0·10 metre in height, and fills it up with alumina slightly calcined. The whole is then heated, when the sulphide is deposited in crystals on the surface of the alumina.

Numerical Application of the Theory of Maximum Result of Two Dynamo-Electric Machines Employed in the Conveyance of Energy.—Maurice Lévy.—This paper is not susceptible of useful abstraction.

Lippmann's Method for the Determination of the Ohm.—M. Brillouin.—The use of open circuits does not simplify but complicates theoretical conditions. If in a closed circuit, suitably chosen, we may regard the current as uniform in the whole extent of the wire, even during the variable period, this is not permissible in an open circuit.

Remarks on the Electrolysis of Water.—D. Tommasi.—On decomposing water with a single element, using a copper wire as positive electrode and a platinum wire as negative electrode, the quantity of copper dissolved is greater than the quantity of copper deposited on the negative electrode.

Glycerin Diformine.—P. van Romburgh.—This compound is a colourless neutral liquid, of a taste bitter at first and afterwards acid. It is soluble in alcohol, ether, and chloroform, insoluble in carbon disulphide. Water resolves it into formic acid and glycerin. Its density is 1·304, and is optically inactive.

Certain Spectral Reactions of Alkaloids and Glycosides.—C. Hock.—The author describes the absorption-spectra of digitaline, delphinine, and belladonnine, all of which are characteristic.

Electric Current Produced by Light.—P. Laur.—The author has observed that the Mexican amalgamation process is rendered more active by solar light. This result he finds due to certain electric currents, which he names photo-electric.

Certain New Cases of Phosphorescence in Plants.—L. Crié.—The author has observed phosphorescence in a number of fungi.

Bulletin de la Société Chimique de Paris, Tome 36, Nos. 4 and 5.

Apparatus employed for Disinfection in the Manufacture of Ammonia from the Distillation of Cesspool Liquids at the Works of the Compagnie Urbaine at Arcueil.—Leon Chateau.—The saturation troughs into which the offensive gases pass are hermetically closed, and placed in communication with a ventilator by an underground channel. The working of the ventilator is calculated to produce in the saturators a draught strong enough to occasion a slight decrease of pressure. Between the saturators and the ventilator is a coke-tower, 5 metres in height, in which is a mixture of ferric oxide and calcium sulphate, prepared in a manner analogous to Laming's mixture for purifying coal-gas. At the upper part of a column is a cistern filled with a solution of ferric sulphate, which flows down continually and moistens the coke of the column.

Chlorides of Iron.—Paul Sabatier.—The author has arrived at conclusions similar to those of M. Ditte (*Annales de Physique et de Chemie*, t. 22, p. 551) as regards the chlorides of manganese, calcium, and iron. He publishes his results regarding the latter, which have not been treated of by M. Ditte.

Determination of Potassa in Potassium Salts and in Potassic Manures.—A. Rousselot.—(See page 290.)

A New Method of Determining the Chlorate in Bleaching Chlorides.—E. Dreyfuss.—(See page 290.)

Tungstoborates.—D. Klein.—Not capable of useful abridgment.

Action of Gaseous Hydrochloric Acid upon Isobutylic Anhydride.—S. Œconomides.—The author has obtained by this reaction an oily body, which he is still studying.

An Accessory Product obtained in the Preparation of Isobutylic Acetal.—S. Œconomides.—The product obtained, $C_{10}H_{20}O_2$, is a non-saturated compound.

Action of Amylene Hydrochlorate and of Amylene upon Benzol in Presence of Aluminium Chloride.—J. Essner.—The principal product formed is amyl-benzene, apparently identical with that obtained by MM. Friedel and Crafts from inactive amyl-chloride.

Essence of Resin.—A. Renard.—From the portion distilling between 103° and 106°, the author obtains heptene, C_7H_{12}. In the products going over about 150° he finds three hydrocarbides, $C_{10}H_{16}$ and two $C_{10}H_{18}$. In the fraction from 169° to 173° there are two terebenic carbides, $C_{10}H_{16}$, the one polymerised by sulphuric acid and the other not attacked by it. Two carbides, C_8H_{14} and C_9H_{16}, are found in small quantity in the portion passing over between 106° and 150°.

Preparation of Meta-toluidine.—O. Widman.—The author dissolves nitrised benzylene chloride in alcohol, adds a considerable quantity of hydrochloric acid, cools to 10°, and adds zinc powder, not allowing the temperature to exceed 12°. When all is dissolved, and the mixture is no longer rendered turbid by water, heat is applied and the escape of hydrogen is allowed to continue for two hours.

Biedermann's Central-Blatt für Agrikultur-Chemie,
Vol. x., Heft 4.

New Researches on the Passage of Rain-waters through Arable Soils.—A. Audoynaud and B. Chauzit.—The chief loss of nitrogen is in the form of nitrates. Sulphuric acid is removed in considerable quantity; phosphoric acid only in traces. The loss of potash and sodium chloride is great.

Flocculation of Small Particles and the Physical and Technical Relations of this Phenomenon.—Prof. E. W. Hilgard.—Under the influence of gentle rotatory movement, small particles suspended in water have a tendency to form larger aggregations, which to a certain extent resist disruption. This tendency decreases near the boiling-point, and is opposed by alcohol, ether, and caustic or carbonated alkalies, whilst it is promoted by acids and neutral salts. Violent agitation destroys the flocks. [This principle has long been known to chemists who have studied sewage precipitation.—*Ed.* C. N.]

Influence of Superficial Desiccation of the Soil upon its Hygroscopic and Thermometric Relations.—Prof. E. Wollny.—The evaporation of water and the escape of heat are reduced by superficial drying.

A New Method of Determining the Absorptive Power of the Soil.—R. Zalomanoff.—The author recommends the filtration method. He concludes that the results obtained by agitation in a flask are conclusive; that Liebig's opinion on the identity of drainage-water and ground-water is erroneous, and that compounds existing in solution and separated on passing through pulverised bodies or through capillary tubes assume another molecular condition.

Manurial Garden Experiments.—W. Lauche and Prof. A. Orth.—The highest results were obtained with farmyard manure plus ammonium and potassium sulphates and superphosphate. The crop was the sugar-beet.

Cultivation with Sewage.—H. M. Davy.—Certain experiments made in the old tanks at Gennevilliers.

Determination of the Albumenoids and the Non-Albumenoid Nitrogenous Constituents of Plants.—Prof. E. Schulze and Dr. J. Barbieri.—The author describes the methods of determining the albumenoids by precipitation with copper solution, by heating the extracts with ferric acetate, with lead hydrate along with a little lead acetate, and with lead acetate alone. The nitrogen existing in crystalline products of the decomposition of albumen is effected by the process of Sachsse and Kormann, which depends on the behaviour of nitrous acids with amides and amidic acids. For nitrogen present as ammonia the author recommends Emmerling's method.

Behaviour of the Sugars with Alkaline Solutions of Copper and Mercury.—Prof. Soxhlet, Dr. Meisl, and Dr. Allihn.—The results obtained are given in the form of tables.

MEETINGS FOR THE WEEK.

ON THE EFFECT OF THE SPECTRUM ON THE HALOID SALTS OF SILVER, AND ON MIXTURES OF THE SAME.*

By Captain W. DE W. ABNEY, R.E., F.R.S.

The author has investigated the discrepancies which appear in the accounts of the action of the spectrum on the haloids salts of silver as given by various authors, and eliminated some sources of error from the results obtained by them.

He has also shown that in mixtures of the haloids a secondary action takes place, by which, in certain cases, the spectra photographed on them take a totally different form to that which they would take, supposing that the effect of the rays is an integration of the effects on each haloid taken separately.

PRELIMINARY REPORT TO THE SOLAR PHYSICS COMMITTEE ON THE SUN-SPOT OBSERVATIONS MADE AT KENSINGTON.†

By J. NORMAN LOCKYER.

Since the commencement of the observations, in November, 1879, of the most widened lines in sun-spots, about 220 observations have been made: the maps for the first and second hundred observations have been drawn up and the tabulation of the first hundred completed. The reductions are being carried on, and I hope shortly to be able to lay a full report upon the 200 observations before the Committee, but desire, in the meantime, to lay the present preliminary one obtained before it.

The reduction of the first hundred observations, extending from November, 1879, to September, 1880, has yielded the following results:—

1. An immense variation from spot to spot is to be observed between the most widened lines seen in the first hundred observations. Change of quantity or density will not account for this variation. To investigate this point I had the individual observations of lines seen in the spectrum of iron plotted out on strips of paper, and I then tried to arrange them in order, but I could not succeed, for even when the observations were divided into six groups, about half of them were left outstanding.

2. If we consider the lines of any one substance there is as much inversion between these lines as between the lines of any two metals. By term inversion I mean of any three lines A, B, C, that we may get A and B without C, A and C without B, B and C without A, and so on.

3. We have reason to believe, from experiments made here, that most of the lines seen in the spectrum of iron volatilised in the oxy-hydrogen blowpipe flame are amongst the most widened lines.

4. Certain lines of iron have been seen at rest, while other adjacent lines seen in the spectrum of this metal in the same field of view have shown change of wave-length.

5. The spectrum of iron in the solar spectrum is more like that of the arc than that of the spark.

6. The greater part of the lines seen in spots and flames are common to two or more substances with the dispersion employed.

7. The first hundred spot observations being compared with a hundred observations of the spectra of flames, made by Tacchini at Palermo, have shown that there is no iron line in the region *b*-F common to spots and prominences.

In addition to these facts, already communicated to the Committee in more or less detail at different times, the following have been noticed in the continuation of the reductions.

8. The lines of iron, cobalt, chromium, manganese, titanium, calcium, and nickel seen in the spectra of spots and flames are usually coincident with lines in the spectra of other metals, with the dispersion employed, whilst the lines of tungsten, copper, and zinc, seen in spots and storms are not coincident with lines in other spectra.

9. The lines of iron, manganese, zinc, and titanium most frequently seen in spots are different from those most frequently seen in flames, whilst in cobalt, chromium, and calcium the lines seen in spots are the same as those seen in flames.

10. Towards the end of the first series a few lines appeared among the most widened ones which are not represented, so far as is known, among the lines seen in the spectra of terrestrial elements. This change took place when there was a marked increase in the solar activity.

So much for the results from the first series of observations.

The second series began on 29th September, 1880, and comes down to October, 1881. From a partial reduction of the observations the following results have been obtained:—

11. The number of new lines seen amongst the most widened lines has been steadily increasing. Many of these lines are very faint in the solar spectrum, and are unrecorded by Angström, while they are wide and dark in the spot-spectrum.

12. In the months of May and June of this year (1881), there was a great change in the spectra of the spots, the old lines dying out and new lines appearing.

13. When series of observations, consisting of ten consecutive observations of the spectra of spots, taken from the commencement of the first series in November, 1879, and from the end of it on 7th September, 1880, were compared with those made towards the end of the second series on 18th July, 1881, it was found that the lines widened in each set were markedly distinct from those in the other sets. To show this, I lay the maps containing the three sets of observations before the Committee.

14. At the commencement of October, 1881, there was a change in the spectra of the spots similar to that which took place in May and June, but much more abrupt, for only one of the old lines remained. This is exactly analogous to the variations Tacchini saw in the spectra of the prominences in the region F to *b*, in December, 1872.

15. In the first series of observations the total number of most widened lines in the region F to *b* was fifty-seven, forty of which were due to iron, whilst in the second series the total number of lines seen was 104, and the iron lines faded away gradually, the last disappearing on 26th July, 1881.

16. So far as the observations have gone there has been no difference caused by the nearness of the spot to the limb.

17. At the present time more than 75 per cent of the most widened lines are not represented in the spectra of terrestrial elements.

18. A line of titanium at wave-length 5865·0 and a line of barium at wave-length 5852·5 are amongst the recent most widened lines. Both these are long lines in the

* Summary of a Paper read before the Royal Society, December 15, 1881.

† A Paper read before the Royal Society, December 15, 1881. Communicated to the Royal Society at the request of the Solar Physics Committee.

spectra of these metals. The line at wave-length 5852·5 has been seen by Young in flames, with a frequency of eight.

ON A NEW ELECTRICAL STORAGE BATTERY.*

By HENRY SUTTON, Ballarat, Victoria.

THE great utility of some thoroughly practical method of conserving electric force has caused a great deal of attention to be applied to the subject; no system of electric supply can be considered as perfect until some means is used to so store the force generated that it may be drawn off equally and regularly, and this whether the generator be on or off. If we take, as an example of electric supply, the present systems of electric lighting, it is at once seen, should an accident or stoppage take place in the machinery generating the current, the whole of the apparatus, such as lamps or motor-machines are influenced; should there be a reservoir of electricity between the generator and the apparatus of whatever sort for utilising the force this inconvenience would not occur.

All the present systems of storing electricity depend on certain chemical changes produced by electrolysis.

I have gone through a long series of experiments on storing electricity and made many forms of cells, one being a porous pot containing dilute hydric sulphate, and a sheet of lead, in an outer vessel, containing a sheet of lead in solution of acetate of lead, the plate in the porous pot being made the positive electrode: this cell had the power of storing electricity, by peroxidising the positive electrode, and depositing from the acetate of lead solution metallic lead on the negative electrode, the hydrogen having combined to form acetic acid. On discharging the peroxide is reduced, and the oxide formed during discharge on the other plate dissolving in the acetic acid forming the original solution of acetate of lead; by this means I eliminated the injurious effects of the hydrogen on charging.

During my experiments I found that red oxide of lead is a very bad conductor of electricity, and the peroxide a good conductor. I also discovered that by amalgamating lead plates with mercury a marked increase was immediately manifest in polarisation effects, the plates becoming more uniformly and rapidly peroxidised when used as positive electrodes, and local action entirely disappearing. These mercury amalgamated plates at once gave me an advance of other cells. I used them in many ways, constructing cells in which the positive plate was amalgamated, and the negative coated with red oxide, or with peroxide, produced by treating red oxide with dilute hydric nitrate till the brown precipitate of peroxide fell, the precipitate being washed and painted on the electrode. I also amalgamated the negative electrode simply. I found that in every way positive electrodes amalgamated produced the best results. I also made cells in which either peroxide or red oxide was formed into a porous conglomerite, using the conglomerites as electrodes, immersed in dilute hydric sulphate. I constructed cells with parallel plates, red oxide or peroxide being filled in between the plates: in this experiment red oxide is useless and peroxide efficient. In all these experiments I succeeded in storing electricity to different extents.

Having thoroughly satisfied myself that positive electrodes amalgamated with mercury were the best, I investigated the behaviour of various forms of negative electrode, having in view the conservation of the hydrogen; this I thought to do by occluding the hydrogen in suitable electrodes, as spongy platinum or metallic palladium; but as both these methods would be useless owing to expense I did not even experiment on them.

I further thought that by having negative electrodes, whose oxides should be soluble in the solution, and which could be re-deposited from the solution, or by having metallic solutions from which metal could be deposited, the resulting solution being such that should, on the oxidation of the deposited metal, combine with the oxide and again form the original solution.

I thought that success in this manner would result in a powerful and constant source of stored energy, the cell would not polarise itself during discharge, as is the case in both Planté and Faure cells; in these cells the pesoxide formed by the discharge produces a contrary electromotive force.

Experimenting from this train of thought, the results I have obtained are such as to have an important practical bearing on the future of electric work.

The experiments comprised amalgamated lead as a positive electrode with negative electrodes composed of either zinc, iron, or copper, in each case the solution between the electrodes being a salt of the metal composing the negative electrode. With zinc, sulphate of zinc was the solution; with iron, sulphate of iron; and with copper, sulphate of copper being the solution. In all these cases the results were not only far more powerful than any form of cell I had previously devised, but also very constant, the polarisation lasting many times longer than any other form of cell. The cell with zinc negative electrode I discarded, owing to the necessity there would be to keep the zinc plate amalgamated to prevent local action, the iron negative electrode being set aside owing to the iron oxidising when the cell was not in use. The cell having a negative electrode of copper, a positive electrode of lead amalgamated with mercury and a solution of cupric sulphate, I have adopted as a thoroughly economical, lasting, and practical form of storage reservoir. The chemical changes in this cell are exceedingly interesting and beautiful, the cell being composed of a sheet of lead cleaned with dilute sulphuric acid and amalgamated thoroughly with mercury, and a sheet of thin copper a little shorter; the two sheets are perforated with a number of holes and then rolled in a spiral, separated by rubber bands cut every five inches, the holes in plates and cuts in rubber bands being to allow free circulation of the solution (the short plate being uppermost before rolling). This combination is immersed in a solution of cupric sulphate, and the amalgamated lead plate made the positive electrode of a suitable source of electricity. The chemical action being the oxygen of the decomposed solution combines with the lead, forming a perfectly even coating of the insoluble peroxide, the hydrogen replacing the copper of the solution, the copper being deposited in the metallic state on the negative electrode. As the decomposition of the cupric sulphate proceeds it gradually loses its azure blue colour, becoming more acid, and finally when the whole of the copper is deposited, we have the solution colourless and transformed into hydric sulphate and water, the positive electrode peroxidised and copper deposited on negative electrode. During discharge the peroxide is reduced and the copper element oxidised, the oxide combining with the acid and forming cupric sulphate, the solution returning to its original colour. This change of colour forms a beautiful means of telling when the cell is charged; it is a veritable charging gauge. The power of this cell is very great and very constant; it can be made to last for hours, the time being dependent on the quantity of cupric sulphate decomposed.

I have, by the decomposition and recomposition of one pint of cupric sulphate, obtained over two hours' effective work by heating to a red-heat one inch of No. 28 iron wire, the cell measuring internally 4 inches deep and 4 inches diameter.

I constructed cells with free crystals of cupric sulphate suspended in the solution, and found that the presence of free crystals prevented the oxidation of the amalgamated lead electrode, it being essential that the solution becomes slightly acid before the peroxide will form. The cell during charging gives out a peculiar rattling noise, which I consider due to the deposition of copper on negative electrode altering the form of the spiral.

* A Paper read before the Royal Society, December 15, 1881.

A practical form of cell for storing purposes ought to be made by fixing a series of amalgamated lead plates in a box in grooves, as in Cruikshank's trough battery, filling between the plates with solution of cupric sulphate, and passing a current through of sufficient tension to overcome the contrary electromotive force of the series, the positive sides of plates being peroxidised and copper deposited on the negative sides. I have two boxes on this plan, each containing twenty-five plates, the total being equivalent to fifty cells. By this means batteries of great tension can be charged from thirty Bunsens. A number of twenty-five plate boxes can be coupled in quantity for charging and tension during discharge. Twenty such boxes, 1 foot square, internal measurement, will give in series a battery of 500 pairs 1 foot square plates.

It will be seen from the foregoing that this method of conserving energy has a wide field before it, and as it will benefit fellow-workers in science, placing in their hands a means of experimenting with powerful electric currents, I give it without reservation, freely and untrammelled by patent rights for their use.

ON THE

ESTIMATION OF NEUTRAL FAT AND PALMITIC AND OLEIC ACIDS IN PALM OILS AND AUTOCLAVED MATERIAL.

By FREDERICK SEAR, A.I.C.

Dissolve about 5 grms. of the palm oil or autoclaved material with 100 to 150 c.c. carbon disulphide in the cold, in a flask provided with a well-fitting cork. The whole is then allowed to stand for three or four hours with occasional agitation. At the expiration of this time, the contents of the flask are thrown upon a filter (the filtrate being collected in a tared flask), thoroughly washed with carbon disulphide, and the filtrate distilled as low as possible on a water-bath, dried, and weighed. The residue, which consists of neutral fat and zinc oleate, is saponified with alcoholic potash, the soap decomposed with an acid, the aqueous portion separated from the fatty acids, and the zinc precipitated from a hot solution by means of potassium carbonate. The zinc carbonate is then collected, and estimated as such, or as zinc oxide, and the quantity of zinc oleate to which it corresponds calculated. Subtracting this from the weight of the mixture of neutral fat and zinc oleate, the weight of the former is obtained. The amount of oleic acid is calculated from the zinc oleate. By adding together the weights of the neutral fat and oleic acid and subtracting from the weight of the oil taken, the quantity of palmitic acid is ascertained.

The following example will serve to illustrate the above:—

5·439 grms. of a palm oil gave 4·300 grms. neutral fat and zinc oleate.

Zinc carbonate obtained 0·2445 grm., equivalent to 1·2265 grms. zinc oleate and 1·1030 grms. oleic acid.

4·300 − 1·2265 = 3·0735 grms. neutral fat. Therefore 5·439 substance gave:—

		Percentage.
Neutral fat	3·0735	= 56·509
Palmitic acid	1·2625	= 23·208
Oleic acid	1·1030	= 20·283
	5·4390	100·000

Lactic Acid, and the Alcoholic Fermentation of Milk.—Dr. G. Musso.—Lactic acid does not exist in freshly-drawn milk. Whenever it is formed there appears an alcoholic ferment, and ponderable quantities of alcohol are formed.—*Biedermann's Centralblatt.*

CHEMICAL METHODS FOR ANALYSING RAIL-STEEL.*

By MAGNUS TROILIUS, Chemist to C. P. Sandberg, London.

(Continued from page 294.)

Phosphorus Determination.—The greater number of steel-works which I have visited use the Eggertz's molybdic method for determination of phosphorus in steel. Except in Sweden, however, it is only at one large works in Germany that I have seen this method carried out in the way originally described by Professor Eggertz, and at those works superior appliances, &c., enable the manipulators to obtain pretty quick, and certainly very accurate, results, even when using weighed filters, and working upon the small prescribed quantity of one gramme. At other German works it was the practice to re-dissolve the phospho-molybdate obtained, and to finish the analysis by the magnesia method. But at all the English and Welsh works with which I am acquainted the phosphorus is estimated by weighing the phospho-molybdate itself. Several grammes of the steel are always used, and the precipitate is generally brushed off from the filter. Only at one Welsh works have I seen it gently burnt, so as merely to incinerate the filter.

The former of the two last-named modes of manipulation is the one I use. Like so many other useful modifications in the chemistry of iron and steel, this plan was originally introduced at Dowlais by Mr. Snelus. In the following pages I will describe the process, and, at the same time, refer briefly to the Welsh "burning" method and to the magnesia method, &c.

The Burning Method.—The solution of the steel for the determination of phosphorus is an easy operation. Not less than 5 grms. of steel are dissolved in a mixture of equal volumes of strong nitric and hydrochloric acids. (I use for this purpose nitric acid 1·42, and hydrochloric acid 1·195 sp. gr.) No loss through escape of phosphorus in combination with hydrogen is hereby incurred. The solution is evaporated to dryness, and heated until all dark fumes have ceased to escape. A beaker or a porcelain dish may be used, according to circumstances, and evaporations, &c., are performed on the hot plate. By the evaporation to dryness the complete solution of the steel is secured, all organic matter is destroyed, and the silica can be separated, which is advisable if it is present in any noticeable quantity.

The dry mass is then dissolved in strong hydrochloric acid, the excess of acid removed by evaporation, hot water added and the silica filtered off. (If little or no silica is present it is, of course, unnecessary to filter it off, and the precipitation of phosphorus may then at once be proceeded with.) The filtrate is evaporated down to a small bulk, so that it is only just fluid; it is allowed to cool, and then about 4 cc. of the strong nitric acid are added. A little rinsing water is introduced so as to make the bulk about 20 cc. The beaker is strongly shaken in the right hand, while from a pipette, which is held in the left hand, 20 cc. of the solution of molybdate of ammonia are allowed to run into the beaker in a thin stream.

The solution of molybdate is prepared by dissolving 100 grms. of molybdate of ammonia in 1000 cc. of water and 100 c.c. of ammonia, 0·88 sp. gr. It is of no advantage to use less strong solutions of molybdate than this, as one has then to employ a larger quantity of the same, and thus obtain a greater bulk, the work being thereby retarded.

After pouring in the solution of the molybdate a few drops of ammonia (0·88) are added, and the beaker is shaken until the precipitate of iron has disappeared. The phospho-molybdate is then completely down, and you have only to leave the beaker on the less hot part of the plate at least for one hour, during that time allowing it to settle, and

* Read before the American Institute of Mining Engineers October, 1881. From the *Journal of the Franklin Institute.*

shaking it up again repeatedly. After the last shaking the precipitate must separate distinctly, and leave a perfectly clear, supernatant solution. There is no danger of getting molybdic acid down, even if you were to boil for a moment or to use a large excess of molybdate, provided that there is a sufficiently large quantity of nitric acid present; but, if there is arsenic in the steel, this will come down along with the phosphorus, and cause too high results. The using of the ammoniacal solution of molybdate and ammonia causes a considerable elevation of temperature; hence, as will be shown below, the precipitation of arsenic.

After settling, pour the liquid on a good Swedish 4 inch filter; wash the filter with cold water containing 1 per cent of nitric acid until it is quite white; wash the precipitate in the beaker once by decanting with ordinary water, moderately hot, and finally wash the precipitate down on the filter, and collect it at the centre with as few washings as possible with ordinary water, moderately hot. The filter should be quite white before the precipitate is washed on to it.

If the washing is conducted in this way no loss will be incurred in dissolving, neither will the fluid run thhrough turbid. The solubility of the phospho-molybdate precipitate, at 16° C., is given by Professor Eggertz as follows:—

In pure water, ...	1 part in 10,000
In water, with 1 per cent of nitric acid	1 ,, ,, 6,600
In hydrochloric acid, 1·12	1 ,, ,, 550
In nitric acid, 1·2	1 ,, ,, 190

If to the solvent be added a solution of molybdate of ammonia, equal to about half of its volume, the solvent action seems to be considerably lessened.

After washing, unfold the filter containing the precipitate upon another filter and put it upon the edge of the plate to dry. The unfolded filter should be covered with a large watch-glass, so as to prevent dust from getting into it. As to the temperature for drying, this is by no means so essential a point as is often supposed, and the precipitate may be dried for hours at a temperature between 100° and 140° C. without changing its percentage of phosphorus in any noteworthy degree, as stated by Professor Eggertz, whose results in this respect are compiled in the following table:—

Temperature	Loss per cent of weight of precipitate.
95°—100° C.	0·40
100°—120° C.	0·20
120°—140° C.	0·05
95°—140° C.	0·65

The total loss in weight is thus only 0·65 per cent when drying at 140° C., and this has no practical influence, considering the small amount of phosphorus in the precipitate and the large quantity of steel operated upon. The precipitate also retains its yellow colour at the temperature of melting lead (355° C.), but gets black at the temperature of melting zinc (400° C.)

When dry, the precipitate is shaken down into a weighed platinum, or porcelain dish, the brush not being applied until nothing more can be loosened from the filter by mere shaking. It is a convenient practice to hold the filter in the left hand, and to knock gently on this hand with the other.

Having thus given the outlines of my mode of using the molybdic method, I would add the following precautions, which are necessary for attaining accurate results:—

1st. Removing excess of hydrochloric acid from the solution by evaporation.

2nd. Adding the solution of molybdate in a very thin stream, shaking well.

3rd. Great care in the washing and brushing off.

As for the weighing, it is advisable to dry in the vessel repeatedly, and weigh two or three times before deciding the weight finally.

In *Eggertz's original method* there is used for the determination of phosphorus in steel only 1 grm. The solution of molybdate is prepared from 100 grms. pure molybdic acid to 422 c.c. ammonia (0·95 sp. gr.), and 1250 c.c. nitric acid (1·2 sp. gr.). By using such a small quantity of steel one advantage is gained, viz., that no evaporation after separation of the silica is required, the bulk being very small if the washing has been carefully performed. But, of course, brushing cannot be applied when such a small quantity of steel is taken. Weighed filters have to be used.

As to the precipitation in this case, you may manage to have the iron solution of 15 to 20 c.c. volume, and add to the same at least half its volume of the above-mentioned solution of molybdate. The solution is well stirred and left at a temperature of 40° C. for 1 to 3 hours, after which the precipitate is collected on the weighed filter, dried and weighed.

In Sweden it is of great importance to keep the temperature not above 40° C., as some of the very purest Swedish irons and steels contain arsenic, which will come down as a yellow precipitate similar to the phospho-molybdate. At 70° C. this arsenio-molybdate (containing 4·11 per cent of arsenic) comes down pretty quickly, and, on boiling, it precipitates at once. It is easy to understand how important it must be to avoid estimating the arsenic as phosphorus in, for instance, a Dannemora "Walloon" iron, where the phosphorus may be only 0·01 per cent or less. If the right temperature be neglected the phosphorus would, perhaps, appear to be 0·02 per cent; but this would still be serious in such pure material. In fact, it is to be feared that many mistakes on the part of consumers o Swedish steels are committed through overlooking the presence of arsenic.

It falls beyond the limits of this paper to describe Prof. Eggertz's method for separating and determining the arsenic in steel, and I have only to mention that I have not been troubled with arsenic in any of the rail-steels with which I have had to do.

The Burning Method.—As to the method of burning the precipitate above referred to, I may say that I saw it practised two years ago at a large works in South Wales, but not until lately have I had time to try it myself. At the works in question it was the practice to put the wet filter containing the precipitate in a platinum crucible, and to place this in the fore part of a hot muffle-furnace, so as to incinerate the filter. A certain correction, as I was told, was made for the expelled ammonia before taking down the result. However, I have found hitherto that by adding the filter to the precipitate after determination by the brushing method, in the usual way, and putting it all into a weighed porcelain crucible, then carefully charring the filter and burning it over a gentle flame from a Bunsen burner, no very different results are obtained; indeed, in most cases I have found the weight, after burning, only so much *higher* than after brushing, as would correspond with the weight of the filter-ash, and in no case have I found it less than after brushing. It appears that 140° C. is the highest temperature that can be used when only drying of the precipitate is intended, for at higher temperatures the filter paper begins to change. But, as far as the above-named experiments show, it is quite feasible to incinerate the filter without practically altering the composition of the precipitate. A continued series of such experiments will give a list the average of which will show the accuracy obtainable by the burning method.

(To be continued.)

Manurial Experiments on Fruit Trees.—Dr. P. Sorauer.—If liquid manures are too much diluted the trees are injured by being compelled in seeking nourishment to take up more water than they need. On the other hand, too concentrated solutions occasion a decay of the roots. —*Biedermann's Centralblatt.*

PROCEEDINGS OF SOCIETIES.

CHEMICAL SOCIETY.

Thursday, December 15, 1881.

Prof. H. E. ROSCOE, President, in the Chair.

THE following certificates were read:—H. L. Buckeridge, J. F. Heyes, T. Pitt, G. McRobert. During the evening a ballot was held, Messrs. Makins and Warington being appointed Scrutators. The following gentlemen were declared by the President to be duly elected Fellows of the Society:—C. Armitage, D. E. Anatole, J. Bingley, C. H. Bothamley, J. D. Custance, G. W. H. Clements, T. Farmer, A. B. Griffiths, R. P. Gardner, W. B. Harrington, H. E. Head, J. Innes, W. Jackson, R. V. Jackson, P. S. Looker, R. F. Mathews, K. D. Naegamvala, J. B. Orr, W. F. Reid, W. Rupp, H. Ross, F. Sear, C. H. Sieber, J. W. G. Stevens, C. H. Slaytor, D. R. Steuart, B. E. Smith, C. A. Still, R. Tervet, J. S. Topham, Rev. E. W. Volckxson, B. Wilkinson, J. Whitlock.

The PRESIDENT then called on Mr. V. H. VELEY to read a paper entitled "*On some Higher Oxides of Manganese and their Hydrates.*" The author has carefully prepared pure oxides of manganese containing less than 1 per 1000 of potassium and 1 per 6800 of calcium. He has heated the higher oxides in currents of nitrogen and in pure hydrogen, estimating the water evolved and the loss of weight of the oxide. The temperatures used varied between 80° to 200°; a few experiments were made at higher temperatures. At certain points in the thermometric scale the manganese compound remained unaltered on continued heating at that temperature. On this ground the author concludes that a definite oxide or hydrate was formed. On raising the temperature, a further loss of water or oxygen takes place, until another point in the thermometric scale is reached, at which the manganese compound again remains unaltered on continued heating at that temperature; the author concludes that another definite oxide or hydrate is formed, and so on. By such experiments the author has established the existence of the following substances: $Mn_{24}O_{32},3H_2O$; $Mn_{24}O_{44}$ with 8, 6, 4, and 2 molecules of water; $Mn_{24}O_{458}H_2O$; $Mn_{24}O_{46}$ with 3 and 2 molecules of water; $Mn_{24}O_{472}H_2O$. The author has determined the specific gravity of some of these oxides. He concludes with some theoretical discussion as to the probability of the metallic oxides having formulæ much more complicated than those usually assigned to them.

Mr. HOWARD then read a paper "*On a New Alkaloid from Cinchona Bark,*" by D. HOWARD and J. HODGKIN. The authors have discovered in the bark of China *Cuprea*, described by Dr. Flückiger, an alkaloid which appears to be peculiar to the species, which is quite distinct from that described by Arnaad under the name of cinchonamine (*Akad. Sci.*, 93, 593). This bark, first imported in 1871, differs much in its extreme hardness and tenacity from all other cinchona barks. During the last few months large quantities have been sent over from Buccarramanga, in the province of Santander, where it is said to form vast forests. The bark varies greatly in value, some specimens containing no quinine, others upwards of 2 per cent; some quinidin and cinchonin are also found in the bark, but no cinchonidin. The new alkaloid in its general properties and composition of its platinum salt closely resembles quinine. It differs only in the solubility of its salts and the readiness with which the alkaloid crystallises from ether. The authors suggest the name homoquinine. 100 c.c. of ether dissolve 0·57 of the alkaloid at 12°. It is much more soluble when other alkaloids are present, and is very apt to show supersaturation. The sulphate crystallises in shorter needles than the quinine salt, and contains 6 atoms of water. Water at 100° dissolves 1 per cent; at 12°, 0·25 per cent. The disulphate is extremely soluble and fluoresces. The oxalate, tartrate, hydrochlorate, nitrate, and hydriodate were also prepared. The rotation of the alkaloid and its salts is almost identical with that of quinine. Further investigations on larger quantities of the alkaloid are promised.

Mr. COWNLEY said that in conjunction with Dr. Paul, he had discovered some months back an alkaloid in *Cuprœa* bark which differed from the other well-known cinchona alkaloids. They had experienced some difficulty in obtaining it pure, but during the last few weeks had succeeded. The communication was already in type, and would appear in the *Pharmaceutical Journal* of this week. He was therefore very much surprised to hear Messrs. Howard and Hodgkin's paper, which apparently described the same alkaloid.

In answer to several questions, Mr. HOWARD said that in the present state of legislation, he had not thought it desirable to test the physiological action of this alkaloid on any other vertebrate than himself. The amount of alkaloid varied, but was usually about 10 per cent of the quinine present. He was quite delighted to hear that the presence of this alkaloid had been simultaneously confirmed by the experiments of Mr. Cownley.

The PRESIDENT then left the Chair to communicate a paper entitled "*Contributions to the Chemistry of the Rare-Earth Metals,*" by B. BRAUNER.

The Chair was taken by Dr. Voelcker.

The PRESIDENT said that this communication was interesting as being the first fruits of a system of Science Fellowships, founded at Owen's College. The Fellowships were given not by competitive examination, but to those candidates who had shown most ability and power in original research. The principal object of Dr. Brauner's research was to determine the position of the cerite metals in the periodic system by a careful study of their compounds. Mendelejeff places cerium (Ce=140) in the fourth group (vertical), but is doubtful as to position of lanthanum and didymium. Lothar Meyer places cerium (Ce=137) in the third group, La=139 in the fourth group, and Di=147 in the sixth; afterwards he places all three elements—La 139, Di 140, Ce 141—in the third group. The author some years ago proposed that these metals should be placed in the eighth series (horizontal) in the third, fourth, and fifth, thus—

	Group III.	IV.	V.
Series 8	La 139	Ce 141·6	Di 147

If cerium belongs to the fourth group it should have a tetrafluoride, CeF_4, as the existence of such a body was not by any means established. The author first prepared some pure hydrated dioxide, $Ce_2O_4+3H_2O$. By treating this with aqueous hydrofluoric acid, a brownish powder was obtained, having the formula CeF_4+H_2O. When heated this substance evolves hydrofluoric acid and a gas, which liberates iodine from potassium iodide, possibly according to the equation $CeF_4.H_2O=CeF_3+H_2O+F(?)$. A double salt, $3KF.2CeF_4+2H_2O$, was also obtained as a yellowish white crystalline powder. The author then proceeded to study peroxide of didymium. Didymium sulphate was first purified by a long series of crystallisations, and finally precipitated from the hot aqueous solution by oxalic acid. On ignition, &c., a pure oxide was finally obtained, the hydrochloric solution of which gave the spark spectrum of pure didymium. By analysis of the pure sulphate the atomic weight of didymium was determined as 146·58 (O=16, S=32·074). After many unsuccessful experiments the author succeeded in preparing hydrated and anhydrous peroxide of didymium. The hydrated compound is obtained as an amorphous green precipitate by adding dilute caustic potash to a mixture of didymium nitrate and hydrogen dioxide until a slightly alkaline reaction is produced. After drying *in vacuo* a light red powder is obtained, $Di_2O_5+3H_2O$. By heating basic nitrate of didymium in a current of oxygen in a porcelain boat to dull redness, the anhydrous Di_2O_5 was

prepared as a brown mass. It is soluble in dilute acids without evolution of gas, but with strong acids oxygen with some ozone is evolved. It is only slightly soluble in cold concentrated solution of ammonium nitrate. The author then prepared some perfectly pure lanthanum oxide, and determined the atomic weight of that metal to be 139·88 (O = 16). Nilson and Pettersson have recently published a series of objections to the periodic system, one of which was the difficulty of placing the rare-earth metals. The results of the present paper prove that with Ce, Di, and La, this difficulty does not exist, the author placing these elements in the eighth series, and in the fourth, fifth, and third groups, respectively, thus—

Series 8.. Cs 133 Ba 137 La 139 Ce 141·6 Di 146·6

The author points out the relations of these three metals, and expresses his conviction that further research, especially as to the higher oxides, will probably find a satisfactory place for the other rare-earth metals in the periodic system.

Dr. VOELCKER congratulated Prof. Roscoe on the excellent paper which had just been read. Few who had not worked with these rare metals could form any idea of the patience and skill required merely to prepare the substances in a state of purity. The work seemed to have been carried out with great skill and accuracy, and all must agree that it was most desirable that we should know where to place these rare metals in the periodic system.

In answer to Dr. WRIGHT, Prof. ROSCOE said that none of the compounds had been obtained in the state of vapour, and therefore no vapour-density determinations had been made.

Mr. NEWLANDS said that he would like to mention how much pleasure it gave him to see the periodic system prosecuted to such a successful issue by Mendelejeff. When, some years ago, he (Mr. Newlands) first broached the idea that the elements could be arranged in periods of eight, his notions were very unfavourably received; now, although there were undoubtedly gaps in several places, yet further researches seemed to fill up the missing links, and generally confirm the truth of the arrangement.

The Society then adjourned over the Christmas vacation to January 19, 1882.

PHILOSOPHICAL SOCIETY OF GLASGOW.

CHEMICAL SECTION.

Monday, November 7, 1881.

Mr. J. MACTEAR, F.C.S., F.I.C., President, in the Chair.

AFTER the transaction of some formal business, Mr. Mactear delivered the opening address as President of the Section.

On the conclusion of Mr. Mactear's address, Dr. WALLACE, President of the Philosophical Society, on behalf of the Trustees of the Graham Medal and Lecture Fund, presented Mr. Mactear with the Graham Medal for 1881-82. In making the presentation, Dr. Wallace gave an account of the origin and objects of the Graham Fund. He said that it had been instituted for the purpose of commemorating the services rendered by Graham to chemical science. Part of the money subscribed to the Fund had been devoted to the foundation of a triennial gold medal for the encouragement of original research, and the remainder to the foundation of a triennial lecture. The competition for the medal had been thrown open to all comers, and had been advertised in the CHEMICAL NEWS and in *Nature*. Of eight papers sent in for the first competition, four were from gentlemen unconnected with Glasgow. The Committee entrusted with the management of the Fund had placed the papers in the hands of Prof. Williamson, of London, who, after careful and repeated examination of them, had reported in favour of one submitted by Mr. Mactear, entitled "Some Researches on the Reactions involved in the Leblanc Process of Alkali Manufacture." In accordance with this report the Committee had awarded the Medal to Mr. Mactear. Having referred to the high estimation in which Mr. Mactear is held by all scientific chemists, as well as by those more immediately connected with alkali manufacture. Dr. Wallace concluded by handing Mr. Mactear the Medal, which bore the inscription—Graham Medal, 1881-82, Awarded to James Mactear, F.C.S., F.I.C.

NOTICES OF BOOKS.

Letts's Diary for 1882; *No.* 8. *Letts's Housekeeper's Account Book and Diary for* 1882. *Letts's Rough Diary and Scribbling Journal for* 1882, *No.* 36. *Letts's Medical Diary for the Year* 1882. *Letts's Pocket Diary and Almanac for* 1882; *Nos.* 13, 17, 22. *Letts's Metallic Diary for* 1882; *No.* 60. London: Letts, Son, and Co., Limited.

WE have here an assortment of diaries differing widely in price, contents, arrangement, and style, so as to suit varied tastes and requirements. No. 8 is a goodly volume for the office, containing an almanac of a somewhat antiquated character; Jewish and Mahommedan kalendars; telegram rates, both English and foreign; revenue and postal information; directions for making wills; weights and measures; the Corporation of London; the Administration; list of Colonial Governors and of Colonial Agents; the Royal Family; London bankers; a Colonial and Foreign banking, postal, and telegraph directory; a country banking, postal, population, and market table; a parliamentary guide; a list of the Officers of State: British Ambassadors abroad; foreign representatives in England; law and public offices; insurance companies in London; tide tables; London cab fares; registration laws; and a great variety of statistical information. A curious feature is the so-called "Concise Directory." We fail to understand why certain trades and professions have been inserted and others omitted, or why certain tradesmen have been selected in preference to others. We think, *e.g.*, there are in London opticians quite as eminent as Marratt and Ellis, and publishers not less respectable than Burns and Oates. Letts's Housekeeper's Account Book contains the same almanac and directory; a monthly list of articles of food in season; alimentary tables showing the amount of nutrition in 1000 parts and the time required for digestion, and accompanied by the remark that "to generate vital heat is the real object of alimentation." A very useful feature is a register of books, &c., lent to friends. For want of keeping such a record many persons find their libraries waning imperceptibly away.

The Rough Diary is a plain little volume containing the almanac and some statistical information. The diary portion is ruled for money, and contains seven days to the page.

The Medical Diary is bound for the pocket. Here the almanac is freed from the antiquated matter contained in the other diaries in order to allow of entering the meetings of Societies. It is somewhat curious that in none of these diaries do we find a list of the London learned societies with the addresses of their secretaries, &c. Among the peculiar features of the Medical Diary may be mentioned a scale of professional fees. It strikes us that the charges allowed by the Poor Law Board and the Courts of Law are very low. Thus the fee for a *post mortem* examination—which it appears may include analysis of the contents of the stomach—is merely one guinea. We should think five guineas quite little enough for the toxicological examination alone, if it is to be accurately and conscientiously performed. There are tables of poisons and

antidotes, and a classified list of medicines. The diary portion seems exceedingly convenient in its arrangement.

The diary No. 13 is a small volume of a side-pocket size, ruled for memorandums, and giving the week on two pages.

No. 17 is in the form of a neat pocket-book, and gives a week to the page. No. 22 is a more elegant pocket-book, bound in Russia leather, and fitted with pockets lined with green silk. It shows four days to the page. No. 27, lastly, is of a waistcoat pocket size.

All these diaries are neatly and serviceably got up, and well deserve the public patronage.

Experiments showing the Pressure of Gas in the Solid Coal. By Lindsay Wood. Newcastle-upon-Tyne: A. Reid.

This work is a reprint from the *Proceedings of the North of England Institute of Mining and Mechanical Engineers.* The author undertook to ascertain if gas existed at any pressure in the solid coal; what quantity of gas was given off from a given area of a face of working coal; and at what rate this exudation diminishes per hour of exposure. The results are somewhat startling. In the Elemore Colliery, 750 feet below the suriace, a hole was bored into the solid coal to the depth of 7 feet, and fitted with a pipe connected to a Bourdon's pressure-gauge. In the first five minutes the pressure was 13 lbs. per square inch. In eleven and a half hours it had risen to 28 lbs., and at the end of twenty-six days it was found to have fallen to 8½ lbs. At Hetton Colliery an experiment was made at the depth of 1228 feet below the surface with a borehole 9 feet long. The pressure here was at first 8½ lbs.; the next day it had risen to 40 lbs. At 8 p.m. the same day it had fallen to 35 lbs.; but it rose again, and two days eight and a half hours from the beginning of the experiment it reached a maximum of 45 lbs. After this it fell to 40 lbs., and remained at that point till the experiment was discontinued. In the Eppleton Mine, at the depth of 1261 feet, the maximum pressure reached the astonishing figure of 104½ lbs. In another experiment we find a maximum of 204 lbs., the pressure remaining at or above 200 lbs. for nearly two days! At Eppleton, No. VI., we find a pressure of 221 lbs. recorded; at Boldon, 386 lbs.; and in a further experiment 461 lbs. The experiments appear to have been made in five distinct groups of mines. The lowest pressure was found, as might be expected, in the pits which have been longest opened up. The pressure does not seem to have any fixed connection with the depth below the surface, but bears some relation to the distance from the face of the coal in the workings in which it is ascertained. Those places where the pressure of gas is greatest do not seem to give off the largest volumes of gas. Neither is there any connection between the state of the barometer and thermometer on the one hand, and the quantities of gas evolved on the other. The writer having ascertained these important, and we may say suprising, facts, does not profess to enter upon a full discussion of the results, but considers that further experimentation will be needful.

Practical Chemistry, adapted to the Revised Syllabus of the Science and Art Department, with an Introduction to Chemical Analysis. By J. Howard, F.C.S. New and Enlarged Edition. London and Glasgow: W. Collins, Sons, and Co., Glasgow.

This work is distinctly and avowedly examinational. We are told in the preface that the reports of the eminent men who act as examiners for the "Department" had shown that many students who come up for examination were mere readers, and they rightly decried such a system of cram, which could only produce nausea instead of that deep interest in the phenomena surrounding us which would be produced if science were studied practically. We fear that so long as examinations are held up as the end and aim of study no deep interest in natural phenomena will ever be felt. If we could be permitted to study simply in order to know and to qualify ourselves for adding to the present stock of human knowledge a deep interest would not be wanting, but this the department and the eminent men aforesaid will not permit.

We are glad to find that the notation and formulæ used by Professors Roscoe, Williamson, and Thorpe now find a place in this treatise, in addition to the Franklandian system. Mr. Howard's work seems well adapted for its purpose, though how all the numerous elementary works on chemistry find sufficient scope is an unsolved mystery.

Chemical Notes and Equations for the Use of Students. By R. Milne Murray, M.A., M.B., M.R.C.P.E. Second Edition. Edinburgh: Maclachlan and Stewart. London: Ballière, Tindall, and Cox.

This pamphlet—for it does not extend to 110 pages—professes to supply the student with a condensed view of the principles of chemistry, and "a tolerably complete synopsis of the more important relations and reactions of the chief elements and their compounds." It is considered that the work may serve for refreshing the memory of the intending examinee. The selection of the elements is peculiar, forty-two simple bodies only being mentioned, including cæsium and rubidium, which are named merely to be dismissed as not requiring notice. Vanadium, rhodium, iridium, and palladium are not described. Whilst the information here given is generally accurate as far as the very confined space will allow, we think exception may fairly be taken to the process given for obtaining potassium bichromate from chrome-iron ore, viz., obtaining first the mono-chromate and then treating with nitric acid.

CORRESPONDENCE.

SOAP TEST FOR HARDNESS OF WATER.

To the Editor of the Chemical News.

Sir,—During a considerable experience in water analyses one or two points have occurred to me which I think may probably be of interest to my fellow-workers.

Those who have had much experience of the method of determining the hardness of potable waters are acquainted with the difficulty and annoyance experienced in consequence of the decomposition of the soap test solution, which retains its original strength but for a short time after being made. This troublesome character I have succeeded in averting by the following method.

I make the soap test of the best Castile soap, as recommended by Prof. Wanklyn, using methylated spirit diluted with 2 vols. water. When all the soap is dissolved I add sufficient strong ammonia solution to make the test distinctly alkaline, and then standardise the soap solution in the usual way with calcic chloride.

The solution thus prepared will, when kept in the dark, keep for a considerable time without undergoing decomposition. I have had some in use for over two years, and my experience in this respect has been corroborated by several friends.

The alteration of the ordinary soap solution is due, I presume, to the decomposition of the fatty acids contained in the soap, which, when an excess of ammonia is present, remain fixed.

When taking the hardness of a water it is absolutely essential, in order to obtain correct results, to add the soap test until a full lather is obtained, and above all things to be careful to dilute with distilled water after soap test equal to 16° hardness has been added. Neglect of these precautions will often lead to very erroneous re-

sults. A case lately came under my notice in which the chemist added only just sufficient soap test to make a slight lather, and immediately took that point as the true degree of hardness, a practice which, in the case in question, entirely misled him.

In making Nessler's test I find it much better not to heat the solution of potassic iodide and mercuric chloride, but to effect solution in the cold, and to add the caustic alkali when cold also, when no precipitation will take place, and the test will be quick at once, no further addition of mercuric chloride being necessary.—I am, &c.,

W. J. Dibdin, F.I.C., F.C.S.

37, St. Stephen's Avenue, Shepherd's Bush, W.
December 14, 1881.

WASH-BOTTLE.

To the Editor of the Chemical News.

Sir,—Will you kindly allow me to state that the wash-bottle described by Mr. A. E. Johnson in the Chemical News, vol. xliv., p. 213, is, as far as I can make out, almost identical with one described by me in the Chemical News, vol. xxxix., p. 19. The only difference being in the position of the india-rubber tube, which may be made to act as a valve. In Mr. Johnson's it is at the *side*, while in mine it stretches across the *top* of the stopper.

I may be permitted to add that nearly four years' use enables me to recommend the wash-bottle described by me. It may be obtained from Messrs. Townson and Mercer.—I am, &c.,

M. H. Foye.

Crewe, December 20, 1881.

CHEMICAL NOTICES FROM FOREIGN SOURCES.

Note.—All degrees of temperature are Centigrade, unless otherwise expressed.

Comptes Rendus Hebdomadaires des Séances, de l'Académie des Sciences. No. 22, November 28, 1881.

Isomeric States of the Haloid Salts.—M. Berthelot.—The author finds himself led to the conclusion that the exothermic changes effected in the condition of silver iodide correspond either to polymerisation or rather to a true change of chemical function.

The Distribution of Energy by Electricity.—Marcel Deprez.—A mathematical paper which cannot be reproduced without the accompanying diagram.

Decomposition of Watery Vapour by the Electric Effluve.—MM. Dehérain and Maquenne.—The authors mention that the expression "electric effluve" does not designate a unique phenomenon, always identical with itself, but an entire series of effects, which may vary from the spark and the rain of fire to simple phosphorescence, and even electric interchanges, which do not give rise to any luminous appearance. To these various effects correspond different chemical actions; certain effluves neither determine the decomposition of watery vapour nor the combination of oxygen and hydrogen. The experiments performed seem to establish that certain electric effluves, even free from sparks, and at a relatively feeble tension are capable of decomposing water into its elements; this method of decomposition is therefore distinct from that pointed out by M. Berthelot in the case of the spark. The authors cannot yet decide if the decomposition tends towards a fixed limit.

Reply to M. Isambert's Note on Ammonium Carbamate.—R. Engel and A. Moitessier.—The authors uphold the accuracy of their experimental results against M. Isambert.

An Electrolytic Dosometer serving to Measure the Intensity of the Current during the Medical Application of Electricity.—J. L. Pulvermacher.—This instrument is intended to measure, in cubic millimetres, the gases obtained by the decomposition of water during a given time. It is composed of a glass tube voltameter, in the bottom of which are melted the two electrodes of platinum wire. A second glass tube of 0·001 metre is soldered to the upper extremity. The gases produced by the decomposition of the water collect in a kind of chamber contrived at the bottom of the graduated scale. They can escape only by means of an aperture, which can be either closed or opened at will by means of a caoutchouc rod.

Journal für Praktische Chemie.
No. 16, 1881.

A New Method for the Electrolytic Determination of Zinc.—H. Reinhardt and Dr. R. Ihle.—The authors, after careful trial, find none of the existing methods satisfactory. They have succeeded in completely precipitating zinc from an oxalic solution, even by a feeble current, and obtaining it in a compact form, suitable for weighing. They prepare a solution of zinc sulphate or chloride as neutral as possible, and add an excess of neutral potassium oxalate till the precipitate of zinc oxalate is re-dissolved. A current yielding 90 c.c. of mixed gases per hour is strong enough to effect complete precipitation. The zinc oxalate is resolved into Zn and $2CO_2$, and the potassium oxalate into K_2 and $2CO_2$. Free oxalic acid in presence of a sufficient quantity of potassium oxalate, is not injurious, but the precipitation is much more rapid in neutral solutions. The presence of nitric acid, whether free or in combination, is objectionable. A specimen of zinc-blende was dissolved in *aqua regia*; the solution was then diluted, and all the metals of the H_2S group were precipitated by sulphuretted hydrogen. The solution, containing only zinc, iron, and manganese, was concentrated with sulphuric acid on the water-bath, oxidised with bromine water, and the zinc, along with the small quantity of manganese, precipitated as oxalate by Classen's method. The precipitate was washed, first, with a mixture of equal parts of alcohol, water, and glacial acetic acid till the solution of potassium oxalate was removed, and then with pure water till the washings no longer showed an acid reaction. The zinc oxalate, thus purified, was re-dissolved by digestion with a warm solution of potassium oxalate in excess, and the solution was submitted to electrolysis.

Communications from the Chemico-Agricultural Laboratory of the University of Königsberg.—H. Ritthausen.—These communications consist of two portions. In the first the author describes the nitrogenous principles obtained from the seed of vetches, *i.e.*, vicine, convicine, and divicine. In the second, he treats of the action of saline solutions upon the conglutine of lupins and almonds, and the legumine of beans and lentils.

Polythionic Acid contained in Wackenroder's Solution.—T. Curtius.—Wackenroder's solution consists of pentathionic acid. Under the influence of alkaline earthy carbonates it loses sulphur, and passes quantitatively into the aqueous solution of a tetrathionate. The latter, on standing, undergoes further decomposition, in which free sulphur, hyposulphites, sulphites, and sulphates appear. The ultimate products are sulphur, sulphates, and free sulphurous acid.

Action of Chlor-benzoyl upon Glycocoll Silver.—T. Curtius.—This reaction gives rise to three nitrogenous acids, the hippuric, an acid not named, $C_{11}H_{12}N_2O_4$, which can be separated from the hippuric by its total insolubility in boiling chloroform, and a third, $C_{10}H_{12}N_3O_4$, insoluble both in boiling chloroform and in absolute alcohol.

Ethylen-ethers of Phenol and of the Nitro-phenols.—A. Weddige.—The author gives an account of brom-ethylen-phenyl-ether, brom-ethylen-nitro-phenyl-ether, and certain of their derivatives, such as imido-diethylen-phenyl-ether, its hydrobromate and hydrochlorate; ethylen-phenyl-ortho-nitro-phenyl-ether, brom-ethylen-ortho-nitro-phenyl-ether, amido-ethylen-ortho-nitro-phenyl-ether, imido-diethylen ortho-nitro-phenyl-ether, benzoyl-amido-ethylen-ortho-nitro-phenyl-ether, anhydro-benzoyl-amido-ethylen-ortho-amido-phenyl-ether, &c.

Biedermann's Central-Blatt für Agrikultur-Chemie, Vol. x., Part 5.

The Temperature of the Soil underneath Snow.—E. and H. Becquerel.—Contrary to the common opinion a thick covering of snow does not protect the subjacent soil from severe frost as effectually as does grass-turf.

State of Combination of Phosphoric Acid in the Agricultural Soil.—P. P. Deherain and Kayser.—The authors mention that phosphoric acid introduced into the soil in the state of animal charcoal soon passed into combination with alumina and ferric oxide. In cases where the addition of superphosphate was found unremunerative, a considerable part of the total phosphoric acid was found as calcium phosphate. The mud of the Nile was found to contain 2·30 grms. phosphoric acid per kilo. If as much as 0·4 per cent of phosphoric acid is present in the soil, phosphatic manures are useless.

Mechanical and Chemical Analyses of Roumenian Soils.—S. P. Radianu.—Much of the soil is similar to the black earth of Russia. The yellow diluvial soil is very suitable for vineyards.

Quantity of Plant-food in the Refuse of Different Towns.—Dr. M. Fleischer.—The Groningen compost contains on the average:—Nitrogen 0·6, potash 0·24, and phosphoric acid 0·5 per cent. The Bremen compost (pail-system):—Nitrogen 0·52, potash 0·26, phosphoric acid 0·51. The author, taking the value of nitrogen at £60 per ton, that of potash at £11, and that of phosphoric acid at £15, values the excrementitious matter of Groningen at £240 per 1000 inhabitants, and that of Bremen at £150.

Experiments on Manuring Beets.—MM. Champonnois and Pellet.—The authors have tried two manures, one based on Ville's manure and the other on the residue of the refuse from refining beet-sugar on Porion's process. The latter was richer in potash, and of course in organic matter, and gave heavier crops.

Changes in Farm-yard Manure on Prolonged Keeping.—Prof. Birner and Dr. Brimmer.—The loss of nitrogen is considerable, but almost disappears if the manure is protected against moisture. On the addition of 1 per cent kainite and 1 per cent magnesium sulphate, the nitrogen is increased by absorption from the atmosphere.

Manurial Experiments with Saltpetre on Wheat, Barley, and Oats.—Horatio Chancellor.—Saltpetre is most beneficial in dry seasons, and should be applied in successive doses.

Manurial Experiments on the Danube Moor.—F. Schaffert.—Of local interest.

Behaviour of Mould Vegetation in the Animal Body.—P. Grawitz.—One and the same fungus may vegetate harmlessly or may destroy animal organs as a malignant pathogenic parasite.

Cultivation of Hops.—M. Müntz.—The author concludes that hop manures should be especially rich in nitrogen.

Influence of Atmospheric Electricity on Growth of the Vine.—Dr. J. Macagno.—The vines experimented on yielded grapes richer in grape-sugar and poorer in acid than those growing under natural conditions.

Certain Kinds of Sugar, Optically Considered.—Dr. Schmöger, Prof. Erdmann, Dr. E. Meissl, Dr. Kiliani.—This paper does not admit of useful abstraction.

Vol. x., Part 6.

Relations between Dust, Fog, and Clouds.—J. Aitken.—A paper read before the Royal Society of Edinburgh.

The Oxygen of Natural Waters compared with their Proportion of Organic Matter.—T. Weyl and X. Zeitler.—The oxygen was determined by Schützenberger's method—titration with sodium hydrosulphite in an atmosphere of hydrogen. The organic matter was determined by Kubel's process. In most of the samples examined an increase of organic matter was attended by a decrease of gaseous oxygen, but the quantity of the latter forms no standard for the goodness of the water.

The Black Earths of the Governments Ulfa and Samara.—Prof. C. Schmidt.—Examination of a number of samples of soil.

Manuring with Potash Salts.—Adolf Mayer.—A lengthy memoir, not capable of useful reproduction.

The Value of Different Forms of Reverted Phosphoric Acid compared with the Soluble Phosphoric Acid of Superphosphates.—Prof. M. Maercker.—In general, precipitated phosphate of lime appears of equal value with superphosphates with an equal quantity of soluble phosphoric acid. Root crops form an exception, as in them soluble phosphoric acid gives a somewhat better return. In light soils the precipitated phosphate was found much superior. Precipitated aluminium phosphate is of the same value as the calcium phosphate.

Utilisation of Certain Articles of Food in Human Digestion.—Max Rübner.—The proportion of matter assimilated from different kinds of food varies greatly. Of the nitrogenous matter in fresh meat and eggs only 2·5 to 2·7 per cent is rejected; in milk 7 to 12 per cent; in peas, beans, &c., 10·5 per cent. The author maintains that a healthy body can scarcely be formed and upheld with vegetable matter alone.

Areometric Method for Determining the Percentage of Fat in Milk.—Prof. Soxhlet.—The principle of the method is as follows:—If milk is shaken up with ether and potassa lye, the ether dissolves the fat of the milk, and on standing forms a layer on the surface of the liquid. The more fat is dissolved the greater is the specific gravity of this ethereal liquid.

Composition of the Cell-Contents of Different Parts of Grapes with Reference to the Yield of Must.—E. Mach and K. Portele.—The author has examined the relative distribution of sugar and acid in different parts of the berry.

Studies on Blue Milk.—Dr. F. Neelsen.—"Turning blue" is a morbid change which occurs in milk under the action of a specific contagium which is capable of producing a similar change in the milk of other animals and in certain other substances such as boiled potatoes, rice, and vegetable caseine. It does not extend to animal albumen or chemically pure caseine. "Blue" milk possesses no poisonous properties.

Justus Liebig's Annalen der Chemie, Band 210, Heft 1.

Meta-iso-cymol.—Dr. Werner Kelbe.—A bulky memoir, quite incapable of useful abridgment.

Communications from the Chemical Laboratory of the University of Graz.—These consist of a memoir by Karl Garzarolli-Thurnlackh, on the action of zinc-ethyl and zinc-methyl upon the chlorinised aldehyds. As a specimen of these bodies, the author has selected chloral, which by the action of zinc-ethyl was reduced to the

corresponding alcohol, trichlor-ethyl-alcohol. The action of zinc-methyl was different, the chief product being a compound $C_2H_5Cl_3O$, with the examination of which the author is still engaged.

Communications from the Chemical Laboratory of the University of Erlangen.—These consist of memoirs on cotarnine and codeine, both by E. von Gerichten.

Alkylen Substituted Amidic Acids.—Hugo Schiff.—The author has examined isobutylen-amido-benzoic acid, isoamyliden-amido-benzoic acid, œnanthamido-benzoic acid, benzylen-amido-benzoic acid, and isatamido-benzoic acid.

Aldehydo-disulphites of Aminic Acids and Amines.—Hugo Schiff.—A study of benzaldid-amido-benzoic disulphite, œnanthol-amido-benzoic disulphite, œnanthoglycocoll disulphite, benzaldid-glycocoll disulphite, glycosalicyl-glycocoll disulphite, glyco-salicyl-sodium disulphite, œnanthol-leucin disulphite, glyco-salicyl-leucin disulphite, and œnanthol-anilin-anhydro-disulphite.

Les Mondes, Revue Hebdomadaire des Sciences.
No. 2, September 15, 1881.

Absorption of the Ultra-Violet Rays of certain Media.—M. le Comte de Chardonnet.—A solar ray reflected on the metallic mirror of a heliostate traverses a narrow slit and an objective of quartz and Iceland spar. It is then decomposed by a prism of Iceland spar, and its spectrum is projected upon a photographic plate or a fluorescent screen. In this manner a spectrum is obtained the principal rays of which are very distinct. When this arrangement is regulated there is interposed before the slit a quartz trough with parallel surfaces, half filled with the liquid to be examined. In this manner there are projected upon the screen two juxtaposed spectra, one being the normal solar spectrum, whilst the other is the absorption-spectrum of the substance in question.

No. 3, September 22, 1881.

Electric Motors.—A description of the motors of MM. Trouvé and Marcel Deprez.

Thermic Equilibrium in Chemical Actions.—Dr. Donato Tommasi.—Not adapted for abstraction.

No. 5, October 6, 1881.

Formation of Colouring-matters by Electro-Chemical Means.—This subject will be noticed at length.

Galvanic Elements.—Elements composed of simple bodies, one of which is iodine or bromine, manifest a perfectly constant action, and their electromotor forces correspond exactly to the thermic values developed in the course of chemical reactions, so that their action cannot be ascribed to an electrolyte contained in the bromine or iodine. The elements show no trace of polarisation.

No. 6, October 13, 1881.

According to the *Revue Medicale*, M. Dartigues has succeeded in curing three cases of hydrophobia by enclosing the patient in a heated chest, and making punctures in the skin with pilocarpine subnitrate.

Electric Motors: The Trouvé Motor.—H. Valette.—This extensive paper requires the illustrations by which it is accompanied.

No. 8, October 27, 1881.

This number contains no chemical matter with the exception of a paper by M. Gerber, giving a historical survey of chemical theories.

Moniteur Scientifique, Quesneville.
October, 1881.

Electric Exhibition at Paris.—Under this head is given a comparative table of French and English weights and measures, and the principal electric unities.

MISCELLANEOUS.

South London School of Pharmacy.—The prizes were presented to the following successful competitors in the Lecture Room of the institution on December 17, 1881. Senior Chemistry—Medal, E. John Bull; Certificate, Herbert Shaw. Junior Chemistry—Medal, W. T. Mignot Tucker; Certificate, Walter Lloyd. Botany—Medal, Clement Caldecot; Certificate, F. E. Tozer. Materia Medica—Medal, H. Hardy White; Certificate, W. T. M. Tucker. Practical Pharmacy and Dispensing—Medal, Frederick E. Tozer; Certificate, C. Caldecot.

THE CHEMICAL NEWS.

VOL. XLIV. No. 1153.

ON β-LUTIDINE.*

By C. GREVILLE WILLIAMS, F.R.S.

IN the *Bulletin of the Chemical Society of Paris* for June 5, 1880, there appears a notice of a paper read before the Russian Chemical Society, by MM. Boutlerow and Wischnegradsky, in which they state, among other things, that by the action of alkalies on cinchonine they had obtained quinoline (chinoline) almost pure, and a volatile colourless liquid alkaloid boiling constantly at 166°, having the formula C_7H_9N, and which they say appears to be identical with the base obtained by me in distilling cinchonine with potash, and also with the lutidine of Anderson. Of the identity of the base obtained by them with β-lutidine there can be no doubt, the boiling-point (166°) given by them being to half a degree the mean of the range (163° to 168°) given by me in my "Researches on Isomeric Alkaloids."†

With regard to the identity which they assume between lutidine and β-lutidine, it is evident that they have not seen my paper last quoted, or they would hardly have ignored the mass of facts which I have adduced to prove the isomerism, and not identity, of the two bases.

In the *Bulletin of the Chemical Society of Paris*, Nos. 5 and 9, for September 5, 1880, p. 210, M. W. Oechsner de Coninck publishes an investigation on the lutidine, collidine, and parvoline obtained as above from cinchonine, his only reference to my work being to the *Ann. Chim. Phys.*, xlv., p. 488,‡ in which he says that I have shown the presence of a base possessing the composition of lutidine. He then proceeds to give analyses, density, and vapour-densities of β-lutidine, apparently unaware that they were simply repetitions of what I had done many years before. I gave the analysis of the base and the platinum salt in the *Trans. Roy. Soc. Edin.*, previously quoted. I also gave the analyses of the platinum salt of collidine in the same paper. The specific gravity of β-lutidine at 0° was given by me in my "Researches on Isomeric Alkaloids" as 0·9555; M. de Coninck makes it 0·5035 at the same temperature. M. de Coninck gives the vapour-density as determined in Von Meyer's apparatus as 3·80; I gave it as 3·65 in two experiments exactly agreeing with each other, and also made in Von Meyer's apparatus.‖ The formula C_7H_9N requires 3·699. In my paper "On Isomeric Alkaloids" I gave as the result of a determination by Dumas's method 3·787. M. de Coninck also states as a new result that the platino-chloride of the lutidine from cinchonine is modified by hot water, losing two molecules of hydrochloric acid. The extraordinary difference between the decomposability of the platinum salts of lutidine and β-lutidine on boiling with water, with evolution of hydrochloric acid, was one of the numerous illustrations of the isomerism of the two bases which I adduced in my "Researches on Isomeric Alkaloids" seventeen years ago. The tone of M. de Coninck's papers shows that he believes his results to be entirely new. I mention the above facts partly because they *are* facts, but chiefly as showing that other chemists are working on β-lutidine, and that it therefore becomes necessary to publish my more recent experiments somewhat earlier than I should otherwise have done.

The preparation of β-lutidine in a state of purity is a work of much labour. On distilling cinchonine with hydrate of potassium a mixture of at least ten alkaloids is obtained, and the β-lutidine has to be separated by fractional distillation. I have, however, prepared for the purposes of this investigation probably the largest quantity of the base that has yet obtained—rather more than half a pint.

Action of Sodium upon β-Lutidine.

I found that by the action of sodium upon chinoline it became polymerised with the formation of a body having the composition of dichinoline. This substance forms a crystalline hydrochlorate, having, when freshly prepared, a magnificent scarlet colour.* The hydrochlorate of dichinoline dyes silk a brilliant but fugitive orange colour. This reaction, namely, the formation of a coloured hydrochlorate from a colourless oily base, being probably unique, it became desirable to ascertain how β-lutidine would behave under similar circumstances.

Fragments of sodium were added to β-lutidine in the cold; they acquired a brilliant yellow colour, and had exactly the appearance of pieces of metallic gold. The mixture was then warmed until the sodium melted; it was then removed from the lamp. A violent reaction ensued, and the whole turned greenish black by reflected light, and yellowish brown by transmitted light. The product was left until the next day, and was then boiled for five minutes; it thickened, and, on being poured into water, yielded a heavy brown oil. No pyrrol was formed. Excess of hydrochloric acid being added, the oil dissolved, forming a brown solution; this was fractionally precipitated with solution of platinic chloride. Six precipitates were obtained; the first was pale brown, the second fawn coloured, the third a paler fawn, the fourth Naples yellow, the fifth sulphur yellow. The last only was distinctly crystalline under the lens. If put in a wet state into the water oven they melt, but if first dried over sulphuric acid the desiccation may be completed without fusion. The platinum was determined separately in the first four precipitates; the fifth and sixth were so small in quantity that they had to be mixed.

Number of Precipitate.	Percentage of Platinum.
I...	25·28
II...	24·82
III...	26·40
IV...	27·57
V. and VI.	30·28

The second precipitate, in its percentage of platinum, agees with the formula for the platinum salt of the hydrochlorate of di-beta-lutidine containing 2 molecules of di-beta-lutidine, the formula being—

$$2(C_{14}H_{18}N_2)HCl.PtCl_4,$$

or, of a still higher polymer, in which case the formula becomes—

$$C_{28}H_{36}N_4.HCl.PtCl_4;$$

whichever formula we adopt, the percentage of platinum required is 24·61, which agrees closely with the experimental number. The other precipitates were probably mixtures of this salt with the platinum salt of di-beta-lutidine—

$$C_{14}H_{18}N_2.HCl.PtCl_4,$$

which requires 33·53 per cent of platinum.

A second preparation was then made, but the oil obtained on treating the crude product with water was distilled; the boiling-point varied from 180° C. to a temperature above the range of the mercurial thermometer. Four fractions were received, the fourth, which distilled at and above 300°, was dissolved in hydrochloric acid, and fractionally precipitated with platinic chloride.

III.	26·48
IV.	29·60

The second precipitate, therefore, afforded almost exactly the numbers required for the salt $C_{28}H_{36}N_4.HCl.PtCl_4$, and the others were probably mixtures of the kind I have indicated above. It is possible that the fourth precipitate had the composition shown by the formula—

$$C_{14}H_{18}N_2.3HCl.PtCl_4,$$

which would require 29·84 per cent of platinum; I propose to settle this question by further experiments.

During the precipitation of the platinum salts from the distilled base the solution became of a brilliant but fugitive scarlet colour. It is evident from the above numbers that the oil of high boiling-point had the same general character as the crude mixture first examined.

Sodium amalgam, although it so readily polymerises chinoline,* was found to be almost without action on β-lutidine.

The action of sodium was then tried upon β-lutidine dissolved in toluene; two products were obtained, one solid, the other liquid. The solid substance on being dissolved in hydrochloric acid, and fractionally precipitated as before, gave two precipitates.

Number of Precipitate.	Percentage of Platinum.
I.	25·30
II.	33·33

The fluid portion treated as before gave—

Number of Precipitate.	Percentage of Platinum.
I.	26·14
II.	30·69

The results, while proving that β-lutidine is polymerised by the action of sodium, show also that at least two substances are formed, and that separation is not easily effected by fractional precipitation with platinic chloride. It will be seen that the second precipitate from the hydrochlorate of the solid base gave for the platinum a number almost exactly agreeing with that required for the platinum salt of di-beta-lutidine, $C_{14}H_{18}N_2.HClPtCl_4$, which requires 33·53 per cent of platinum.

Compound of β-Lutidine with Nitrate of Silver.

I have shown in my paper "Researches on Isomeric Alkaloids,"† that β-lutidine combines *directly* with platinic chloride; it does the same with nitrate of silver.

When β-lutidine is added to an aqueous solution of nitrate of silver, a white curdy precipitate is thrown down; it dissolves in alcohol, and is re-precipitated by water as a glittering mass of snow-white crystals. These latter crystallise readily from alcohol in beautiful stellar groups. On analysis the following numbers were obtained:—

	Experiment.	Calculation.		
Carbon	50·97	51·32	C_{21}	252
Hydrogen	5·98	5·50	H_{27}	27
Nitrogen		11·41	N_4	56
Oxygen		9·78	O_3	48
Silver	21·03	21·99	Ag	108
		100·00		491

agreeing with the formula—

$$3(C_7H_9N).Ag.NO_3.$$

Compound of Hydrochlorate of β-Lutidine with Chloride of Uranyl.

On mixing solutions of hydrochlorate of β-lutidine and chloride of uranyl, a beautiful yellow salt is formed; it gave the following numbers:—

	Experiment.	Calculation.		
Carbon	26·90	26·67	C_{14}	168
Hydrogen	3·39	3·17	H_{20}	20
Nitrogen		4·44	N_2	28
Chlorine		22·54	Cl_4	142
Uranium		38·10	Ur_2	240
Oxygen		5·08	O_2	32
		100·00		630

agreeing with the formula—

$$2(C_7H_9NHCl).Ur_2O_2Cl_2.$$

Compound of Sulphate of β-Lutidine and Sulphate of Uranyl.

On mixing sulphate of uranyl with sulphate of β-lutidine a yellow mass consisting of small crystals is formed on long standing. The substance was dried at 100°, and burnt, with the annexed result:—

	Experiment.	Calculation.		
Carbon	19·10	19·27	C_{14}	168
Hydrogen	2·54	2·29	H_{20}	20
Nitrogen		3·21	N_2	28
Sulphur		14·68	S_4	128
Uranium		27·52	Ur_2	240
Oxygen		33·03	O_{18}	288
		100·00		872

The above numbers agree with the formula—

$$2(C_7H_9N)H_2SO_4.Ur_2O_2.3(SO_4)$$

Picrate of β-Lutidine.

When β-lutidine is added to a strong boiling solution of picric acid, most of the salt formed settles out as an oil, owing to its insolubility and fusibility, but it becomes a solid crystalline mass on cooling. On re-dissolving the solid in boiling water, and allowing the solution to cool, the vessel becomes filled with brilliant yellow needles. They were burnt with oxide of copper, with the necessary precautions, and gave the following numbers:—

	Experiment.			Mean.	Calculated.		
Carbon	46·77	46·75	46·80	46·77	46·43	C_{13}	156
Hydrogen	4·11	4·16	3·94	4·07	3·57	H_{12}	12
Nitrogen					16 67	N_4	56
Oxygen					33·33	O_7	112
					100·00		336

The formula is therefore—

$$C_6H_2(H.C_7H_9N)3(NO_2).O.$$

Action of Chlorine on β-Lutidine in presence of Iodine.

The chlorination of β-lutidine was effected by Hugo Müller's method; for this purpose iodine was added to the alkaloid, the mixture was heated to 100°, and a current of chlorine was passed through until complete saturation. The product was a dark reddish-brown fluid, which was distilled. The portion boiling below 220° was washed with a dilute solution of hydrate of sodium, and then treated with hydrochloric acid; a viscid green substance of peculiar odour remained undissolved. On adding solution of platinic chloride to the filtered liquid, a granular precipitate was obtained; it was washed, dried, and the percentage of platinum determined: it amounted to 23·49 per cent. The formula $2(C_7H_6Cl_3N.HCl)PtCl_4$ requires 23·74. This result shows that the product is a trichlorinated β-lutidine retaining the basic properties of the original alkaloid.

Use of Electricity for Purifying Porcelain Paste.—Ferruginous matter is removed by passing the paste in a very liquid state between the poles of powerful electromagnets.—*Les Mondes.*

* *Proc. Roy. Soc.*, No. 211, 1881.

† *Proc. Roy. Soc.*, vol. 13, p. 508. There is a misprint in this paper, the formula for the direct compound of β-lutidine with platinic chloride is given as $C_7H_9N.PtCl$, it should have been $C_7H_9N.PtCl_2$; or, in modern notation (Pt=198) $2(C_7H_9N)PtCl_4$.

DETECTION OF OLEOMARGARINE.*

By P. CASAMAJOR.

In the *Moniteur Scientifique* for April, 1881, is an article on butter analysis, in which are given the processes used at the Municipal Laboratory attached to the Prefecture of Police in Paris, for the detection of foreign fats in butter. This is followed by an account of an areometric method, used for the same purpose and based on the difference of density between butter and the fats with low melting-point, extracted from tallow, which are made to resemble genuine butter, and which are known under the commercial name of *Oleomargarine*.

The sale of oleomargarine has become so extensive in this country that a purchaser of butter is never sure whether he is getting true butter or its imitation. In view of this fact, I have thought it useful to give a process, based on the difference of specific gravity between butter and oleomargarine, of such simplicity that it can be easily applied by any person having rudimentary ideas of manipulation.

Processes of this character are those which can be used with greatest efficiency to check adulterations. I have, in previous communications, given such processes for the detection of starch sugar mixed with cane sugar, and for the detection of starch sugar syrup mixed with sugar house syrups.

Although my concern is principally with the difference of density between butter and oleomargarine, I propose to very briefly call attention to the processes used at the Municipal Laboratory of the Prefecture of Police, as these show important differences in chemical composition between true butter and its adulterant, which confirm the difference in the specific gravity. Such an important character as the specific gravity would not differ to any marked extent without a corresponding diversity in the composition of the two substances.

One process used at the Municipal Laboratory is the following: the sample of butter to be tested is melted, so as to separate water, salt, &c., which are deposited, and a certain amount of scum, which comes to the surface. Of the clear melted fat, under the scum, about 3 or 4 grms. are taken and saponified by 1 or 2 grammes of potassic hydrate. The fat and potassa should be mixed with 50 c.c. of alcohol. In about five minutes the saponification is complete, and the cautious addition of water should not produce any turbidity. If any takes place, the operation must be begun anew. The soap formed is afterwards decomposed with weak sulphuric acid, and the insoluble fat acids are collected and weighed. The result of a great number of experiments is that in butter the percentage of fat acids thus obtained is usually 86·5 to 87·5 per cent, and that sometimes it is as high as 88 per cent. In animal fats from tallow the percentage of insoluble fat acids is 95½. The difference $95\frac{1}{2} - 87\frac{1}{2} = 8$ per cent, is attributed to the absence in tallow of volatile and soluble fat acids which exist in butter.

Another process is given in which the result is obtained volumetrically, by estimating the quantity of potassa used in saponifying the fat. One gramme of butter requires 225 to 232·4 c.c. of potassa solution, while 1 grm. of tallow, or other animal fat of the same nature, requires from 195 to 197 grammes of the same potassa solution.

Mr. Charles Girard, director of the Municipal Laboratory, considers as adulterated any butter requiring, for saponification, less than 221·5 c.c., of the potassa solution. In some unfavourable cases this volume may represent nearly 30 per cent of foreign fat.

The method for detecting the difference between butter and oleomargarine by the difference of specific gravity is one proposed by Messrs. Leune and Harburet.

The butter to be tested is first melted so as to separate the pure fat from water, salt, &c. The clear melted fat is placed in a cylinder, heated by the vapour escaping from a water-bath, kept boiling, but no part of the cylinder is to be in the boiling water. I understand that by heating in this way, the temperature of the melted fat remains at about 93° C. To determine the density of this fat an areometer is placed in it. This areometer is graduated in such a way that, in butter, it will sink to the lowest mark of the scale, while oleomargarine corresponds to the highest point in the graduation. The intervening space is divided into ten equal parts, each one of which corresponds to one-tenth of oleomargarine, mixed with butter. More than 600 experiments made by Messrs. Leune and Harburet with artificial mixtures show that, within an approximation of 10 per cent, the instrument gives correct results.

Soon after this areometric method was published, it was announced that the difference of the specific gravities of butter and of oleomargarine was too slight to distinguish the one from the other. As Messrs. Leune and Harburet had not stated what the specific gravity of each was, it was impossible to judge of the truth of this statement, and it became interesting to ascertain the facts of the case. The following process is the result of my attempts to determine the specific gravities of butter and of oleomargarine. I chose in the first place to ascertain the specific gravity of each at 15° C, which is the usual temperature for such determinations. The process consisted in finding for each a liquid in which, at 15° C, a portion of butter or of oleomargarine, freed from impurities by previous melting and containing no air bubbles, would remain in equilibrium in any portion of the liquid, without any tendency to rise to the top or sink to the bottom. The readiest liquid for this purpose was a mixture of alcohol and water, as this is easily prepared and it has no dissolving action on the fats to be tested. As the density of the liquid in which a body remains in equilibrium is the density of the body itself, the problem was narrowed down to finding the difference of density between two mixtures of alcohol and water of different strengths. It was found that pure butter, at 15° C. would remain in equilibrium in alcohol of 53·7 per cent. This corresponds to specific gravity 0·926. This butter was obtained from a gentleman, at whose country place the butter was made. I obtained oleomargarine from melted warm beef suet by pressure. At a temperature of 25° C. this expressed fat had the consistency of butter. The alcohol which at 15° C. would hold it in equilibrium had a strength of 59·2 per cent, which corresponds to a specific gravity of 0·915.

The question of the possibility of distinguishing butter from oleomargarine becomes equivalent to the possibility of distinguishing alcohol of 53·7 per cent., from alcohol of 59·2 per cent. As this difference is 5·5 degrees of Gay-Lussac's alcohometer, it is very evident that the specific gravity is a sufficient character for distinguishing butter from oleomargarine. This difference may appear more clearly to persons not familiar with alcohometry by stating that it is the difference between 0·926 specific gravity and 0·915.

By means of the tables of Gay-Lussac and of Tralles,* it is a very easy matter to prepare alcohol of the required strength at any temperature, to be kept in bottles for future use.

As the expansion of fats is different from that of alcohol, it is advisable to bring the alcohol to 15° C. when making an observation, which can be easily done by any one provided with a thermometer.

To deliver the sample of fat on the alcohol, I have found that the best plan is to melt the fat and let a large drop of it fall into the liquid. The fat should be melted in a little spoon or a little scoop, and the drop should be delivered by bringing the spoon or scoop close to the surface of the alcohol. It requires a little practice to do this neatly, so as not to get an air bubble in the ball of melted fat. When an air bubble becomes imprisoned in the fat,

* Read before the American Chemical Society, Sept., 1881.

* See the excellent tables of Prof. McCulloh.

I have had no difficulty in removing it with a strip of paper, while it lies on top of the alcohol. Sometimes the globule of fat only partially sinks in the alcohol; the top of it becomes flat and remains exposed above the liquid. A slight tap on the side of the glass is then generally sufficient to form a wave and sink the globule.

If we take alcohol at 56½ per cent, which represents equal volumes of alcohol of 53·7 per cent, and of 59·2 per cent, and if we deliver on the surface of this alcohol a globule of melted butter and one of oleomargarine, the butter will sink to the bottom and the oleomargarine will remain at the top, while the two globules are still warm and liquid. Afterwards, if the alcohol has a temperature of about 30° C. the butter will become solid, while the oleomargarine may still remain liquid. Then the butter will rise to the top of the alcohol, which is due to the expansion of butter on solidifying. If the alcohol be then kept for a few minutes at 15° C. the oleomargarine will become opaque and remain at the top while the solid globule of butter will sink to the bottom.

If instead of taking alcohol of 56 per cent we use alcohol of 59·2 per cent, oleomargarine will remain on top and butter will sink to the bottom at all temperatures above 15° C. At 15° C. oleomargarine will remain in equilibrium in any portion of the liquid in which it may be placed.

If oleomargarine was always sold pure, the foregoing indications would be sufficient to distinguish it from butter, but the oleomargarine found in the market is always more or less mixed with true butter to improve its taste and appearance. This being the case, alcohol of 59 per cent is not the proper liquid to detect oleomargarine. We should use alcohol of 55 per cent and consider as oleomargarine any so-called butter which will not sink to the bottom in alcohol of this strength at 15° C. This is founded on the fact that not more than one-third of butter is ever mixed with oleomargarine to improve its taste and appearance.

Bearing in mind the experiments of Messrs. Leune and Harburet, already cited, the proportion of butter and of oleomargarine in a mixture could be easily detected by finding what strength of alcohol will hold in equilibrium at 15° C. a globule of fat under examination. As the difference of 59·2 and 53·7 is 5·5, the proportion of oleomargarine is the difference between the strength of the alcohol and 53·7, divided by 5·5, or more conveniently multiplied by 0·18. If the alcohol required to hold a globule of fat in equilibrium at 15° C. has a strength of 57 per cent, then: $(57-53{\cdot}7) \times 0{\cdot}18 = 3{\cdot}3 \times 0{\cdot}18 = 5{\cdot}95$, or say six-tenths of oleomargarine. If the alcohol had a strength of 58, then $58-53{\cdot}7 \times 0{\cdot}18 = 4{\cdot}3 \times 0{\cdot}18 = 7{\cdot}72$, or about eight-tenths of oleomargarine.

The proportions of butter and oleomargarine in a mixture may be also determined without the aid of an alcohometer, by using the two solutions of 53·7 per cent and of 59·2 per cent. These may be placed in graduated glasses and poured cautiously into a third glass, until an alcohol of sufficient strength is obtained to keep in equilibrium a globule of the fat under examination at 15° C.

The relative volumes of the two solutions used in making the mixture give the proportions of butter and oleomargarine.

CHEMICAL METHODS FOR ANALYSING RAIL-STEEL.*

By MAGNUS TROILIUS, Chemist to C. P. Sandberg, London.

(Continued from page 300.)

Magnesia Methods.—In some laboratories it is usual to re-dissolve the phospho-molybdate obtained, and then to precipitate with magnesia mixture. This is a rather slow and wasteful way of procedure, and the direct (Riley's) method seems then preferable.

In the direct method one may use at least 10 grms. of steel. The hydrochloric acid solution is reduced by means of sulphite of soda, the excess of sulphorous acid is removed by boiling, the solution is then neutralised with ammonia and bromine added, so as to oxidise about 0·3 to 0·4 grm. of iron. The sesquioxide of iron is precipitated by means of acetate of soda, and the whole of the phosphorus in the steel is supposed to be precipitated along with it.

The precipitate is filtered off and dissolved in hydrochloric acid, about 13 grms. of citric acid are added, and the solution is neutralised with ammonia; 20 to 30 drops of magnesia mixture are then added, and some ammonia. The whole should then be left for two days, and be stirred up now and then during that time before it is finally filtered. The precipitate is washed with ammoniacal water, ignited, and weighed.

It is difficult to see where the advantage of using this method would lie, as compared with the direct weighing of the phospho-molybdate. The ignited phosphate of magnesia contains 27·95 per cent of phosphorus, and an error in weighing must have, therefore, a serious influence on the result, unless a very large quantity of the steel be used. But altogether, the magnesia method requires much more time, skill, and labour than the molybdic method. To this should be added the statement by Professor Eggertz, that it is exceedingly difficult to obtain the reagents used in the magnesia method free from phosphorus, whereas in the molybdic acid method it is only the nitric acid which may contain phosphorus. Too high results are, therefore, frequently obtained by the magnesia method.

In conclusion I may say that the above-described brushing method, which I use daily, has given very accurate results, as the same borings have been checked by some of the leading chemists of the day. As to the time required, if several analyses are performed at the same time, and suitable arrangements made, two or three, or even more, results may be obtained in a day.

Silicon Determination.—For determining silicon in rail steel I use the aqua-regia and the sulphuric acid methods. The former has been sufficiently described in connection with the phosphorus determination, and I will here, therefore, only mention the principal details of the latter.

For each gramme of steel I use 14 c.c. of a mixture of sulphuric acid and water, in the proportion of 1 of sulphuric acid to 6 of water. If I wish to estimate the silicon only, no oxidising of the solution is necessary, and I have only to boil (with exclusion of the air as far as possible) until all is dissolved, and then completely evaporate the water so as to render the silica insoluble. The white salt is then taken up with hot water and a few drops of strong hydrochloric acid, and the silica filtered off and washed with hot water containing 5 per cent. of nitric acid.

If manganese is to be estimated in the solution obtained the solution should be boiled with a few cubic centimetres of nitric acid for about one-quarter of an hour before evaporating down. After dissolving the salt in water and hydrochloric acid, boiling should be continued for another quarter of an hour before filtering off the silica, so as to insure the manganese being converted to manganous oxide. The silica must, in this case, be washed, first with ordinary cold water, and then with the nitric acid water, which should flow into a separate beaker and not into the first filtrate, where it might produce a higher state of oxidation of the manganese.

I find that the aqua regia and the sulphuric acid methods yield results which are quite uniform and concordant. The sulphuric acid method can be quite as rapidly used as the aqua-regia method by means of the hot-plate. Two years ago I worked this method in a steel laboratory in Wales, and the chemists at the place took

* Read before the American Institute of Mining Engineers, October, 1881. From the *Journal of the Franklin Institute.*

such a liking to it on account of the absence of the disagreeable fumes, which are evolved in the aqua-regia method, that they started working it for the daily determination of silicon in their pigs. At the present time they use the sulphuric acid method exclusively, and are by practice enabled to work it quite as rapidly as the aqua-regia method. Besides being a neater method, the sulphuric acid process effects no inconsiderable economy in daily practice, where otherwise large quantities of aqua-regia must be consumed.

When using acid water, as in the sulphuric acid method, or strong hydrochloric acid, as in the aqua-regia method, for washing the silica, I make no deduction for filter-ash. The best Swedish filter-paper dees not leave any practically estimable quantity of ash when treated in that way. Otherwise a deduction is made according to Eggertz's formula:

$$\text{Ash, grms.} = 0{\cdot}0001\ D_2,$$

D being the diameter of the filter.

Manganese Determination.—For determining manganese in rail steel I use the acetate of ammonia and bromine process, with *final additions of ammonia*, as usual in English and Welsh steel laboratories. In Germany, the method with acetate of soda and bromine or chlorine, and *no final addition of a strong base*, is used, and in Sweden the acetate of soda and bromine method, in accordance with Prof. Eggertz's directions. In describing my mode of operating, I will also try to point out the great difference between the method with *ammoniacal salts and bromine and ammonia combined*, and the methods with *fixed alkaline salts*; and to show what are the precautions to be taken in each case to attain accuracy.

Bromine and Ammonia Process.—3 grms. of steel are dissolved in a flask of 1 litre capacity by aid of aqua-regia; the solution is boiled down, and finally dried. The mass is then dissolved in hydrochloric acid by boiling; water is added to about 750 c.c. volume, and the solution neutralised with ammonia or carbonate of ammonia. If too much ammonia is added, care must be taken immediately to add some hydrochloric acid and to boil for a short time, so as to prevent manganese being precipitated. When neutralising is completed add 20 to 30 c.c. of strongly concentrated, thick acetate of ammonia, and boil until you see the precipitate settle clear after lifting the flask off from the lamp. If the supernatant liquid will not become clear, add cautiously a few drops of strong ammonia (0·88), shake the flask, and boil for a moment again. In this way you are certain to obtain a clear supernatant liquid; but you must be very careful not to add too much ammonia, as the manganese may then be partly precipitated as hydrated oxide. After settling, the clear liquid is passed through a filter of ten inches diameter into a large flask, and finally the precipitate of basic acetate of oxide of iron is poured on to the filter and the remainder of the fluid allowed to filter well off. When no more drops seem to come from the funnel the basic acetate is washed down into the first flask by means of boiling water, and hydrochloric acid is added. The flask is well shaken and heated to boiling, in order to insure the remainder of the manganese being present only as manganous oxide. Neutralising and precipitation is then repeated as before, and the filtrate added to the first one obtained. For rail steel I find two precipitations like these quite sufficient, the manganese in such steels rarely exceeding 1 per cent. But for spiegeleisen, ferro-manganese, &c., it is certainly desirable to re-dissolve twice, as the more manganese there is in the substance the more of it will be retained in the iron precipitate. Anyhow, it should be borne in mind that a good boiling is necessary after every re-solution, in order to convert the manganese to *manganous* oxide.

The collected filtrates contained in the large flask are then allowed to cool (this takes only a short time, the first filtrate cooling the second, and so on), about 4 c.c. of bromine are added and the flask well shaken, so that the fluid may be well saturated with bromine. It is the safest always to add so much bromine as to have quite a reddish colour in the solution. Ammonia (0·88) is then added in excess, and the flask well shaken. At first the solution generally becomes quite colourless, but after continued shaking the brown colour begins to be more and more evident, and soon the oxide of manganese separates in lumps. It is then boiled for a few minutes, the precipitate allowed to settle and then filtered off, washed with hot water, dried, ignited, and weighed.

It is necessary to have the solution quite cold and a large excess of bromine present when precipitating the manganese in this way. If the solution be hot a violent evolution of nitrogen gas will take place, and the manganese remains in the solution. Insufficient bromine also causes only a partial precipitation. One may write the reactions in this process as follows:—

I. *Insufficient bromine:*

$$2[MnO_2(C_2H_3O)_2] + 5Br + 8NH_3 + (x+2)H_2O = (MnO_2 + xH_2O) + MnO_2(C_2H_3O)_2 + 5NH_4Br + 2[NH_4O(C_2H_3O)].$$

II. *Sufficient bromine:*

$$MnO_2(C_2H_3O)_2 + 5Br + 8NH_3 + (x+2)H_2O = (MnO_2 + xH_2O) + 5NH_4Br + 2[NH_4O(C_2H_3O)] + N.$$

(To be continued.)

AN APPARATUS FOR THE DISTILLATION OF MERCURY IN VACUO.

By ARTHUR W. WRIGHT.

THE importance of pure mercury in many of the operations in the laboratory makes a simple and efficient means of freeing from its impurities the ordinary commercial metal, or that which has become fouled by use, an object greatly to be desired. The familiar chemical methods, aside from their inconvenience, are not entirely satisfactory, and often leave the condition of the product uncertain. Distillation in the usual way, in retorts open to the air, does not prevent contamination by oxidation, and the purity of the metal is further endangered by the liability to spurting and the possible presence of substances volatile at the boiling-point of mercury. When the process is conducted in a vacuum, however, these drawbacks are avoided, and a perfectly pure product is obtained.

A very elaborate and complete apparatus for this purpose has been devised by Professor Weinhold,* which fully satisfies all the conditions of the problem. This instrument has provisions for the maintenance of the vacuum by means of a Sprengel pump which constitutes a special part of it, with suitable arrangements for adjustment of the mercury supply, the heat from the gas burner, and the like. The devices for securing these objects, however, render the apparatus somewhat bulky and complicated in structure. A far simpler construction has been employed by Dr. L. Weber,† which, however, has no contrivance for maintaining or renewing the exhaustion, except by re-filling with mercury, and otherwise leaves much to be desired. It consists essentially of a long glass tube, bent into a U-shape, so that when filled with mercury and inverted with the ends of the tubes in vessels containing mercury it forms a double barometer, the bend of which is above the level of the metal and therefore vacuous. An enlargement at one side where the heat is applied by a small Bunsen flame gives an increased surface of evaporation. The mercury vapour condenses in the upper portion of the empty space and flows out through the other branch of the tube.

The apparatus devised by the writer is based upon Weber's plan of a double barometer tube, but with important modifications which secure substantially the

* Carl's *Repertorium für Physik*, vol. xv., p. 1.
† *Ibid.*, vol. xv., p. 52.

advantages of the more complicated system of Weinhold. The most essential portions of it are represented, in section, in the accompanying sketch, which is drawn to a scale of one-tenth that of the instrument itself. The principal member of the still consists of a single continuous piece of glass work, which, for convenience of description, may be regarded as made up of several distinct parts designated by the letters *b*, *c*, *d*, *e*, *f*, *g*, *h*.

The portion *b* is a straight, rather heavy piece of tubing, of about one centimetre exterior, and five or six millimetres interior, diameter. Its length is a little more than 76 centimetres. It is open at the lower extremity, and at the other is enlarged to an oval bulb, *c*, about 85 m.m. in diameter and 120 m.m. long. At the upper end of this is joined the portion *d*, *e*, having an interior calibre of about 15 m.m. The vertical portion next to *c* is 25 m.m., the inclined portion, *d*, 130 m.m., and the sloping part, *e*, 300 m.m. in length. The object in making *d* so long and giving it the inclined position was to prevent any globules of mercury thrown up from the bulb entering the portion *e*. But it might well be somewhat shorter, as with proper care in the application of the heat no shocks of the mercury in boiling ever occur.

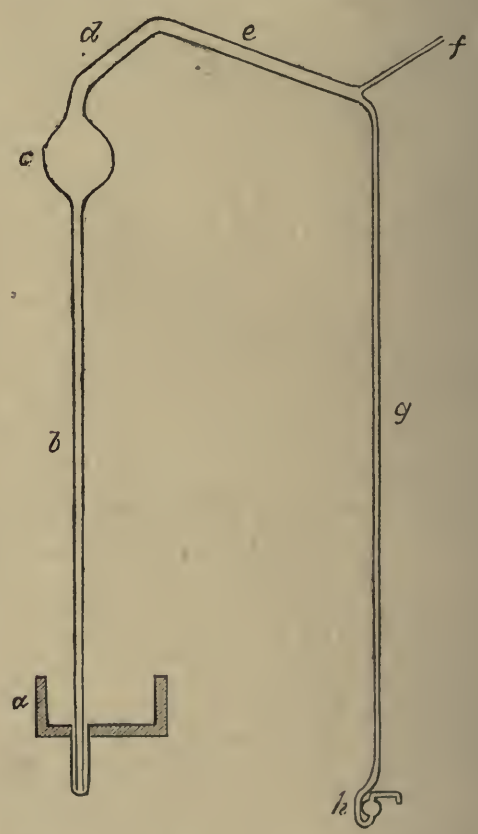
Toward the end of *e* the glass is narrowed, and, at the angle, it passes to a continuation *g*, which is a straight, vertical tube having an interior diameter of about one millimetre. The angle is so formed that the globules of mercury running down from *e* fall freely into *g* without accumulation at any point. This part of the apparatus is in fact a Sprengel pump, and the mercury as it passes out maintains the exhaustion of the whole tube at a very high point. A small tube, *f*, serves to make connection with the air-pump at the beginning of the operations. The tube *g*, at its lower end, *h*, is bent upward and a small bulb blown upon it, sufficiently large to hold enough mercury to fill *g* itself. Above the bulb the tube is bent into a horizontal direction, this part being 30 or 40 millimetres long, and then directly downward, forming the outlet for the mercury. The total length of *g* is 90 centimetres.

A cistern, *a*, serves for the reception of the metal to be operated upon. It is a wooden box 150 m.m. square, and about 60 m.m. deep. The joints are carefully fitted, and the wood oiled and then well varnished, being thus rendered quite impervious. A small well, 80 m.m. deep, for the reception of the end of the main tube, is made by inserting a thick glass tube in the bottom of the box. This arrangement, with the large area of the cistern, increases the range of adjustment of the latter, and makes it possible for several kilogrammes of mercury to pass through the apparatus before any such alteration of level in *c* is produced as to require a new supply or a readjustment.

The glass tube and cistern are mounted upon a light wooden frame, the weight of the former with its contents being chiefly sustained by an iron ring which touches the bulb some distance below its widest part. Several layers of fine wire gauze carefully fitted to the lower half of the bulb are interposed between it and the ring, forming an elastic bed, and serving also to distribute the heat. A cylinder of thin sheet copper just large enough to slip through the ring, is supported upon the latter by a narrow flange at the top. It extends downward about 60 m.m., and is pierced with a number of holes just beneath the ring. It serves to direct the heated current from the burner upon the bulb, as also to protect the flame from movements of the air, and render it steady in its action.

The heating apparatus consists of a hollow ring having upon the upper surface 12 holes 2·5 m.m. in diameter, spaced uniformly in a circle of 25 m.m. radius, and concentric with the glass tube which passes through it. The ring is fitted to the top of a common Bunsen burner, and the whole moves upon a vertical slide, with a clamp screw, by which it may be fixed at any point desired. It has been found advantageous in practice to use but six of the openings, and these all upon one side. A conical hood of sheet copper encloses the upper half of the bulb, and is prolonged by a tube of the same material, which covers the glass tube as far as the angle above *d*. The lower edge of the hood is at nearly the same level as the top of the cylinder above mentioned, and is about six centimetres wider than this, so as to project laterally some three centimetres all round. The upper portion of the copper cone and tube are wide enough to leave an interval of five or six millimetres between them and the glass. The heated gases from the holes in the cylinder, streaming through this space, envelope the bulb *c* and tube *d*, thus preventing condensation of the mercury vapour before it reaches *e*.

The cistern is mounted upon a vertical slide with a clamp screw, and can be moved up or down, the range of motion being about six centimetres. This makes it possible always to bring the mercury to the proper height within the bulb, and to suit the adjustment to the varying atmospheric pressure.



The apparatus is put in operation as follows: Connection having been established with a Sprengel air-pump by means of the tube *f*, mercury is poured into the cistern so as to cover the bottom of it to the depth of a centimetre or two. If pure mercury is at hand, the bulb at *h* may be filled with it, if not the extremity of the outlet tube is sealed or otherwise tightly stopped. As the exhaustion proceeds the mercury rises in *b*, finally reaching *c*, and if all the air were removed, it would stop at the barometric height above the surface in the cistern. The latter is adjusted so that the top of the column is a little below the centre of the bulb, *c*. When no more air can be withdrawn by the pump, *f* is sealed with a gas flame and the connection with the pump severed. The apparatus is thus exhausted once for all, as subsequently it maintains the vacuum by its own operation. The burner, previously set some distance below the bulb, is now lighted and the flame made

very small at first. The mercury soon becomes heated, vapour is formed, and after a time drops begin to fall from the interior surface of the bulb and tube above it. The flame is slowly increased and raised, until, in fifteen or twenty minutes, the vapour passes the angle at the top, and begins to condense in *e*. As the globules of mercury fall into *g* they carry with them the residue of the air, gradually filling the bulb at *h*, and later the tube *g* itself. The point of the tube at *h* is now unsealed or broken off, and the mercury issues drop by drop into a vessel placed to receive it. The operation now proceeds continuously, and the apparatus requires scarcely any attention, further than to keep the cistern properly supplied with mercury, and to remove the pure metal when necessary. The residual air is quickly removed from the tubes by the pumping effect in *g*, and after a time each drop falls with a sharp click in the tube. The construction of the part *h* makes it easy to obtain pure mercury from the very beginning of the operation, an advantage not furnished by the other forms of the apparatus mentioned.

In adjusting the height of the cistern, *a*, allowance must be made for the tension of the mercury vapour in the upper portion of the tube. The cooling effect of the condensing tube, *e*, is such that this is usually from four to six millimetres, and it rarely or never exceeds one centimetre. The temperature of vapourisation corresponding to the latter tension is less than 180°, as, according to Regnault's results, this is the temperature at which the vapour has a tension of eleven millimetres. The low temperature is of itself a matter of importance, both as regards economy in the application of the heat, and as diminishing the probability of volatilisation of any substances which the mercury may contain as impurities.

The apparatus here described, when in use, consumes from one-third to one-half the amount of gas required for an ordinary Bunsen burner. The mercury does not come into active ebullition, but vapourises quietly and entirely without shocks. The rate of distillation varies of course with the heat applied, but is from 400 to 450 grms. per hour. After the burner is once adjusted the apparatus requires no attention, and may be left to itself for hours, care being taken that the cistern contains sufficient mercury. When out of use the tubes are left with the mercury in them, remaining thus exhausted and ready for use at any time.

As the mercury in the bulb and the tube *b* retains all the impurities left behind in the process of distillation, these may at length accumulate in such quantity as to interfere with the proper operation of the apparatus, and to necessitate their removal. This is not likely to occur for a long time unless the mercury used is excessively impure. But when the removal is indispensable it may be effected either by opening *f*, allowing the mercury to descend into the cistern and thus be withdrawn, then refilling and exhausting as at first; or, more simply, by lowering the cistern until the mercury sinks below the bulb, in which case all but the small portion contained in *b* will run out into the cistern and can be drawn off by a syphon or otherwise, care being observed that it is not carried so low as to allow of the admission of air at the bottom of the tube.

The apparatus in operation has proved entirely satisfactory in every respect, and extended use of it in the laboratory has suggested no modification. As mounted upon its frame it has a height of about 125 centimetres, and the base covers a space 45 centimetres long and 33 wide. It is so light that it may readily be lifted and carried with one hand. The glass work was very skilfully constructed, after the design of the writer, by Mr. W. Baetz, of 96, Fulton Street, New York City.—*American Journal of Science.*

New Multiple Telegraph.—M. l'Abbe Laborde.—The author describes at great length an arrangement by which eight, ten, and perhaps even twelve dispatches may be forwarded at once by a single wire.—*Les Mondes.*

PROCEEDINGS OF SOCIETIES.

MANCHESTER LITERARY AND PHILOSOPHICAL SOCIETY.

Ordinary Meeting, November 15, 1881.

E. W. Binney, F.R.S., F.G.S., President in the Chair.

"*On the Pronunciation of Deaf-Mutes who have been taught to Articulate*," by William E. A. Axon, M.R.S.L.

"*On Professor C. A. Bjerkness's Experiments to Demonstrate the Analogies between Electrical and Magnetical Phenomena and some Hydrodynamical Phenomena*," by William H. Johnson, B.Sc.

Among the many interesting exhibits at the Paris Electrical Exhibition, there is nothing more likely to engage the attention of the scientific observer than the simple apparatus and experiments of Professor Bjerkness, of the University of Christiania.

The apparatus consists in the main of metal spheres about one inch in diameter, and drums also an inch in diameter with indiarubber ends. These spheres and drums communicate by means of indiarubber tubes with a pair of air-pumps, which, by an ingenious contrivance, cause the spheres to oscillate and the drums to pulsate isochronously. If the two air-pump pistons go in and out at the same time, the spheres connected with them will oscillate concordantly. If, on the other hand, one piston goes in while the other comes out, the respective spheres connected with the air-pumps will oscillate in opposed phase. The same will take place with the pulsating drums.

When these spheres and drums are allowed to oscillate and pulsate rapidly in a vessel of water, they are found to attract each other if they vibrate in accord, and to repel each other if the vibrations are opposed. Nor is this all, for Professor Bjerkness, by carefully modifying his apparatus, which has been very imperfectly described above, has been able to imitate all the phenomena of magnetism and para-magnetism, but always in an inverse way.

Many phenomena of statical and dynamical electricity can also be imitated by these vibrating bodies, but likewise in an inverse manner.

The whole subject has been investigated mathematically by the Professor, and the laws which govern the attractions and repulsions of these vibrating bodies have been shown to be in accordance with his formulæ.

General Meeting, November 29, 1881.

R. Angus Smith, Ph.D., F.R.S., &c., in the Chair.

Mr. Richard Peacock, of Gorton Hall, Manchester, and Mr. Edmund Salis Schwabe, of 41, George Street, Manchester, were elected Ordinary Members of the Society.

Ordinary Meeting, November 29, 1881.

R. Angus Smith, Ph.D., F.R.S., &c., in the Chair.

The following letter from Mr. Joseph Sidebotham, F.R.A.S., was read :—

"Some few years ago, when I was at Mentone, I wrote to you concerning the aniline colours, so much used on the Continent in water-colour drawings. Since that time Holman Hunt and others have called attention to the fading of these and some other colours prepared for artists, and I hoped the practice of making and using these colours had ceased : however, I find this is not the case. A friend of mine was on his way to the south of France, and I asked him to see if these colours were still sold and used, and he tells me they are extensively, and sent me

cakes of them. He also sent the enclosed sheet of the colours on drawing-paper, half of it having been exposed to the light a fortnight, the other half covered up. He thought that by putting gum over the colours they might be made more permanent, and you will see he has put a band of gum across them: the colours exposed have faded in a great degree, some of them almost disappearing. The band of gum has retarded the fading, but the colours are even there much lighter and all the brightness gone. It is most desirable that artists should entirely give up the use of all these colours, and then the makers would cease to supply them. When we see the sad effects of a fortnight's light upon them, what can we expect to see in drawings hung on the walls of a room for a few years?"

"*On Cyclic Motions in a Fluid, and the Motion of a Vortex Ring of Varying Curvature*," by R. F. GWYTHER, M.A.

NOTICES OF BOOKS.

Handbook of the Collection Illustrative of the Wild Silks of India in the Indian Section of the South Kensington Museum. By THOMAS WARDLE. London: Her Majesty's Stationery Office.

THIS very interesting and important pamphlet reminds us on its title-page of an unfulfilled promise, or at least announcement. Some few years ago it was declared officially that the Indian Museum was only for the time being to sojourn at South Kensington, and was destined to form the nucleus of a grand Indian and Colonial Museum in a central and convenient position. These hopes have not been realised,—a return from South Kensington being apparently more difficult than the familiar "reascent" from Avernus.

The author of the work before us is well known as an eminent silk dyer and printer, and has been engaged for years in the study of the so-called "wild silks" of India with a view to their utilisation. The term wild silks is commonly applied to all kinds of silk other than that produced by *Bombyx mori*. Hitherto these silks have not been cultivated. The small and uncertain supplies which have found their way into commerce are derived from cocoons collected at hazard in the forests, but no organised and systematic attempts have been made to form plantations of the various food-trees and to rear the insects in a state of domestication. There can be no doubt that to do so, to attend to the proper collection of the cocoons, and to make use of improved machinery for reeling the silk, and for carding and spinning that from imperfect cocoons, would prove a remunerative undertaking, and, like the introduction of the cinchona and the tea culture into India, would add to the resources of that country and of the Empire at large. To give encouragement to so desirable an undertaking ought to be the task of the Indian Government. Mr. Wardle meantime has greatly improved and developed the methods of dyeing and printing these silks. From trials which he has had made in Italy it has been found possible to convert the Tusser raw silk into tram and organzine of very great fineness. It appears that this silk, the product of *Antheræa mylitta* or *paphia* and some allied species, differs from common silk in its behaviour with reagents. A neutral solution of zinc chloride, gently heated, dissolves common silk instantly, but only acts slowly upon the Tusser. In a cold solution common silk dissolves in three days, whilst immersion for a fortnight produces no effect upon the Tusser. With ammoniacal solution of copper oxide a similar difference of action is observed. Hence we may well infer, as is actually the case, that the wild silk must be the more difficult to dye. The great difficulty as far as Tusser silk is concerned lies in the bleaching process. Being naturally of a darker colour than common silk, and incapable of bleaching by means of sulphurous acid—a deoxidising agent—oxidisers were tried. M. Tessié du Motay proposed potassium permanganate, which certainly removed the brown colour, but unfortunately injured the texture of the silk. With barium peroxide he was perfectly successful. This reagent is, however, as yet too costly for very general use. The author refers to a method not yet fully developed, of presenting nascent oxygen to the silk from a liquid instead of from a solid. He mentions also that Major Coussmaker has succeeded in obtaining perfectly white Tusser silk by modifying the conditions under which the worm spins its cocoon. If his method is practicable upon a commercial scale the necessity for bleaching would be superseded. As the colours most adapted for dyeing Tusser silk, the author mentions lac, safflower, indigo, the leaves of *Phyllanthus emblica*, the calyces of *Thespesia populnea*, and the flowers of *Butea frondosa*, of Hursinghar, and of *Cedrela toona*. Eria silk has less affinity for dye wares than has common silk, and takes up a greater quantity of tinctorial matter. The author, however, has succeeded in producing on it a variety of shades which leaves nothing to be desired.

The work is enriched with illustrations of several of the most important silk-yielding insects in their different stages of growth, of their food plants, and of the machinery for reeling cocoons. Mr. Wardle has deserved well of British commerce and industry for his prolonged investigations.

A Study of the History and Meaning of the Expression "Original Gravity" as applied to Beer, Worts, and Distillers' Wash; also a full description of the Apparatus required. A practical Method for the Analysis of Fermented Liquors is also described. By J. A. NETTLETON, of the Inland Revenue Laboratory, Somerset House. London: Lamprey, *Brewers' Guardian* Office.

THE author of this work claims for the "Inland Revenue Act" of 1880 that it will make brewers more conversant with their own business than they were before. If such shall prove to be the case, it will prove a result diametrically opposite from what has occurred in chemical manufactures, with which we are better acquainted, as, for instance, soap manufacturing, glass making, and tannery. In each of these branches of industry, the removal of excise interference has led to more scientific management, to a better understanding of principles, and to their more careful and accurate application. It is possible, however, that as regards brewing Mr. Nettleton may be in the right. The author's first step is to define the term "original gravity"—hitherto a mystery not merely to the outside public, but to the vast majority of scientific men. It means, we learn, the original specific gravity of any wort, beer, or wash before yeast had been added and before fermentation had been commenced.

The principal object of the work before us is to show how this original specific gravity may be found at subsequent stages of the process. Fermentation changes the specific gravity of a saccharine liquid because the sugars present are split up into alcohol and carbonic acid, with the simultaneous production of a quantity of a carameloid body lighter than the original sugar. The soluble albumenoid matters contained in malt or grain are also in great part destroyed by the action of the yeast. These changes reduce the specific gravity of the liquid, and are technically known as attenuation. The method recommended for finding the original specific gravity of a beer is the so-called distillation process, the description of which is much too long to be quoted. Three other methods, less accurate, are also given.

In the last part of his work the author gives what, on the title-page, is styled a method for the analysis of a "fermented liquor." This term is too wide, as the process indicated would not be satisfactory in case of wines and other fermented liquors prepared from fruits. The points determined are alcohol, mineral matter, organic matter, acid, and water. Of possible adulterations no notice is

taken. It is singular how the Excise authorities still cling to the somewhat antiquated notion of "proof spirit," instead of calculating the strength of fermented liquids in absolute alcohol.

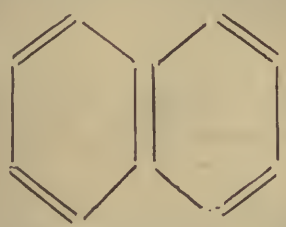
This little work will evidently be of great use to the trade and to analytical chemists. Some peculiarities of expression call at first sight for a little consideration on the part of the reader. Thus Mr. Nettleton speaks of the specific gravity "held" by a liquid, and the operation of shaking or agitating a liquid to expel gases he terms "tossing."

CORRESPONDENCE.

KEKULE'S THEORY.

To the Editor of the Chemical News.

Sir,—In the Chemical News, vol. xliv., p. 260, Mr. Alfred M. Pagan asks in which manner Kekulé's theory of the oscillating linkings would express the second moment of oscillation of naphthalen if the first moment were—



Though no friend of Kekulé's theory, I think it possible to imagine the structure of naphthalen in the second phase in the manner shown by—

—I am, &c.,

A Reader.

CHEMICAL NOTICES FROM FOREIGN SOURCES.

Note.—All degrees of temperature are Centigrade, unless otherwise expressed.

Comptes Rendus Hebdomadaires des Séances, de l'Académie des Sciences. No. 23, December 5, 1881.

Chemical Studies on the Skeleton of Plants.—MM. E. Fremy and Urbain.—The bodies which form the skeleton of plants are chiefly pectose and its derivatives, the cellulosic compounds in their different isomeric states, cutose, and vasculose. To determine pectose, the authors converted it into pectates by the action of alkaline carbonates, and decomposed these pectates by hydrochloric acid, which precipitates pectic acid as an insoluble jelly. Among the cellulosic compounds found in plants, the authors distinguish cellulose, para-cellulose, and meta-cellulose. All these bodies possess the common character of dissolving without colouration in sulphuric acid. Their distinctive characters are:—Cellulose dissolves at once in the ammonio-cupric reagent; para-cellulose dissolves in this liquid only after the action of acids; and meta-cellulose is insoluble even after such treatment. It is dissolved by nitric acid and the hypochlorites. Vasculose forms the principal part of the vessels of plants. It is insoluble in the ammonio-cupric liquid, even after a previous treatment with acids. It resists for a long time the action of sulphuric acid, but it is rapidly attacked by oxidising agents. Cutose is the transparent membrane which covers the aërial organs of plants. It is dissolved neither by sulphuric acid nor by the cupric reagent; it is attacked by the oxidising agents, and is dissolved by dilute caustic alkali in the cold and at the ordinary pressure. Vasculose, on the contrary, resists caustic alkalies, except they are applied with the aid of heat and under pressure.

Electric Deposition of Metallic Strata of Different Colours.—F. Weil.—The author, by a process, not indicated, has succeeded in coating all metals and alloys at the common temperature, and by means of a single copper bath with a permanent and brilliant layer of various sub-oxides of copper, the chemical nature of which has not yet been studied.

Distribution of Energy by means of Electricity.—Marcel Deprez.—A mathematical paper not susceptible of useful abridgment.

Determination of the Ohm.—G. Lippmann.—A reply to M. Brillouin.

Variations of the Resistance of Electric Machines with their Speed.—E. Lacoine.—The author's experiments lead to the conclusion that these variations of resistance are explained by those of contact between the movable commutator and the friction springs.

Determination of the Illuminating Power of Simple Radiations.—MM. A. Crova and Lagarde.—The photometric process, suggested by one of the authors (*Comptes Rendus*, xciii., p. 512), pre-supposes a knowledge of the coefficients of illumination of the various simple rays which compose the light to be compared. This question the authors have investigated experimentally.

Speed of Refrigeration in Gases at Elevated Temperatures.—MM. Mallard and Le Chatelier.—Not suitable for abstraction.

Combination of Hydrogen and Oxygen under the Influence of the Electric Effluves.—MM. Dehérain and Maquenne.—It seems established by the experiments of the authors that the state of moisture of the surfaces between which the effluve is produced is capable of modifying the nature of the discharge, both in its outer aspect and in its action upon the gases. In dry apparatus the effluves never determine the detonation of the gases, but their gradual combination. In moist apparatus the tubes are often burst at the beginning of the experiment.

Titration of Œoline and of Œnotannin in Wines.—F. Jean.—The author finds that œoline and œnotannin are the sole constituents of wine which act upon the solution of iodine mentioned in his memoir on the titration of tannin communicated to the Academy in 1876. It is well, however, to check the results obtained by titration by a colorimetric test made comparatively with a solution of œnoline containing the quantity of this substance indicated by titration. The natural tannin of wine, derived from the seeds and stalks of the grape, gives a greenish black colouration with ferric chloride.

Moniteur Scientifique, Quesneville. October, 1881.

M. Pasteur at the International Medical Congress at London.—A brief notice of the sessions devoted to the question of microbia in reference to disease.

The Congress of Electricians.—An account of the inaugural speech of M. Cochery, with a notice of the representative deputations of different countries, and a general programme of the Exhibition.

Diseases of the Skin in Infancy and Old Age.—A purely medical paper.

Observations on Gums, Resins, and Waxes.—C. G. Warnford Lock.—A translation from the *Journal of the Society of Arts.*

The Resins of the Xanthorrhœa.—J. M. Maisch.—From the *American Journal of Pharmacy.*

Studies on the Alkaloids.—Dr. W. Kœnigs.

A Compiled Account of Cinchonine and Quinine.

Official Reports on the Universal Exhibition of 1878.—The first part of this report treats of pharmacy in France and abroad. The second part is devoted to soaps and stearine. The author remarks that for the preparation of stearine fatty bodies are treated by one of the two following methods:—Saponification with lime under pressure, either with or without agitation, in autoclaves of iron or copper, and without distillation; or saponification with an acid either with or without subsequent distillation. Then follows a description of the mottled soaps made at Marseille and in other parts of France; of the colourless Marseille soap, and the oleic acid soaps. An account of mineral colours is chiefly devoted to ultramarine in its various forms, followed by short notices of vermillion, Prussian blue, and of green, yellow, and black pigments.

Determination of Potash in Agricultural Substances by means of Perchloric Acid.—Armand Bertrand.—In the first place it is necessary to examine if the substance in question contains an ammoniacal salt. If this is the case the ammonia must be expelled by boiling with a little caustic lime. It is necessary that the substance should be perfectly clear. The filtered solution of the sample is evaporated on the water-bath in a small porcelain capsule with 5 c.c. of perchloric acid at 45° B. until the volume of the liquid is reduced to about 10 c.c. The capsule is taken off the water-bath, alcohol at 95 per cent is added; it is let cool, and the potassium perchlorate is collected upon a small filter. The precipitate is washed with alcohol at 95 per cent containing 10 per cent by volume of perchloric acid, until the liquid running through no longer shows the reactions of sulphuric and phosphoric acids. The washing is then completed with alcohol at 95 per cent without the admixture of perchloric acid. It is then dried in the stove. At the end of twenty to thirty minutes the precipitate is detached from the filter and spread out in a tared watch-glass. It is weighed twice, to be certain that the desiccation is complete, and the weight of the potassium perchlorate thus obtained is noted. On the other hand, as there always remains a little perchlorate adhering to the filter, instead of using a tared filter, the author considers it more expeditious to operate as follows:—During the desiccation of the perchlorate in the watch-glass the filter is burnt in a platinum capsule fitted with a lid. The potassium chloride resulting from the calcination is washed into a glass, and the chlorine is determined with a centinormal silver solution. A multiplication indicates the perchlorate to be added to that which has been weighed. This process gives accurate results in presence of lime, magnesia, soda, baryta, iron, alumina, and sulphuric or phosphoric acids, free or combined. The author prepares his perchloric acid as follows:—He dissolves purified barium chlorate in lukewarm water, and precipitates with dilute sulphuric acid. He lets settle, draws off the clear liquid with a syphon, and washes the precipitate of barium sulphate. The solution of chloric acid is evaporated in a porcelain capsule over a naked fire until the concentrated liquid becomes yellow and emits a peculiar sound if heated further. It is then divided in capsules of 19 centimetres in diameter, each capable of containing about 700 c.c., and the evaporation is continued until the liquid is completely colourless, and emits dense white fumes. In order to diminish the inevitable loss of perchloric acid, a little water may be added from time to time during the concentration. Four parts of barium chlorate yield in general 1 part of perchloric acid at 45° B. The colourless liquid is distilled in a retort heated on the sand-bath. A long-necked tubulated receiver is adapted to the retort without the use of a cork.

The Electric Light.—A notice of the various appliances for the electric light on view in the late Exhibition. Mention is made of a lamp with enormous carbons, having an intensity equal to that of 150,000 candles, and proposed for service in lighthouses.

Industrial Preparation of Coniine and its Compounds.—Dr. J. Schorm.—From the *Berichte der Deuts. Chem. Gesellschaft.*

Annales de la Société des Sciences Industrielles de Lyon. No. 2, 1881.

Glycerin as an Agent for the Preservation of Meat and Organic Matter.—H. Danzer.—The author recommends glycerin for the preservation of a great variety of organic substances, both articles of food and even manures. [Will not the rising price of glycerin interfere?—*Ed.* C.N.]

Verhandlungen des Vereins zur Beförderung des Gewerbfleisses. October and November, 1881.

These numbers contain no chemical matter.

Revue Universelle des Mines, de la Metallurgie, &c., No. 1, July and August, 1881.

The only chemical matter in this number is taken from the *Proceedings* of the Iron and Steel Institute (at their meeting in London, May, 1879) and from *Comptes Rendus*

MISCELLANEOUS.

Society of Arts.—The first meeting of the Applied Chemistry and Physics Section of the Society of Arts will be held on Thursday, January 26th, when a paper by Dr. Thudichum, on "Recent Researches into the Theory of the Living Contagium, and their Application to the Prevention of certain Diseases in Animals," will be read, The following papers will be read at subsequent meetings: "Photometric Standards," by Harold Dixon; "Practical Hints on the Manufacture of Gelatin Emulsions and Plates for Photographic Purposes," by W. K. Burton; "Some Practical Aspects of Recent Investigations in Nitrification," by R. Warington; "The Manufacture of Steel from Phosphoric Pig-Iron," by S. G. Thomas and Percy C. Gilchrist.

MEETINGS FOR THE WEEK.

Monday, Jan. 2nd.—London Institution, 5.
Tuesday, 3rd.—Royal Institution, 3. "Jupiter, Saturn, Uranus, Neptune," by Prof. R. S. Ball.
—— Pathological, 8.30. Anniversary.
Thursday, 5th.—Royal Institution, 3. "The Solar System further Considered," by Prof. R. S. Ball.
—— London Institution, 7.
—— Royal Society Club, 6.30.
Friday, 6th.—Geologists' Association, 8.
Saturday, 7th.—Royal Institution, 3. "How we Learn Facts in Astronomy," by Prof. R. S. Ball.

Erratum.—P. 299, col. 1, line 28 from top, after the words "well-fitting cork," *insert* "and 2·5 grms. of finely-powdered zinc oxide added."

OATS, composition of, 37
Obituary, 34
Odling, W., C. M. Tidy, and W. Crookes, London water supply, 33, 86, 140, 186, 254, 288
Œconomides, S., action of ammonia upon isobutylen chloride, 13
preparation of isobutylic acetal, 169
and M. Hanriot, metaldehyd, 204
Œoline and of œnotannin, titration of in wines, 315
Œrum, N. P., and M. Ditzel, nutritive value of gelatin, 239
Ohm, Lippmann's method for the determination of, 295
Oil, cotton-seed, 107
of bitter almonds, ethereal, 82
of wine, 122
seeds, crystalline albumenoids from various, 122
Oils, neutral refined, 275
separation of hydrocarbon from fat oils, 161
Oldenberg, F., manurial experiments with phosphoric acid, 238
Oleic and palmitic acids, estimation of in palm oils, 299
Oleomargarine, detection of, 309
Oliver, G., "Harrogate Water" (review), 70
O'Neill, C., "Introductory Lecture on Dyeing, Calico-Printing, and Bleaching" (review), 272
Optical rotatory power of malic acid, 83
Orcine, a product of the action of aqua regia upon, 204
Ores, sulphur in sulphur, 47
Organic impurities in drinking-water, 82
manurial matters, decomposability of nitrogenous, 49
matter, not sugar, action of on alkaline solution of copper oxide, 99
"Organic Chemistry, Short Text-book of" (review), 259
"Organic Chemistry, Text-book of for Elementary Students" (review), 59
Orr, J. B., curious actinic phenomenon, 12
Ortho-anisidin and amido-dimethyl-hydroquinon, 83
Orthose, reproduction of in the wet way, 59
Ost, H., compounds of the meconic acid group, 122
Ostwald, W., determinations of chemical affinity, 24, 122
O'Sullivan, C., α- and β-amylam, 258
Oudeman's, A. C., Jr., conchinamine, 274
Owens College, course of technological chemistry, 56
Manchester, 154
Oxalates, double and triple, containing chromium, 187
of iron, 262
Oxalic acid from paraffin oil, 284
Oxford University, 149
Oxide of iron, magnetic, 93
Oxide of copper, action of organic matter not sugar on alkaline solution of, 99
Oxides, action of on salts, 259
and salts, hydration of, 209
composition of the hydrates of stannic, manganic, and silicic, 71
ferric and chromic, separation and determination of alumina and of the, 85
of ethylen, glycolic ether and the, 143
of manganese, 241
higher, and their hydrates, 301
of nitrogen, action of on glass at high temperatures, 253
Oxychloride, formation-heat of calcium, 60
Oxychlorides, strontium and barium, 106
Oxygen and hydrogen, combination of, 315
of natural waters, 305
ozone, &c., action of upon benzene, 219
Oxyiodide, phosphorus, 268
Oysters, sewage in, 52
Ozone, action of on the germs in the air, 93
oxygen, &c., action of upon benzene, 219

PABST, J. A., question of the rosanilines, 107
Pagan, A., symbolical notation, 260
Palmitic and oleic acids in palm oils, 299
Para-cholesterin from æthalium septicum, 83
Paris, native sulphur in the soil of, 60
odours, 61
Parke's method for the volumetric determination of copper, 82
Parmentier, F., silico-molybdates, 13
Paros, Maxos, and the Cyclades, mineral wealth of, 144
Pasteur, M., vaccination for splenic fever, 59
Pegna, E., detection of nitrobenzol in oil of bitter almonds, 34
Pellet, H., ammonia in plants, 37
and J. De Grobert, colorimetric determination of salicylic acid in alimentary substances, 168
and M. Champonnois, manuring beets, 305
Peppermint camphor and some of its derivatives, 283
Perchloric acid, 168
Peroxide, lead, determination of the value of, 226
Perrot, E., determination of phosphoric acid by standard solutions, 214
Peru, working guano in, 143
Petermann, A., African guano, 192
Petersen, T., green-stones, 122
Petit, A., rapid process for the determination of uric acid, 215
Petroleum, danger-test for, 81
springs, the, 94
Pettigrew, J., and E. J. Mills, "steeping" of barley, 258
Pharmacy, South London School of, 306
Phenol, direct production of from benzene, 229
ethers of morphine considered as a, 106
Phenyl-naphthalen, 237
Philosophical and Literary Society of Manchester, 211, 313
Society of Glasgow, 49, 302
Phipson, T. L., actinium, 180, 191
curious actinic phenomenon, 73
new metal actinium, 138
Phloron and xyloquinon, 122
Phosphate, aluminium, 82
bicalcic, decomposition of by water, 93

Phosphates and arseniates, new series, 180
Phosphonium and arsenium compounds, 83
Phosphorescence, history of, 94
Phosphoric acid, determination of by standard solutions, 214
in the agricultural soil, 305
manurial experiments with, 238
part played by in volcanic soils, 36
reverted, determination of by means of ammonium nitrate, 76
value of different forms of, 305
soluble, reverted, and precipitated, action of in light sandy soils, 192
and arsenic acids, action of upon sodium tungstates, 60
Phosphorus oxyiodide, 268
penta-chloride, products of the action of upon acroleine, 193
Phospho-tungstic acid, 13
Photographic exhibition, 262
Photography of colours by dyeing layers of coagulated albumen, 70
Photometric comparison of sources of light of different colours, 214
standards, report on, 243
Photophone, selenium and its application to the, 1, 18
Physical Society, 12, 248, 270, 294
"Physics and Chemistry, Report on Teaching in the United States" (review), 190
Picart, A., explanation of the tails of comets, 105
Pickering, S. U., constancy of thiosulphate solutions, 277
Picrate, potassium, decomposition of, 106
Pictet, R., bleaching of silk and wool by liquid sulphurous acid, 275
Pisani, F., vanadiate of lead and copper from laurium, 23
Pitsch, O., humoid matters extracted from the soil of alkalies, 192
Plants, ammonia in, 37
assimilation of nitrogen, 215
chemical studies on the skeleton of, 315
Platinum, atomic weight of, 82
chloride, gold chloride in commercial solutions of, 47
on exposure to flame, 169
salt, estimation of potassium as, 77, 86, 97, 129
salts, new, 83
"Poisoning, What to do in Cases of" (review), 212
Polytechnic Institution, Royal, 25, 101
Polythionic acid contained in Wackenroder's solution, 304
Porcelain paste, use of electricity for purifying, 308
Potash, analysis of German muriate of, 80
determination of in agricultural substances, 316
sources of, 224
Potassium and ammonium tetrachromates, 71
cyanide, action of on bismuthous nitrate, 236
estimation of as platinum salt, 77, 86, 97, 129
picrate, decomposition of, 106
salts, application of in agriculture, 193
&c., determination of potash in, 290
manuring with, 192
sulphate, determination of in kainite, 71
volumetric determination of, 144
Potato-sugar, injurious action of, 192
Poulichambaroff, E., petroleum springs, 94
Precht, H., determination of potassium sulphate in kainite, 71
Propionyl-quinine, 48
Protoplasm, composition of, 192
Prout, J., "Profitable Clay Farming" (review), 57
Pulvermacher, J. L., electrolytic dosometer, 304
Pyrites, copper, 268
Pyruvic acids, condensations of the, 250

QUALITATIVE test for carbon disulphide, 221
Quassia wood, new uses of, 94
Quinamine, studies on, 83
Quincke, M., determination of acetic ether in urine, 48
Quinine, oxidation of, 144
sulphate, commercial, detection of the accessory alkaloids in, 61
Quinquand, M., determination of urea, 106

RADIOPHONIC receivers of selenium, influence of temperature on, 59
Radiophony, 13
produced by lamp-black, 204
Rail-steel, chemical methods for analysing, 292, 299, 310
Rainbow, splitting up and enlargement of the bands of the, 143
Rainfall, determination of, 192
Rammelsberg, M., new products of the alkali manufacture, 71
Raoult, F. M., basic calcium carbonates, 60
Raynaud, M., glycerin in wines, 49
Regnauld, J., and F. Valmont, atropine, 215
Reichel, F., arsenic as magnesium pyro-arseniate, 82
Reidemeister, C., loss of soda in the alkali manufacture, 71
Reinhardt, H., and R. Ihle, electrolytic determination of zinc, 304
Reinke, J., and H. Rodewald, composition of protoplasm, 192
para-cholesterin from æthalium septicum, 83
Rémont, A., attack of platinum on exposure to flame, 169
determination of salicylic acid in beverages, 226
of tannin, 81
separation of wool and silk in woven goods, 261
Remsen, I., conduct of finely divided iron towards nitrogen, 54
Renard, A., essence of resin, 296
Rennie, E. H., benzyl phenol and its derivatives, 283
Resin, essence of, 296
Resistances compass of proportion for the measurement of, 260
Reyman, S. A., product of the action of aqua regia upon orcine, 204
Reynolds, O., drops floating on the surface of water, 211
"Rheumatism" (review), 91
Riche, M., butter and margarine, 81
Ringstead chalybeate spring, analysis of, 140
Ritter, C., splitting-up and enlargement of the bands of the rainbow, 143
Ritthausen, H., crystalline albumenoids from various oil seeds, 122
Robbs, C. E., and M. M. P. Muir, action of sulphuric acid on zinc and tin, 237
Robinet, E., salicylic acid, 107
Robinson, A. E., treatment of hydrofluoric acid wounds, 92
Rodewald, H., and J. Reinke, composition of protoplasm, 194
para-cholesterin from æthalium septicum, 83
Rosaniline question, present state of, 92
Rosanilines, question of the, 107
Roscoe, H. E., "Description of the Chemical Laboratories at the Owens College" (review), 249
indigo, 53, 67, 74
and C. Schorlemmer, "Treatise on Chemistry" (review), 249
Rosenstiehl, A., angular distance of colours, 159
artificial preparation of indigotin, 72
present state of the rosaniline question, 92
theory of the three fundamental colour sensations of the eye, 23
Ross, W. A., blowpipe chemistry, 224

Voltaic arc, action of cold on, 273
Volumetric determination of potassium, 144

Von Baumhauer, E. H., crystallisation of the diamond, 193
Von Liebenberg, Dr., researches on the heat of the ground, 238
" Von Liebig, Justus, Memorial Address on " (review), 132
Von Sommaruga, E., action of ammonia upon isatin, 114
Vulcanised caoutchouc, recovery of old, 61

WAGNER, A., analysis of gunpowder, 47
determination of ash in coal and coke, 47
water analysis, 176
Warden, C. J. H., analysis of soil from Cuttack, 244
Wardle, T., "Wild Silks of India" (review), 314
Warington, R., alteration in the properties of the nitric ferment by cultivation, 217
" Chemistry of the Farm " (review), 69
Wash-bottle, new form of, 213, 304
Water, action of in irrigation, 49
analysis, 176
drinking, organic impurities in, 82
drops floating on the surface of, 211
electrolysis of, 260, 295
potable, estimation of nitrates in, 23, 46, 70, 80
soap tests for hardness of, 303
solubility of cane-sugar in, 82
Water supply, London, 33, 86, 140, 186, 254, 288
Waters, carbonated ferruginous, 204
city, of the United States, relative purity of, 265
natural, oxygen of, 305
" Waters, Harrogate " (review), 70
Waterpipes, prevention of bursting, 248
Watery vapour, decomposition of by the electric effluve, 304
Watts, H., " Dictionary of Chemistry " (review), 141
Weil, F., electric deposition of metallic strata of different colours, 315
Wells, the blowing, near Northallerton, 242
Wershoven, F. J., " Technical Vocabulary " (review), 223
Wesendonck, C., spectrum of carbonic acid, 42
Weyl, F., and X. Zeitler, oxygen of natural waters, 305
White, J. F., asbestos stopper for combustion tubes, 65
Wideman, M., cotton-seed oil, 107
Widman, O., preparation of metatoluidin, 296
Williams, G., β-lutidine, 296
Williamson, A. W., address to Chemical Section of the British Association, 123
Wine, determination of the dry extract left in, 251
oil of, 122
Wines, glycerin in, 49
Wines, titration of œoline and œnotannin, 153
Wittenburg, M., action of sulphuric acid upon citric acid and resorcin, 274
Wleigel, S., spectroscopic detection of indium, 82
Wolff, C. H., universal spectroscope, 82
Woolny, E., carbonic acid in the ground air, 48
Wood, L., " Presence of Gas in Solid Coal " (review), 303
Wood, manufacture of gas from, 31
quassia, new uses of, 94
Wood-spirit, commercial, intended for the " denaturation " of ethylic alcohol, assay of, 261
Wool and silk, bleaching of by liquid sulphurous acid, 275
separation of in woven goods, 261
Wright, A. W., distillation of mercury in vacuo, 311
L., spirals observed in crystals, 218
Wroblewsky, E., isomeric xylidines, 83
Wurth, A., dialdanic alcohol, 59
preparation of aldol, 60
Würzburg Laboratory, communications from, 61
Wyrouboff, G., potassium and ammonium tetra-chromates, 71

XYLIDINE, isomeric, 83
Xyloquinon and phloron, 122

YEAST, determination of, 82
Yellow fever, sodium salicylate in, 61
Yorkshire College, Leeds, 153
Yoshida, H., and R. W. Atkinson, peppermint camphor and some of its derivatives, 283
Yver, A., vanilla and vanilline, 81

ZALOMANOFF, R., absorption-power of the soil, 296
Zeitler, X., and T. Weyl, oxygen of natural waters, 305
Ziegler, J., certain compounds of the leuko-base from cuminol and dimethyl-aniline, 204
Zinc and cadmium sulphates, crystallisation of, 295
and tin, action of sulphuric acid on, 237
electrolytic determination of, 304
separation of from cadmium, 215
strontium, and calcium cyanides, 60
Zublin, H., the halogens, 274
and V. Meyer, volatile chlorides, 205
Zurich, University Laboratory of, 274
Zygomycetes, chemical composition of, 122
